Introduction

This reference text is an expanded and updated version of the text by the same name published eight years earlier. As such, this text is a compilation of many classical and more modern approaches to analyzing and modeling subsurface flow and transport.

Since Darcy's pioneering work well over a century ago, our qualitative and quantitative understanding of the flow of water and transport of chemicals in the subsurface has soared to great heights. Much of our current understanding of flow processes has been developed over the past 40 years, and our understanding of transport processes has developed mainly over the last 25 years. Substantial recent advances have been driven largely by two factors: (a) the development of inexpensive high-speed computing, and (b) the international focus on environmental quality and global change.

Much of the groundwater work performed earlier in this century revolved around very simplistic conceptualizations of the subsurface, simplifications that were so drastic as to allow analytical solutions to flow problems and the subsequent development of type-curves. Consequently, well installation and design, and groundwater maintenance revolved around such idealizations as homogeneity, isotropy, and infinite domains, which as we all know, are completely unrealistic assumptions.

With the advent of computing in the 1960s, through its modern refinements in software and hardware, and derivation of new sophisticated numerical algorithms, we have made a quantum leap forward in our ability to predict the behavior of our groundwater resources. This, coupled with the tremendous amount of research dollars, tied mainly to the environment, has led to a flood of research manuscripts, new engineering tools, and commercially available groundwater flow and transport software.

Unfortunately, while we have made tremendous advances in our ability to model the subsurface, our ability to cost-effectively measure material coefficients that go into the models has not kept pace. Thus, modern models are full of uncertainty in input data, and hence, their output is uncertain. This uncertainty has led to the introduction of stochastic tools to the field of subsurface hydrology.

This reference text is a compilation of many classical and more modern approaches to understanding and modeling subsurface flow and transport. Chapters 1 through 4 provide an introduction to the subject. In Chapter 1, the basic functions and terminology requisite to the study of flow and transport are presented. This chapter also provides a historical background of the field. Subsequently, steady one- and two-dimensional flow and transport (Chapter 2) and deterministic two- and three-dimensional flow (Chapter 3) are discussed. Chapter 2 gives an overview of the occurrence of groundwater, while Chapters 3 and 4 present basic principles.

Flow and transport in geologic media are characterized by tremendous uncertainty in the geological environment. One can safely say that in no other field of engineering are we faced with more complexity and uncertainty than in groundwater flow and transport engineering. Uncertainty is dealt with in a number

of different ways in Chapters 5, 8, 16, 18, and 19. Stochasticity in unsaturated flow and transport is dealt with in Chapters 5 and 8, while Chapters 18 and 19 handle the stochastic saturated transport problem. Interpolation via geostatistics is studied in Chapter 16. Deterministic unsaturated flow and transport are handled in Chapters 6, 7, and 22, while Chapters 9, 12, 13, 20, 21, and 23 handle the saturated problem. Chapters 9, 20, and 21 deal with preferential flow and fractures. Chapter 13 extends the classical isothermal model to the nonisothermal case and Chapter 12 focuses on seawater intrusion. While most chapters involve modeling to one degree or another, Chapters 23, 24, and 26 specifically focus on issues related to modeling, such as verification and case studies. Chapters 14, 15, and 17 focus on characterizing aquifers and contaminants.

Remediation or containment of contaminants in the subsurface has become critically important in recent years. This involves observation, injection, and pumping well design and these topics are covered in Chapters 10 and 11. Chapter 27 discusses sustaining our potable water. Landfill design and monitoring are discussed in Chapters 33, 34, 35, and 37, while Chapters 36 and 37 focus on remediation strategies. In remediation and containment strategies for contaminated sites and for water rights in general, legal issues continually crop up and these are discussed in Chapter 32.

Most recently, climate change (Chapter 28) has come to the forefront of science. In the context of groundwater, this has given rise to the field of echo-hydrology (Chapter 29) and the use of GIS (Chapter 30).

This revised text has been in the works for a little over two years. The authors are considered to be among the best in their fields. All chapters have been peer-reviewed.

Preface

A substantial amount of new knowledge in the field of groundwater engineering has been accumulated over the last decade. In particular, many new developments have taken place in the analysis of contaminant transport in the saturated and unsaturated zones. New techniques for the remediation of contaminated groundwater have been implemented. New approaches in computer modeling of the flow and movement of contaminants have appeared. The problem of modeling the heterogeneity of the geological formations and their effects on the flow and transport continue to be a challenge and have been the subject of many papers. This information is dispersed in many professional journals, textbooks, and reports. This second edition of the *Handbook of Groundwater Engineering* attempts to synthesize these facts and to provide this information in an easily accessible form. It contains a blend of professional practice and scientific information.

The typical readers of the handbook are expected to be geohydrologists and engineers possessing bachelors or masters degrees in applied sciences or in engineering, possibly with some years of experience.

The first chapter sets the stage by giving an introduction to the history of water management before the 19th century and an overview of the progress in groundwater hydrology until the 1980s. Chapters 2 and 3 provide an introduction to the geological setting and the analysis of simple flow and contaminant transport problems. Chapters 10 and 11 are concerned with the production of groundwater and hydraulics of wells. The last seven chapters (31 to 37) provide practical information concerned with pollution remediation, landfills, and the associated legal and regulatory aspects. The remaining 27 chapters deal with the analytical tools for the description, modeling of flow, and transport phenomena in the saturated and in the unsaturated zones.

This second edition includes 11 new chapters: History of Groundwater Hydrology (1), Infiltration and Run-on under Spatially Variable Hydrologic Properties (8), Sea Water Intrusion into Coastal Aquifers (12), Groundwater and Heat Flow (13), Groundwater Model Validation (24), Scale Issues (25), Accounting for Aquifer Heterogeneity in Solute Transport Modeling: A Case Study (26), Determining Sustainable Groundwater Development (27), The Impact of Global Change on Groundwater (28), Ecohydrology (29), and Evapotranspirative Cover Systems for Waste Containment (34). Three chapters have been completely rewritten: Infiltration (7), Nonreactive Contaminant Transport (18) and Contaminant Transport in the Unsaturated Zone—Theory and Modeling (22). Most of the remaining 23 chapters received substantial updating as needed.

I am grateful to have an excellent group of authors who are leaders in their respective specialties. Their names and affiliations appear in the headings of the individual chapters. The chapters were reviewed in a manner similar to papers in scientific and professional journals. I am grateful to the reviewers. They made a special effort to ascertain that the information presented is sound. Some reviewers read two chapters.

Editor

Jacques W. Delleur received his doctor of engineering science degree at Columbia University in New York City in 1955, his master's degree in civil engineering at Rensselaer Polytechnic Institute in Troy, New York in 1950, and his civil and mining engineering degree at the Universidad Nacional de Colombia (National University of Colombia) in 1949. In 1955, he joined Purdue University where he currently is Professor Emeritus of hydraulic engineering and was Head of the hydraulics and systems engineering area in the School of Civil Engineering. Dr. Delleur taught intermediate and advanced graduate courses in subsurface hydrology, surface hydrology, statistical hydrology, and hydraulics. He founded the graduate program in hydrology and hydraulics in the School of Civil Engineering at Purdue. He is author or coauthor of two books on hydrologic time series analysis. He is author or coauthor of more than sixty papers in refereed journals, seventy papers in conference proceedings, and sixty technical reports. These cover the areas of subsurface hydrology, hydrologic modeling, stochastic hydrology, urban hydrology, and hydraulics. The most recent publications related to groundwater coauthored by J.W. Delleur are concerned with the flow and transport of dissolved substances and how they are affected by geologic heterogeneity.

Dr. Delleur's research has been supported by the U.S. Department of the Interior, the National Science Foundation, the U.S. Department of Transportation, and the U.S. Department of Agriculture. He has served as an advisor to the U.S. Geological Survey, is a member of the international board of advisors of the American Society of Civil Engineers (ASCE) *Journal of Hydrologic Engineering*, is an associate editor of the *Journal of Hydraulic Engineering* (ASCE), and is a member of the scientific council of the *Revue des Sciences de l'Eau/Journal of Water Science*. He served as a reviewer for the National Science Foundation, for the Natural Sciences and Engineering Research Council of Canada, and for the scientific journals *Water Resources Research*, *Journal of Hydrology*, *Journal of the American Water Resources Association*, and the *Journal of Hydraulic Engineering*. He is a Fellow of the Indiana Academy of Sciences; received the 1961 Freeman Fellow Award of the ASCE; in 1983, received the NSF/CNRS US-France Senior Scientist Exchange Award; in 1992, received the Charles Harold Bechert Award of the Indiana Water Resources Association for significant contribution to the water resources profession in Indiana; and in 2002, received the Ven Te Chow Award from the ASCE for lifetime achievement in the field of hydrologic engineering. While on sabbatical leave, Dr. Delleur did research in hydrology at the French National Hydraulics Laboratory (1968–1969 and 1976–1977), at the University of Grenoble, France (1961–1962 and 1983–1984), and at the Vrije Universiteit Brussel (Free University of Brussels, Belgium (1991). He has been a guest lecturer

at the École Polytechnique Fédérale de Lausanne (Federal Polytechnics School, of Lausanne), Switzerland, at the Free University of Brussels, Belgium, at Imperial College in London, at the University of Tokushima, Japan, at the Indian Institute of Technology in Kanpur, India, at the Mahommadia School of Engineering in Rabat, Morocco, at the Taiwan National University in Taipei, Taiwan, and at the Universidad de los Andes (University of the Andes) in Bogotá, Colombia.

Acknowledgments

I am grateful to this excellent group of authors, who are leaders in their respective specialties. Seventy-one authors from eight countries contributed their knowledge to this handbook. Their names and affiliations appear in the headings of the individual chapters and in the List of Contributors.

The chapters were reviewed in a manner similar to papers in scientific and professional journals. I am also grateful to 29 reviewers from five countries. They made a special effort to make certain that the information presented is sound. Some reviewers read two chapters. Their names appear in the List of Reviewers.

I wish to acknowledge the support I received from the School of Civil Engineering at Purdue University, in particular the encouragement of Dr. Fred Mannering, former head of the School, and Dr. Katherine Banks, current interim head. I also wish to acknowledge the encouragements of my colleagues Dr. John H. Cushman of the departments of earth and atmospheric sciences and mathematics and Dr. G.S. Govindaraju of the hydraulics/hydrology group. I also wish to acknowledge the valuable assistance of the CRC Press/Taylor & Francis Books staff, in particular Mr. Matthew Lamoreaux, editor, civil and environmental engineering and Ms. Jessica Vakili, project coordinator.

1.1 Introduction

Although water is a renewable resource and we use little more than 10% of the total precipitation surplus for public water-supply, irrigation, and industrial processes, its availability is restricted through an uneven distribution, both in time and space. In this respect, there is no essential difference between ancient times and the present day; society has always experienced problems with water: too little, too much, too variable, too polluted. Over more than 6000 years mankind has tried to manage these water problems: by intervening in its natural courses through redistribution, storage, and regulation, to accommodate their requirements for irrigation, drainage, flood protection, drinking water, sanitation, and power generation.

Management and exploitation resulted in systematic knowledge of behavior of water under more or less controlled conditions. Gradually, from the Renaissance onwards, this empirical knowledge merged

with scientific developments into a basic understanding of the hydrological cycle and the mechanics of flowing water.

Scientific developments in subsurface hydrology emerged in the early 19th century in western Europe, particularly in connection with the search for unpolluted drinking water for the growing cities, and in relation to land drainage and dewatering of excavations for building or for mining. The center of progress subsequently shifted to the United States at the beginning of the 20th century, notably because of the importance of groundwater for the development of the semi-arid mid-western areas. The focal point of developments remained with North America, but merged with advances elsewhere from the mid-20th century, due to the expansion of international communication and dissemination of knowledge. Several parallel, but more or less isolated developments, had taken place in different countries prior to the mid-20th century. The results often remained unnoticed internationally because communication in applied science and engineering was often restricted to national journals.

The aim of this chapter is (1) to present a brief eclectic introduction to the history of water management and hydraulics before the 19th century, based on secondary literature, and (2) to give a more detailed overview of the advancement of scientific knowledge of groundwater hydrology until the 1980s, based on primary sources. The present overview is necessarily restricted to the mainstream of developments that has become known through widely accessible publications, but a few lesser known discoveries from the Netherlands are also included, illustrating regional achievements in connection with specific hydrogeologic conditions and needs. Many key contributions have been referenced, either because of their ground breaking nature, or to exemplify current developments; though the account does not aspire to being totally comprehensive. For further explanation of the theoretical concepts in this chapter, the reader is particularly referred to Chapter 2, Chapter 3, and Chapter 4 of this volume.

1.2 Water Management and Water Science before the 19th Century

1.2.1 Water Management in Ancient Societies

The oldest civilizations emerged predominantly in relation to the use of river water for irrigating crops under (semi-)arid climatic conditions. Most probably this process began with small-scale irrigation units, regulated by autonomous communities and gradually extended over larger areas with expanding feeder, distribution, and drainage systems. Control of these schemes included technical aspects such as channel and levee construction, as well as administration related to maintenance, taxation, and legislation. The technicians involved in these waterworks made use of rational empirical knowledge and can be considered as professional hydraulic engineers, who mastered the skills of writing and the application of basic mathematics.

All these so-called “hydraulic civilisations,” which developed from the 4th millennium B.C. (notably along the Nile, the Euphrates and Tigris, the Indus, and the Hwang-Ho as well as the Inca civilization in the downstream areas of the rivers at the western slopes of the Andes mountains), showed essentially the same evolution with a strong bureaucratic and stable government, concentrated in urban centers, and characterized by excess production of staple food. This food surplus allowed the development and diversification of non-directly productive professions like priests, architects, surveyors, bookkeepers, astronomers, and warriors. The large population allowed for expansion by trade, craft, and combat, and led to unification of regional power to large kingdoms or empires (cf. Smith, 1976; Back, 1981).

The oldest large-scale irrigation and drainage works began about 4000 B.C. with the Sumerians, between the Euphrates and Tigris. Lifting devices were until Hellenic times (ca. 500 B.C.) restricted to the chain of pots, drawn over a pulley by man or animal, and by the *shaduf* — a lowering and rising bucket on a counter-balanced pole. The most remarkable hydraulic structures that originated in pre-Hellenic times are the *qanats*; underground galleries fed by a spring, or one or more mother wells, dug in an aquifer and connected to the surface by vertical servicing and ventilation shafts at about 50-m intervals. They

originated in the Middle East early in the 1st millennium B.C., and spread rapidly over North Africa, India, and China. Some are tens of kilometers long, collect their water from alluvial fans or springs at the foot of a hill-slope and carry it, without being subjected to evaporation, to the dry plains. Tens of thousands of qanat systems are still in use, particularly in Iran where they drain the large alluvial cones that fill the valleys of the arid highlands. Some reach depths of more than 50 m (cf. Issar, 1990, p. 157).

Accounts of dug wells are found in ancient literature and records from all over the arid regions of Asia and the Mediterranean. Depths seldom exceed 50 m, but their diameters are sometimes such as to allow spiralling paths for donkeys. Core drilling is known from around 3000 B.C. in Egypt and has also been practised for thousands of years in China. Depths of more than 1000 m are reported from the latter country, where churn drilling with bamboo casing was used. These small diameter wells were, except under artesian conditions, not suitable for groundwater extraction in the absence of pumping techniques; they seem to have been used mainly in the mining of minerals, brines, and gas. Artesian wells, among others, are known from oases in the western desert of Egypt where, from 2000 B.C., many shafts and wells reached depths of 100 m (Tolman, 1937, p. 12).

One of the oldest wells discovered in the western world was found in 1991 near the German village of Erkelenz, close to the German–Dutch border. It is a square dug well with a depth of 15 m in a wooden casing of oak. Dendro-chronological and C-14 dating of the wooden framework revealed its age to be about 5300 B.C.; it is the oldest wooden structure known to date (TNO-NITG, 2004). Well-drilling in Western Europe began in the 11th century after the discovery of flowing wells in Flanders by Carthusian monks from a convent near Lille. Several wells were subsequently drilled to depths of almost 100 m by percussion techniques and were used to drive a mill. The wells tapped water from fractured chalk, which outcrops and is recharged in higher plateaus of the Province of Artois. These flowing wells were called artesian wells after the name of the region (Tolman, 1937, p. 316).

1.2.2 Techniques and Concepts in the Hellenic-Roman Civilization

The Roman Civilization became famous for its development of hydraulic construction technology. Most of their ideas, however, were of an innovative character and adapted from well-established technologies from surrounding societies. Architecture and the use of water resistant concrete (cement of clay and lime, made water tight by volcanic ash) were taken mainly from the Greeks, whereas their famous semi-circular arch in bridge-building was of Etruscan origin.

The most remarkable Roman achievements were their water-supply systems, with aqueducts bringing water from outside the cities into complex distribution networks within the cities, similar to the modern public water supply schemes. The Romans made use of long arcades or siphons to bridge deep valleys, constructed tanks and water towers to feed the city's distribution system, and used lead pipes and copper valves for pressurised flow. Rome was probably the first city to enjoy a closed sewer, as early as 500 B.C. Water-raising machines were clearly adopted from the Persians and the Greeks. The *Archimedean screw* (dating from about 250 B.C.) was widely applied in Roman times for irrigation, land drainage, and dewatering of mines. Larger quantities of water could be lifted by the *noria* (also called *Persian wheel*), a large wheel with pots or flow-boards, driven by the stream and thus lifting water under its own power. In case of a well, water could be raised by a chain-of-pots, powered by man or animal via a horizontal, right-angled gear with toothed wheels (cf. Smith, 1976).

Hellenic science was certainly inherited from the older civilizations in the Middle East, but unique was their initiation of intellectual thinking and inquiry, purely as a game. Several philosophers developed speculative theories about the origin and interconnection of elements of the hydrological cycle, particularly the origin of springs and river flow. Their knowledge, however, remained fragmentary because of a lack of adequate information and interest in experiments and systematic observations. The concepts of the Greeks were dominated by the idea that rivers and springs were recharged by way of subterranean channels from the sea. The driving forces were sought in processes such as pressure differences exerted by wind or by rock weight, and suction through vacuum. Desalination was attributed to filtration and distillation. There were also theories about subterranean evaporation and subsequent condensation as well as condensation

from atmospheric water; Aristotle (385–322 B.C.), in particular, propagated this so-called *condensation theory*. Closer to the concept of the hydrological cycle were the theories proposed by Xenophanes of Colophon (about 570–475 B.C.), who associated evaporation from the oceans with clouds, rain, and the origin of springs and streams (Brutsaert, 2005, p. 561). In general, however, rainfall alone was considered quite insufficient to feed rivers and its ability to replenish groundwater and springs was doubted. This is understandable in an arid environment where rainwater seldom seems to penetrate more than a few decimeters before it evaporates. Seneca (3 B.C.–A.D. 65) declared: “As a diligent digger among my vines I can affirm my observation that no rain is ever so heavy as to wet the ground to a depth of more than ten feet” (Biswas, 1970, p. 97; Brutsaert, 2005, p. 567).

A still unanswered interesting question is whether the Romans possessed the conceptual insight to combine flow velocity and cross-sectional area to arrive at the flow quantity per time unit, and if they had any knowledge of pipe and open channel hydraulics to connect hydraulic gradient, friction, and cross-sectional area to the water flux. The accounts of the famous Roman water-supply engineer Frontinus (A.D. 1st century), do not reveal a comprehensive understanding of these hydraulic interactions. Although he seemed to be aware of the continuity principle, he nowhere mentioned the use of flow velocities, but based his flow considerations on cross-sectional area. He possibly used standard channel slope and roughness, so that the cross-sectional area was indeed indicative for the water fluxes, although he seemed to be vaguely aware of the interrelationship between velocity and roughness. Nevertheless, there is an explicit indication that Hero of Alexandria (around 100 B.C.) recognized that flow quantity depends on area and velocity (cf. Biswas, 1970; Dooge, 2004).

Roman concepts of the hydrological cycle did not differ much from speculations by the Greek philosophers, as can be read in Marcus Vitruvius' famous books on Roman architecture and technology (ca. 27 B.C.). However, Vitruvius did mention existing ideas about rainfall being the origin of springs, at least at the foot of mountains (cf. Biswas, 1970, p. 89).

1.2.3 Evolution of Water Science during the Renaissance

Developments in water technology in Medieval Europe were mainly focused on the improvement of power generation by water mills to accommodate the emerging industry, as well as on the reclamation of fertile, wet, alluvial soils. An important innovation in the Low Countries in the 15th century was development of the wind-powered mill to lift water for land drainage, and for reclamation of land from lakes and sea embayments. These ingenious technological developments were not based on theoretical insight, but did encourage the adaptation of the scientific traditions of antiquity, which entered Europe notably via contact with the Moslem and Byzantine civilizations in the Early Renaissance.

Scientific thinking related to the dynamics of water began in the Early Renaissance, notably with the genius Leonardo da Vinci (1452–1519), who was probably the first to arrive at the determination of stream discharge by multiplying the flow velocity by the stream's wetted cross-sectional area. He was surely the first to clearly formulate the law of continuity, with his statement: “Each part of the river gives in equal time the same quantity, whatever the slope, width, depth or roughness.”

The dawn of modern scientific thinking in hydraulics in the 17th century is exemplified by Benedetto Castelli (1578–1643), who studied under Galileo Galilei (1564–1642) in Padua and was Professor of mathematics in Rome. He presented a theoretical analysis of flowing water, and extended the principle of continuity for nonuniform flow. Domenico Guglielmini (1655–1710) subsequently connected a constant flow velocity on a sloping surface with a balance between the gravitational force and resistance. This would eventually lead, in the 18th century, to a general formulation of the relation between friction, slope, and velocity (Dooge, 2004).

Quantitative hydrology began with the lawyer Pierre Perrault (1608–1680) and the scientist Edmé Marriotte (1620–1684), who definitely proved rainfall to be more than enough to support the flow of springs and rivers by comparing the results of their discharge measurements in the Seine basin with the amount of precipitation on the catchment. Perrault, however, believed that surface runoff was the source

of river flow and that springs were mainly fed by streams. He probably considered infiltration to be just sufficient to keep groundwater in balance with evaporation.

A better understanding of the process of infiltration and subsequent discharge of groundwater by springs and rivers was earlier proposed by craftsman (inventor of enamelled pottery) and amateur naturalist, Bernard Palissy (1510–1590), on the basis of sound observations and deductions. He did not master Greek and Latin, and was therefore not hindered by the ideas of the old philosophers; his scientific attitude is evident from his statement: “I have no other books than Heaven and Earth, which are open to all.” Palissy had also assumed rainfall to be sufficient to feed the rivers, in a century that great scientists like Johannes Kepler (1571–1630) and René Descartes (1596–1650) still adhered to the concepts of the Greek philosophers.

The picture of the hydrological cycle was finally completed with the evaporation experiments by the astronomer Edmond Halley (1656–1742), who assessed the water balance of the Mediterranean sea by up scaling evaporation measurements in cylinders. He concluded the evaporation on the oceans to be more than enough to generate the necessary rainfall to feed the rivers (Brutsaert, 2005, p. 583).

1.2.4 Foundation of Hydraulics and Hydrology

The 18th century saw the various hydraulic concepts gradually merging toward a comprehensive theory of hydrodynamics based on Newtonian mechanics. Henry de Pitot (1695–1771), a French hydraulic engineer, studied the distribution velocity within streams and was not satisfied with the use of floats. He therefore developed his well-known L-shaped tube to determine the rise of the water head above stream surface as a measure for the velocity, making use of the principle that the velocity head under ideal conditions must equal the pressure head. The same principle was the subject of a more theoretical treatise on fluid flow published in 1738 by the Swiss physicist and mathematician, Daniel Bernoulli (1700–1782). His equation of the pressure–velocity relation in permanent flow without friction was subsequently extended by a potential energy term, and is now known in that form as the Bernoulli equation for conservation of energy. From this equilibrium principle, Daniel Bernoulli and his father, Johann Bernoulli, both arrived in 1738 at the basic hydraulics equation: $v^2 = 2gh$, where v is velocity, g is acceleration due to gravity, and h is hydraulic head.

Based on the same principles, Antoine Chézy (1718–1798), a professor at the École des Ponts et Chaussées, developed his well-known stream flow equation. He argued that velocity due to gravity is only uniform if the acceleration due to gravity equals the resistance caused by the wetted perimeter. In this approach, that is still widely used, the resistance due to friction along the stream bed, as well as the internal friction, has to be determined empirically. Many attempts were made to obtain resistance coefficients based on velocity distribution and channel geometry, including the Darcy–Bazin experiments on open channel flow and pipe flow, and the stream channel experiments by the Irishman Robert Manning (1816–1897).

Henry Philibert Gaspard Darcy (1803–1858) was a mechanical and hydraulic engineer who was, among others, concerned with water-supply systems. His treatise on the successful design and construction of Dijon’s public water supply, published in 1856, contains the results of his famous experiments on groundwater percolation through sand filters. From this study he derived his well-known linear law of groundwater flux and hydraulic gradient, which became the foundation of quantitative groundwater hydrology. This law of groundwater flow through porous media shows similarity with the Hagen–Poisseuille equation for laminar viscous flow through small-diameter pipes, developed earlier by the French physician Jean Louis Poisseuille (1799–1869) and the German hydraulic engineer Gotthilf Heinrich Ludwig Hagen (1797–1884). Darcy, who had a sound theoretical background, was certainly aware of this analogy (cf. Biswas, 1970).

Other important contributions to water science at the beginning of the 19th century were discovery of the composition of the water molecule, H_2O , by Jöns Jacob Berzelius (1779–1848), and the fundamental law of evaporation by diffusive and turbulent transport of vapor, formulated in 1804 by the founder of atomic chemistry, John Dalton (1766–1844).

1.3 Developments in Subsurface Hydrology

1.3.1 Emergence of Basic Understanding of Subsurface Water Behavior

1.3.1.1 Groundwater Dynamics

Interest in subsurface water origin and movement has a long history, notably in arid areas where it was often the only source of drinking water. In humid areas curiosity arose especially in connection with the intriguing, not to say mysterious, phenomena of springs and artesian wells, which were usually supposed to be connected to powerful subterranean water arteries. A more scientific approach to groundwater hydrology was possible only after the fundamentals of geology were established at the end of the 18th century. These principles provided the essential framework of the properties and structure of the rock strata, including the role of fractures, joints, solution cavities and weathering horizons, and the perception of water-bearing and water-confining layers. A well-known pioneer in connecting rock properties with groundwater behavior was the Englishman William Smith (1769–1839), who, in the early 19th century, applied his knowledge to improve the supply of groundwater for the town of Scarborough (Biswas, 1970, p. 306). However, it was discovered recently (Stephens and Ankeny, 2004) that Smith was preceded by Joseph Elkington (1739–1806), a farmer who developed his knowledge by drainage work on his swampy lands. He showed remarkable understanding of the control of geologic structure and topography on groundwater circulation, including the location and discharge of springs, artesian pressure, and perched aquifers. The successful and widespread application of his knowledge on horizontal as well as vertical drainage with auger holes for pressure relief, in the second half of the 18th century, made him (according to Stephens and Ankeny), perhaps the first professional consulting hydrogeologist.

Interest in groundwater as a source of drinking water emerged in the western world at the beginning of the 19th century particularly because of the increasing pollution of surface water caused by the fast growing population and industrial activities in many cities in Europe and the United States. Free flowing artesian wells were notably considered as a potential source of drinking water, particularly after a number of successful drillings in France. The French scientist and politician François Arago came to the conclusion, on the basis of geologic considerations, that artesian water could be encountered in the water-bearing Albian Greensands of Cretaceous age; these he believed to extend under Paris below Tertiary confining clay layers. On his instigation drilling started in 1831 at the Grenelle location and reached the Greensands in 1841 at a depth of 548 m. This was much deeper and much later than expected by Arago, and taking into consideration his rather simple percussion drilling tools and man-powered thread-wheels, one can imagine the immense technical and mental difficulties that Arago and his engineer Murot faced. The artesian pressure spouted water to a height of 33 m above surface and initially produced 4000 m³/d, which was a substantial boost to the Paris water supply (cf. Smith, 1976, p. 108).

The explanation of artesian pressure produced by an elevated groundwater table in aquifer outcrops had already been proposed by the Italian Bernardino Ramazzini (1633–1714), in his 1691 treatise on the artesian wells of Modena; this contained ideas which he, in turn, seemed to have obtained from the Arabian philosopher Al Biruni (973–1048). Ramazzini already understood the meaning of a hydraulic gradient between an artesian well and the pressure source in the case of flowing groundwater (cf. Biswas, 1970, p. 190). A comprehensive treatise on artesian wells was produced by the French engineer Garnier (1822). Early concepts relating to artesian water supposed rigid rock conditions, but Arago also mentioned (according to Versluys, 1931) existing ideas of artesian pressure generated by downward bending confining layers, which were deformed by overburden loading. However, he finally adhered to the explanation of hydraulic pressure propagation from an elevated outcrop.

A quantitative approach to groundwater hydrology began with the previously mentioned work of the French engineer Henry Darcy (Figure 1.1). In the framework of his ingenious work for the Dijon central drinking water supply system, he carried out percolation experiments using purification filters as depicted in Figure 1.2 (see also Chapter 3, Figure 3.5 and Figure 3.6, this volume). From these investigations, he derived his well-known law for the linear relation between hydraulic gradient and groundwater flux, which he published as an appendix to his monumental treatise on the water-supply scheme (Darcy, 1856). This

FIGURE 1.1 Henry Philibert Gaspard Darcy (1803–1858). Portrait by Perrodin, Collection of the Bibliothèque Municipale de Dijon.

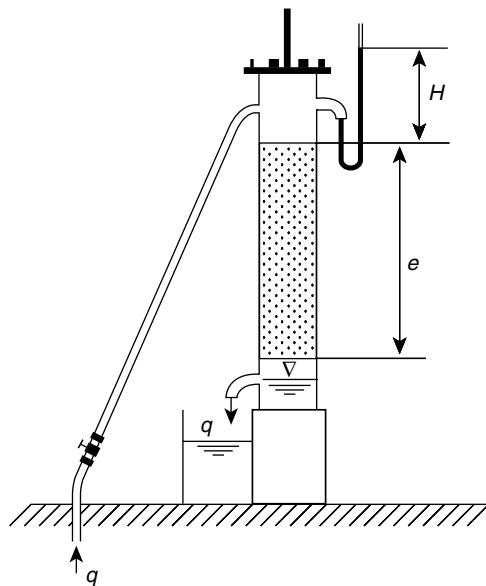

FIGURE 1.2 Principle of Darcy's percolation experiment with outflow under atmospheric (=zero) pressure. The results are formulated in Equation 1.1 for the case that the lower boundary of the column is chosen as reference elevation level, so that elevation head and pressure head are both zero at the outflow surface.

work not only revealed Darcy's technical skills, but also accounted for his thorough understanding of the role of topography and geology for the groundwater conditions and their meaning for his water-supply scheme (cf. Brown et al., 2003).

For percolation through a cylinder with outflow under atmospheric pressure, he derived his well-known formula:

$$q = Ks(H + e)/e \quad (1.1)$$

where q = percolation flux [$L^3 T^{-1}$], K = permeability factor [LT^{-1}], s = surface area of the sand filled cylinder [L^2], e = length of the sand column [L], and H = hydraulic pressure at the upper boundary of the sand column [L]. $(H + e)$ = hydraulic head and $(H + e)/e$ = hydraulic gradient (Figure 1.2).

Darcy also derived the non-steady flow equation for the condition of a falling pressure head:

$$q_t = q_0 \exp(-Kt/e) \quad (1.2)$$

where t = time [T] and q_0 = percolation flux [$L^3 T^{-1}$] at $t = 0$.

This non-steady groundwater flow equation was later applied and further expanded by Edmond Maillet (1905) to analyze the dry weather discharge recession of rivers and springs. Darcy certainly realised that his experiments were carried out under ideal conditions with rather homogeneous porous media, which may differ substantially from actual field conditions. However, he had previously studied the changing discharge of artesian wells as a function of their changing water pressure; these findings complied with his linear law and thus suggested its universal validity for groundwater flow through porous media (Brown, 2002).

Many investigators around the turn of the century repeated Darcy's experiments and confirmed their applicability for conditions of non-turbulent flow (*inter alia*: Seelheim, 1880; Hazen, 1893; King, 1899; Slichter, 1905). All these studies included the establishment of semi-empirical relationships between the mechanical composition of sediment and its permeability, in an attempt to find a physical expression for the Darcian permeability factor on the basis of the Hagen–Poisseuille theory for viscous flow in pipes. This resulted in a characterization of permeability as a quadratic function of the pore size or its related grain size. Well-known was Hazen's *effective grain-size* D_{10} , which represents the size which is finer than 90% of the grains, and his study on the influence of the particle distribution uniformity, represented by the D_{10}/D_{60} ratio. More elaborate experiments on permeability and sediment properties include those of Zunker (1923), who introduced the concept of the *specific surface*. Related formulae were proposed by Terzaghi (1925), Kozeny (1927), and Carman (1937, 1956), leading to the well-known Kozeny–Carman equation. Graton and Fraser (1935) included the influence of the arrangement of the particles on porosity.

Darcy's law allowed groundwater flow problems to be formulated in mathematical models, and to solve these for given boundary conditions. In this way, the French engineer Jules Dupuit (1804–1866) derived his famous solution for steady horizontal flow to a well at the center of a circular island in an unconfined aquifer (Dupuit, 1863, Figure 1.3):

$$\pi K(h_R^2 - h_r^2) = Q \ln(R/r) \quad (1.3)$$

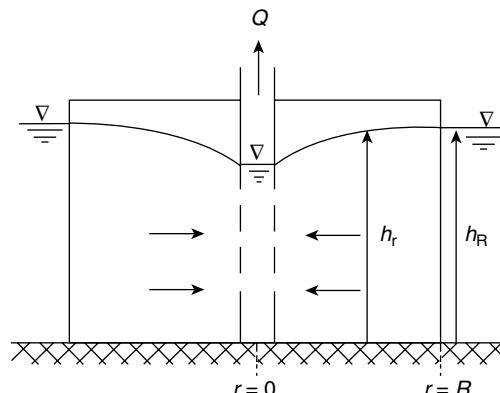

FIGURE 1.3 Horizontal, radial-symmetric groundwater flow to a well in the center of a circular island with radius R ; h = hydraulic head relative to the impervious base ("Dupuit assumptions").

where h_R and h_r are the hydraulic head relative to the base of the aquifer, at distance R and r from the well, respectively; R is the island's radius; Q is the groundwater extraction, replenished from the constant-head boundary at distance R . Dupuit's simplification of horizontal flow under a sloping water table is now generally known as the "Dupuit Assumption."

The German Adolph Thiem (1836–1908) developed (probably independent of Dupuit) identical formulae for unconfined and confined well flow, which he extensively applied in projects on groundwater extraction for public water supply for several large cities in Europe (Thiem, 1870). His son Günther Thiem (1906) was probably the first to explicitly apply the well flow formula in test-pumping experiments, with observation wells to determine aquifer properties. He systematically evaluated the results of his field observations under different boundary conditions, and particularly considered the relevance and physical meaning of the concept of the "radius of influence R " for the usual conditions where the well is not in the center of a circular island.

It is evident that to use Darcy's formula for engineering problems that were dominated by horizontal, vertical, or radial-symmetric flow did not pose too many difficulties, but application to more complicated, two-dimensional (2D) field conditions was hampered by a lack of insight to the actual flow field and the associated hydraulic head distribution. This is exemplified by discussion in the Netherlands in the 1890s in connection with the use of groundwater from the coastal dune area for drinking water. In 1852, Amsterdam began groundwater extraction from the dunes using a system of drainage canals. A scientific-technical committee which investigated the efficiency of the system, applied in their report the parallel flow version of Equation (1.3) for discharge to a channel fed by uniform infiltration. They assumed horizontal flow with the bottom of the canal forming the lower boundary of the flow system, and arrived at a parabolic drainage formula, which is also known from earlier work by the Danish engineer Ludvig Colding (cf. Section 1.3.4.3). In the committee's notation:

$$qx^2/kcb^2 + y^2/b^2 = 1 \quad (1.4)$$

where q = discharge = recharge [LT^{-1}]; k = quotient of hydraulic conductivity and porosity c [LT^{-1}]; y = groundwater level (hydraulic head) relative to the bottom of the channel [L]; $y = b$ at the water divide, where $x = 0$.

The assumption that the drainage base must constitute the lower flow boundary in an aquifer that extended further downward was in accordance with their idea that groundwater flow, under water table conditions, could not move in an upward direction (cf. De Vries, 2004). This doctrine was derived from the authoritative book by the German water-supply engineer, professor Otto Lueger (1883).

However, subsequent measurements of drainage water yield in the canals by the Director of the Amsterdam waterworks, engineer Johan M.K. Pennink (Figure 1.4), resulted in three times the amount that was calculated from Equation 1.4 for horizontal flow. This gave him the idea that the thickness of that part of the subsurface participating in the groundwater discharge was possibly underestimated in the then current theory. He therefore postulated radial converging and upward bending flow lines in a vertical section perpendicular to the channels. Pennink splendidly demonstrated the flow pattern below the channels from both field evidence and experiments with parallel-plate models for viscous flow (Pennink, 1904, 1905). The laboratory models consisted of spaces bounded by parallel glass plates, initially filled with liquids and in later experiments filled with sand. His field experiments were carried out with rows of piezometers to measure the hydraulic head at different distances from the canals and at various depths. From these observations he constructed the spatial pattern of hydraulic head contours and associated flow lines (Figure 1.5), which proved his concept of radial flow. Pennink thus clearly understood that the driving force at a point in the flow field is formed by the gradient of the summed elevation and pressure heads. This application of the concept of hydraulic gradient under field conditions in a 2D flow field was certainly not common knowledge. Pennink in fact solved graphically, more or less intuitively, the continuity equation.

Pennink's experiment also clearly explained the increase in hydraulic head with depth under areas of discharge. This phenomenon, as well as strong up welling of water in excavations at the foot of

FIGURE 1.4 Johan M.K. Pennink (1853–1936). Photograph Amsterdam Water-Supply.

the coastal dunes, had previously been misinterpreted as an indication for the occurrence of artesian water veins beneath the dunes; the artesian water hypothesis was incorrectly used as an alternative for the right explanation of the more than 150 m thick fresh water pocket below the dune area by way of the *Ghijben–Herzberg principle*. This principle of equilibrium between a fresh water pockets floating on surrounding salt groundwater was previously formulated by a captain in the Dutch Army Corps of Engineers, Willem Badon Ghijben (1845–1907). His ideas (Drabbe and Badon Ghijben, 1889) did not receive proper recognition until the German engineer Herzberg (1901) independently reached the same conclusions, after discovering fresh water extending to a depth of 60 m under the North Sea island of Norderney. It should be noted that the idea of fresh groundwater floating on salt water was predicated in the United States by Joseph Du Commun [1818], a French instructor of the West Point Military Academy (cf. Carlson, 1963).

Pennink furthermore produced the rather precise figure of 350 mm/year for the natural recharge of the dunes, and persistently warned for over-exploitation and salinization. He also designed a scheme for artificially recharging the dunes with river water, which was only executed half a century later following serious salinization problems (cf. De Vries, 2004).

The French physicist Valentin Joseph Boussinesq (1842–1929) and the Austrian hydraulic engineer Philipp Forchheimer (1852–1933) were the first to explicitly recognize, from theoretical considerations, that an analytical solution of a groundwater flow problem cannot be solely based on Darcy's law of motion, but should also obey the continuity principle, the combination yielding the Laplace equation. Boussinesq (1877) also noticed that horizontal one-dimensional (1D) transient groundwater flow is mathematically analogous to the transient diffusion equation for heat flow as proposed by Fourier in the early 19th century. This paved the way for applying the mathematical solutions for heat flow problems to equivalent groundwater problems. In 1886, Forchheimer solved the 2D Laplace continuity equation for steady-state, 2D groundwater flow in a homogeneous and isotropic medium using the conformal mapping technique, a method that was previously applied by Holzmüller (1882) for heat flow problems. He arrived at the basic formula:

$$\delta^2 h / \delta x^2 + \delta^2 h / \delta y^2 = 0 \quad (1.5)$$

which he combined with Darcy's flow formula to generalize Dupuit's well flow formula for confined horizontal flow conditions.

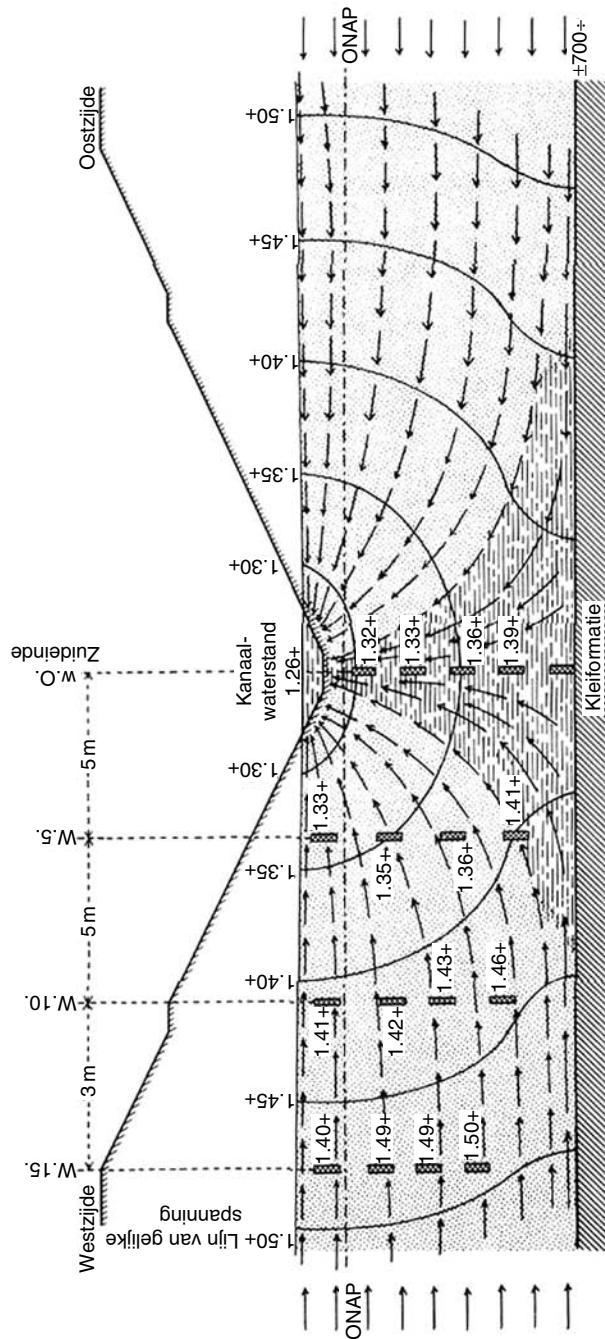

FIGURE 1.5 Flow net around a drainage canal based on hydraulic head observations, according to Pennink, 1905.

Forchheimer (1898) subsequently extended the general differential equation to the 2D unconfined “Dupuit free-surface” problem, for which he arrived at the formula that is now commonly known as the “Dupuit–Forchheimer equation”:

$$\delta^2(h^2)/\delta x^2 + \delta^2(h^2)/\delta y^2 = 0 \quad (1.6)$$

The transient version of Forchheimer’s Laplace equation appeared in the work of Boussinesq (1904). The professor of mathematics and collaborator with the US Geological Survey (USGS), Charles S. Slichter (1864–1946) arrived at the same results for steady-state flow and extended Forchheimer’s approach by including a vertical flow component (Slichter, 1899). Remarkably, he did not mention Forchheimer, although he was obviously familiar with German authors as he referred to Thiem and Lueger. Another associate with the USGS and professor of soil physics, Franklin H. King (1848–1911), in a companion paper, gave a general description of groundwater flow under the influence of a topography-controlled groundwater table and presented a sketch for the flow pattern near a stream which was similar to Pennink’s case (cf. Figure 1.5). King clearly explained that the flow of water beneath a channel or depression is forced upward under hydraulic pressure, driven by the inflow, and accumulation of water percolating downward through the surrounding higher land. In contrast to Pennink, however, King did not verify his ideas by field experiments. Conversely, Pennink was obviously not familiar with the theoretical approach, or at least did not know how to connect the results of his experiments with this theoretical knowledge; his work was mainly based on intuition and observation.

Slichter (1902) applied King’s sketch to discuss the flow pattern in a framework of general theory. He emphasized that it would be misleading to compare groundwater flow with pipe flow and stream flow because, as he stated, the frictional resistance in groundwater is not transmitted by the fluid layers. It is interesting, in this connection, that he considered the influence of an undulating impervious base for the flow pattern in an aquifer: “The contention of some German hydrographers (he then refers to Lueger; deV.) that there can be no motion in a region like ASB (referring to a figure with a concavity ASB in the impervious base of the aquifer; deV.) must be entirely abandoned. Water must circulate in all parts of the enlargements in the porous medium, for the same reason that heat would be conducted over similar enlargements in a conductor.” He further specified: “If it were not for the ever present controlling influence of gravity the motion would be entirely analogous to the flow of heat or electricity in a conductive medium.”

1.3.1.2 Geological Aspects

An extensive general study on the relation between geological structure and the occurrence and flow of groundwater was published in three volumes by Gabriel Daubrée (1887). Another outstanding French contribution was the study on the interaction of aquifers and rivers by Maillet (1905), who analyzed stream-flow recession curves to evaluate and forecast low flow. In this he made use of the principle of linear reservoirs (as represented by Equation 1.2) and the theoretical considerations of Boussinesq relating to non-steady flow, including the aspect of nonlinearity in shallow aquifers.

The misconception of stagnating water below the drainage base (as particularly propagated by Lueger, cf. Section 1.3.1.1) was also reflected in the sub division by Grund (1903) for karst areas, in which he made a distinction between moving karst water above sea level and stagnant groundwater below sea level. Grund considered karst aquifers as continuous systems, much like groundwater bodies in other porous media. This concept was challenged by Katzer (1909) who observed complex behavior, including diffuse flow through a porous medium as well as cave-river circulation. Katzer’s ideas were largely based on the results of extensive exploration by the French speleologist Martel (1894). Classical studies of the interaction between karst morphology and karst water circulation and dissolution, including the origin and evolution of cavities, and swallow holes, were carried out by the Yugoslavian Jovan Cvijić (1893, 1918). His excellent work is still the basis of modern karst hydrology and karst morphology.

The role of CO₂ in limestone dissolution was already understood at the end of the 18th century, but before the 1930s it was generally assumed that CO₂-driven dissolution could only be active in the zone near

the water table. It was notably the famous American geomorphologist Davis (1930) who found convincing arguments for active dissolution below the water table in cavity structures. Unsaturated conditions with respect to CaCO_3 , even at greater depths below the water table, was subsequently convincingly proved (e.g., Back, 1963), and Alfred Bögli (1964) demonstrated the process of mixing corrosion as a powerful means of continuous dissolution (cf. Section 1.3.5.1). Discussion on the possibility of a diffuse groundwater flow with a continuous water table (as propagated, among others, by Grund) vs. the idea of a restricted circulation by independent cave-river networks, continued for quite some time, notably in Europe (cf. Bögli, 1980, Chapter 6). A well-known protagonist of the latter view was Lehmann (1932). However, extensive research in the United States in the 1960s, in the deep carbonate rocks in the South Nevada mountains and intermountain valley systems, convincingly illustrated the ability of karst processes to create continuous aquifer development under complex structures (cf. Bredehoeft et al., 1982). Zötl's (1974) comprehensive text *Karsthydrologie* finally put an end to the debate in Europe with sound arguments in favor of the occurrence of large-scale connected karst water bodies with a coherent piezometric surface.

Nevertheless, karst hydrological systems can be extremely complex in structure and dynamics which often cause very specific behavior; for example, the occurrence of intermittent springs with their rhythmic periodicity. Katzer (1909) was the first to explain this remarkable phenomenon by a system of interconnected storage cavities and siphons.

1.3.1.3 Soil Water Physics

At the turn of the century a lack of insight to the nature and flow of water in the unsaturated zone hampered understanding of the process of infiltration and groundwater recharge. Particularly the observation that often after rainfall only the upper soil seemed to have become wetted, and that even after heavy rainfall no subsurface inflow was observed in depressions above the water table, made even serious scientists doubt that rainfall was the source of groundwater. Time and again the so-called *condensation theory*, as advocated by some philosophers of antiquity (cf. Section 1.2.2), emerged as the alternative source of groundwater production. This hypothesis was further supported by the observation that in confined aquifers the groundwater level sometimes rose before rainfall; a phenomenon that was later attributed to a decline of atmospheric pressure. Moreover, the results of poor lysimeter experiments often suggested evaporation on a drainage basin scale to be larger than the rainfall, so that an additional source of water was required to satisfy a balance. The controversy surrounding this subject was not only of scientific importance; emphasis on condensation as the single source of groundwater also threatened public health. For example, the influential antagonist of the rainwater-infiltration theory in Europe, the German geologist Otto Volger (1877), argued that concern for groundwater contamination by infiltration from polluted soil was a fear of phantoms, which would lead to unnecessary costs with the expensive construction of extraction wells for public water supply outside urban areas(!)

The dawn of understanding of the physics of the unsaturated zone began in the United States with studies by King and Slichter on soil water retention in relation to capillarity in porous material, but a breakthrough was the introduction in 1907 of the concept of capillary potential by Edgar Buckingham (1867–1940), then a physicist with the US Department of Agriculture. He recognized that, apart from gravity, the driving force of water flow in unsaturated soils is the difference in capillary suction, which in turn depends in homogeneous material on a difference in water content. He was also aware of the dependence of capillary conductivity on pore geometry and moisture content. Buckingham's theory can be formulated for the basic, 1D vertical steady-state flow case, by:

$$\nu = K_c(dh/dz \pm 1) \quad (1.7)$$

where ν = soil water flux [LT^{-1}]; K_c = capillary conductivity [LT^{-1}]; h = soil water head (capillary suction head) [L]; z = elevation above datum plane [L]; the gravity component = +1 for infiltration and -1 for capillary rise. The continuity between the flow in the unsaturated and the saturated zone is

evident from the equivalence of Equation 1.1 and Equation 1.7. However, because of the dependency of K_c on the moisture content, the flow in the unsaturated zone is generally strongly nonlinear.

The Australians W.H. Green (1868–1932) and G.A. Ampt (1887–1953) subsequently developed a theory of infiltration based on the Hagen–Poisseuille equation. They linearized Equation 1.7 by assuming vertical steady-state penetration by gravity of a wetted front with a sharp interface with the unsaturated underlying material (which means in Equation 1.7 that $dh/dz = 0$ at the interface). Their solution is still widely used (Green and Ampt, 1911). Interest in capillary processes and soil evaporation in the United States was particularly connected with the practise of dry farming.

Willard Gardner (1883–1964) incorporated Buckingham's capillary potential into a more complete flow theory (Gardner, 1920). This was put in a more definitive form by his student Lorenzo A. Richards (1931), who combined the flow equation with the continuity equation into the general nonlinear flow equation for water in unsaturated soils, now generally known as the "Richards equation." Another significant contribution by Gardner was the development of a porous-cup tensiometer. This instrument allowed systematic study of the soil water retention characteristics, for which Schofield (1935) in the UK introduced the concept of the *pF curve*, after Veihmeyer and Hendrickson (1931) had introduced the related *field capacity* concept, and Haines (1930) had discussed the *hysteresis effect*.

These developments established a basic understanding and mathematical expression of flow processes in the unsaturated zone, although application remained restricted to laboratory and plot-scales because of the strongly spatial heterogeneity within the unsaturated zone, and the complicated transient and nonlinear nature of the flow processes.

1.3.2 Aquifer Exploration

In the period around World War I the origin of groundwater, and the physical basis for the process of infiltration as well as a sound theory for groundwater flow, were well-established. The solution of a groundwater flow problem in idealized and schematized situations was essentially reduced to the mathematical solution of the general groundwater flow equation for specified boundary and initial conditions. Adequate dissemination of the theoretical knowledge in Europe was notably effected by Forchheimer's (1914) textbook *Hydraulik*, which contained a chapter on the theory of groundwater flow. Other more general German language books on hydrology were those of Konrad Keilhack (1912) and Prinz (1919). In the United States the knowledge to date was summarized in the volumes by Adolph F. Meyer (1917) and Daniel W. Mead (1919). In France, Daubrée's work was succeeded by Martel's (1921) thorough text on the geological aspects of groundwater occurrence. These early texts combined descriptive characterization of hydrogeologic conditions with basic mathematical treatment of groundwater flow, and stream- and groundwater hydrograph analyses. International exchange of knowledge was largely stimulated, notably in Europe, by the founding in 1922 of the International Association of Scientific Hydrology (IASH) as subsection of the International Union of Geodesy and Geophysics. Until the establishment of specialized hydrology journals in the 1960s, the IASH conferences and their proceedings remained the most important means of information exchange.

Groundwater hydrology developed as an empirical science by way of interaction between conceptualization and mathematical solution of flow cases on one side, and assessment and observations of the physical characteristics and behavior of aquifers and groundwater basins on the other. This approach was particularly related to more or less controlled engineering conditions such as groundwater extraction by wells for water supply, or dewatering of excavations for building, or for mining purposes and land drainage. This association of hydrogeology with societal-driven problems was particularly successful in the Netherlands, where shallow water tables demand adequate groundwater control, and where the hydrogeological framework is relatively simple (cf. De Vries, 2004). The subsurface consists of unconsolidated, relatively homogeneous Quaternary sediments with artificially controlled groundwater and surface water levels, and well-defined boundary conditions. The western part of the country can be characterized as a coastal lowland, consisting of leaky aquifers formed by a subsurface of more than 150 m

of medium-coarse Pleistocene fluvial sand, which is confined by a semi-pervious layer of up to 15 m of Holocene clay and peat with shallow water tables and abundant surface water.

A first theoretical analysis of groundwater flow to extraction wells and to deep circular polders in these leaky aquifers was presented by Kooper (1914), an officer in the Army Corps of Engineers and employed by the National Bureau for Drinking Water Supply (RID); the Bureau was established in 1913 to support the development of water-supply schemes, notably in rural areas. Kooper arrived at a mathematical expression using Bessel-functions, which proved to be quite adequate for groundwater exploration and management. The solution for this steady-state flow case was subsequently elaborated and made more accessible by Gerrit J. de Glee (1897–1975) in his 1930 Ph.D. thesis; his well flow formula for leaky aquifers is generally referred to as the “De Glee formula,” which is equivalent to that published in the United States by Jacob (1946). Similar formulae were developed in Germany by Schultze (1924), and were extensively applied in the drainage of excavations for hydraulic engineering construction in the coastal lowland of the northern part of that country.

Rather different hydrogeologic conditions and needs for groundwater were encountered in the United States (cf. Rosenshein et al., 1976; Bredehoeft et al., 1982). Interest in groundwater emerged in the last decades of the 19th century in connection with the opening of the semiarid midwestern plains. Water was demanded by the settlers for household use, stock breeding, irrigation and railroads, and the occurrence of groundwater with artesian properties was, in the absence of a suitable power source for mechanical pumps, a favorable condition for development. After the founding of the USGS in 1879, many eminent geologists received the task to investigate the large artesian basins, where the geologic structure has an important control over the movement of groundwater and the character of the aquifers and confining layers. Thomas C. Chamberlin (1885) produced the first studies on artesian basins, based on the assumption that the pressure-producing mechanism is the hydrostatic weight at the outcrop area, the influence of which extends down-dip. Another classic study was the exploration of the Dakota sandstone by Nelson H. Darton (1909). More difficult to visualize in those early days were the flow processes in the phreatic aquifers where hydraulic head is a subdued replica of the topography, and where the complex 2D regional flow patterns between recharge and discharge areas were difficult to understand (cf. Section 1.3.1.1).

A systematic approach to the regional hydrogeology of the United States and the underlying principles emerged under the eminent leadership of Oscar E. Meinzer (1876–1948), who became chief of the USGS Groundwater Branch in 1911 and who successfully integrated geological information with groundwater hydraulics. Exploration was concurrently advanced by the introduction of hydraulic rotary drilling and the deep-well turbine pump, which enabled to lift water from greater depths. Meinzer began with a systematic inventory of all regional information into a complete description of the various hydrogeological provinces and terrains, including a characterization of the porosity and permeability of different rock types. This information was laid down in a textbook that presented an outline of groundwater hydrology with clear, concise definitions; for example, of concepts such as *specific yield* and *specific retention* (Meinzer, 1923a, 1923b).

Meinzer’s contribution to scientific concepts is particularly related to his classical work on the origin of artesian pressure and its connection with rock compressibility. Studies and analyses of the Dakota sandstone artesian aquifer became classic in this respect. Many facts, concepts, and arguments were put together and evaluated to arrive at a sound understanding. A key argument was based on the observation that groundwater production in excess of replenishment resulted in a decline of both yield and artesian pressure in the vicinity of the well, but did not cause a lowering of the pressure at the recharge area. Since the confined aquifer remained full of water all the time, this could only be explained by the delivery of water from an elastic change in the aquifer’s volume by compression, through reduction in the buoyant force (Meinzer and Hard, 1925; Meinzer, 1928). Other arguments in favor of the elastic nature of aquifers were derived from observations on tidal and earthquake effects on well levels, water level reaction to an increase in overburden load caused by passing trains, slow expansion and recovery of depression cones around wells, and land subsidence near wells. Subsequent analysis of the different reactions of rigid and compressible aquifers to changes in atmospheric pressure helped to obtain insight on the nature of

compressibility (cf. Meinzer, 1942). Meinzer can, because of his unifying work, be considered as the architect of modern hydrogeology.

According to Tolman (1937, Chapter XI), discussion arose on the question whether artesian pressure could be produced solely by the load of the confining overburden, or if a combination with hydraulic pressure from the intake was a prerequisite. Meinzer was in favor of the latter view, but others argued that the Dakota sandstone was not continuous from the outcrop and showed an irregular pressure distribution (e.g., Russel, 1928). Discussions followed on the question of whether the yield from storage was from the aquifer itself, or from the confining layers or from both. Further insight to the processes of compressibility and consolidation were advanced on the basis of the classic work of (Czech-born) Karl Terzaghi (1883–1963) on soil mechanics, with his concept of *effective stress* as the total lithostatic pressure minus the hydraulic (buoyancy) pressure (Terzaghi, 1925, 1929).

Terzaghi's studies on land subsidence caused by groundwater extraction and subsequent compression and compaction of the aquifer and connected water-saturated clays, including the process of consolidation, were further advanced by Skempton (1944) and Terzaghi and Peck (1948). Analysis of the geological process of deformation in a three-dimensional (3D) stress field was pioneered by Biot (1941) and Geertsema (1957), and further extended by many others (e.g., Bredehoeft and Hanshaw, 1968). Myron L. Fuller of the USGS was probably the first in the United States to speculate on the relation between groundwater extraction and land subsidence (cf. Helm, 1982). Studies on such phenomena have been carried out in the United States for decades under the leadership of Joseph F. Poland, who established a research center in Sacramento, California (e.g., Poland, 1961; Poland and Davis, 1969). Another process of land subsidence took place in the Netherlands where drainage of coastal marshland has resulted in a lowering of the surface of more than 5 m during the last 800 years.

1.3.3 Advanced Developments in Groundwater Hydraulics

1.3.3.1 Flow Analysis and Aquifer Tests

Prior to the mid-1930s pumping tests were predominantly based on the Thiem-formula for steady-state radial flow from a circular fixed head boundary at the so-called distance of influence (cf. Figure 1.3). In response to needs of engineering practice, many attempts were made to assess the distance of influence and to evaluate other effects like hydraulic boundaries, hydraulic gradients previous to pumping, anisotropy, influence of diffuse infiltration, and so on. The most extensive evaluation of the limitations of this method was performed by Leland K. Wenzel from a large pumping and recovery test on Grand Island (Nebraska), using an analysis of the drawdown in 80 observation wells (Wenzel, 1932, 1936).

A breakthrough in the development of well hydraulics were the analyses by Charles V. Theis (1900–1987) of the nonsteady state conditions during groundwater extraction and recovery. Theis (1935) derived his formulae for drawdown and recovery of the water level in the vicinity of a pumped well through a delivery of water from storage, by making use of an analogy with heat conduction and capacity. Theis assumed an instantaneous release of water at the falling water table, and introduced the related concept of *storage coefficient*. He also adequately simulated the recovery phase by assuming a recharge of the well at the same constant rate as the extraction rate. Theis was assisted in these studies by his friend the mathematician C.I. Lubin who, however, refused co-authorship. An earlier attempt to solve the same problem was made by the German Weber (1928). His solution was based on a constant drawdown and a shifting radius of influence, whereas Theis considered an infinite distance of influence. Norman S. Boulton, in the UK, also predated Theis with a transient solution in the early 1930s, but according to Downing et al. (2004) his paper was rejected for publication. Transient flow in confined aquifers with change in storage from compressible fluids was further considered in research connected to oil exploration by Hurst (1934) and Muskat (1934).

Charles E. Jacob (1914–1970) subsequently derived non-equilibrium theory on the basis of pure hydrological concepts, and arrived at a formula for the confined storativity based on the physics of compressibility of both rock and water. He in fact produced the first comprehensive formulation of transient confined flow (Jacob, 1940, 1950). Jacob also analyzed the effect of a change in atmospheric

pressure on the water well level (*barometric efficiency*) in terms of compressibility of the aquifer. Subsequent mathematical solutions for unsteady-state radial flow in a leaky aquifer, without release from storage from the confining layer, were given by Hantush and Jacob (1955). These formulae were expanded by (Iraq-born) Mahadi Hantush (1921–1984) for conditions where water is released from storage in the confining layer (Hantush, 1960, 1964).

An engineer with the Amsterdam waterworks, L. Huisman, and mathematician J. Kemperman, extended the “Kooper–De Glee formula” for an aquifer between two semi-confining layers (Huisman and Kemperman, 1951). The solution of this problem was needed to adequately analyze multi layer pumping tests in the Amsterdam dune catchment. The theory was tested by data from a large-scale pumping test for design of a deep-well drainage scheme for a tunnel excavation below the shipping canal between Amsterdam and the North Sea. Subsequently, a solution for transient well flow in a leaky double-layered aquifer was derived by Hantush (1967).

Prediction of the decline in shallow groundwater levels by groundwater extraction or by land drainage has always been an important question in the Netherlands in connection with land subsidence, reduction of crop yield, up-welling of salt water, and damage to wooden foundation piles in the old cities. Large-scale exploitation of a 250 m thick, complex stratified aquifer system in the Netherlands Rhine-Meuse delta initiated in the 1980s rigorous mathematical analyses of steady and transient well flow in multiple-leaky aquifer systems by, notably, G.A. Bruggeman, C.J. Hemker, and C. Maas. They applied combined analytical-numerical techniques in a model that has some similarity with the double porosity concept in hard rock aquifers (see below), and verified the results by extensive field experiments. In the United States, Dutch-born Otto Strack developed his multilayer analytical element model. Recently Hemker and M. Bakker (Dutch Ph.D. graduate of Strack) extended the multilayer approach to include different horizontal anisotropic conductivities in one or more layers. 3D flow pattern analysis in such aquifers revealed that stream lines often create spirals, a bundle of which is termed “groundwater whirl”.

Advances in groundwater hydraulics in the first half of the 20th century, and notably in the period 1930–1960, were dominated by analysis of groundwater extraction by wells, though other subjects like flow in the vicinity of canals and seepage through and below dikes and dams were also considered, particularly in the Netherlands coastal lowlands. For example, by using a complex variable technique C.G.J. Vreedenburgh (De Vos, 1929) was probably the first to derive an exact mathematical solution for flow through a dam under free water table conditions. Moreover, he solved the problem of flow through an anisotropic medium (Vreedenburgh, 1935), and simulated 2D groundwater flow in an electrolyte tank on the basis of analogy between Darcy's law and Ohm's law (Vreedenburgh and Stevens, 1936). At that time Vreedenburgh was a professor at the Technical University of Bandung (former Dutch East Indies), and although his studies basically originated from the problem of seepage through dams and levees in irrigated fields, this work was also applicable to Dutch polder conditions. The problem of flow pattern analysis in an homogeneous but anisotropic medium was later on extensively discussed in the United States by (Dutch-born) M. Maasland in the framework of land drainage studies (Maasland, 1957).

Further mention should be made of Steggewentz' (1933) Ph.D. thesis on the propagation of ocean tides in coastal aquifers, which included an early solution for delayed vertical flow near the water table in response to water pressure oscillations. Steggewentz assumed that this flow resistance at the capillary fringe explained the relatively fast propagation of water pressure in phreatic aquifers in the coastal dune area. It was only in the 1950s that this concept appeared in the international literature as the *delayed yield* principle, in connection with the early phase of transient well flow (Boulton, 1954). Boulton's semi-empirical approach with exponentially decreasing leakage flux with time was further mathematically and physically extended in the 1970s, notably by S.P. Neumann and T.D. Streltsova. Several Dutch contributions to the analysis of ocean tides in leaky and compressible aquifers, including the problem of the finite response time, were subsequently produced (cf. Raats, 1969; Van der Kamp, 1973). Considerations in the United States of periodic groundwater flow and bank storage induced by stage oscillations in adjacent open water are notably known from Ferris (1951), and Cooper and Rorabaugh (1963).

More general analyses of the transient, nonlinear interaction of the saturated–unsaturated zone near the water table became within reach after soil scientists (notably Klute, 1952) introduced the numerical

finite difference approach of the Richards equation. In particular, the problem of pore-space drainage due to a rapidly falling water table was studied with respect to the meaning and process-dependence of the *specific yield* concept (e.g., Dos Santos Junior and Youngs, 1969). The soil physicist Don Kirkham (1967) examined in this connection the position of the moving free surface (flow line boundary) in the Dupuit–Forchheimer flow case. This problem is dominated by the paradox of a changing storage, without possible interaction of the saturated–unsaturated zones by a front that crosses the flow-line boundary.

The requirement for information on small-scale spatial variability of hydrogeologic properties came particularly into perspective with the need for a distributed flow approach in heterogeneous aquifers, in connection with numerical modeling of combined water and solute transport. These developments were stimulated and accelerated by the environmental pollution problems which surfaced especially in the early 1970s, after publication in 1972 of the Club of Rome report *The Limits to Growth*. There was a developing awareness that contamination by leaking waste disposal, oil spills, and by agriculture activities, together with increasing extraction of groundwater, had continuously deteriorated groundwater quality. Groundwater hydrologists evidently had to shift their focus from water quantity to water quality, and needed to include spatial heterogeneity in their flow analyses (cf. Section 1.3.5). Pioneering geostatistical studies of the transport parameters were carried out, among others, by Freeze (1975) in Canada, Gelhar (1977) in the United States, and Delhomme (1979) in France.

Many other studies have subsequently been carried out in the framework of reservoir engineering, particularly in connection with the disposal of hazardous and radioactive wastes. These studies include flow through fractured media and are closely related to regional stress and strain-field analysis in structural geology. A first approach to a general theory of inhomogeneous fractured media was the *double-porosity* concept, initially developed by the Russians Barenblatt et al. (1960). This concept is based on a division of the subsurface into a storage-providing matrix block and a transport-facilitating fracture system. Boulton and Streletsova (1977) pioneered well flow in a fissured medium in this way, after earlier work had been carried out on flow in single-fracture systems (Gringarten and Witherspoon, 1972). Important in this respect are the continuing advances in exploration technology, including surface and subsurface geophysics and remote sensing techniques, which have contributed to a better determination of the distribution of hydrogeological structures and flow patterns. In addition, inverse numerical computer modeling became a tool in the 1970s to study subsurface structures and associated distributed parameters.

Other aspects of groundwater in relation to geological structure and geo technical problems are associated with the geothermal gradient and temperature distributions in regional groundwater systems. Most accounts of groundwater temperatures are, however, concerned with thermal springs and date back to the 19th century. Early analysis concerning the simultaneous flow of water and heat are from the 1940s by Henri Schoeller in France (cf. Schoeller, 1962, Chapter VI). More recent, well-known studies from the United States are those by Stallman (1963), and Bredehoeft and Papadopoulos (1965). In a classic paper, Hubbert and Rubey (1959) analyzed the influence of groundwater pressure on fault movement, and notably explained the overthrust faulting on the basis of Terzaghi's theory of effective stress. Bredehoeft (1967) considered earth-tide induced groundwater level oscillations on the basis of the elastic vertical deformation of the earth crust due to the moving tidal bulge in the solid earth. Evidently, geology and hydrology strongly interact with processes on a geological time scale; examples are thermo-chemical convection, and water and geochemical-related diagenesis and consolidation processes.

1.3.3.2 The Problem of the Fresh–Salt Water Interface

Salinization of the coastal dune area in the Netherlands, caused by over exploitation of groundwater for drinking water, proceeded until artificial recharge with river water after World War II began to reverse the process. Different exploitation strategies had been exercised in the preceding period to prevent salinization; these were mainly based on a choice between either deep extraction from a semi-confined part of the subsurface or shallow extraction from the upper phreatic aquifer. Mazure (1943) presented an analytical solution for predicting the evolution of the fresh water pockets for these different scenarios. His approach was further elaborated by Todd and Huisman (1959) for the Amsterdam dune water catchment, making use of the first main frame electronic computer at the Amsterdam Mathematical Center for the laborious

numerical calculations. More advanced analyses, including the flow of salt water below the fresh water pocket toward the deep polders behind the dunes, as well as the influence of artificial recharge, were subsequently carried out when the computing power increased.

Further theoretical analyses of transient flow were initiated to predict groundwater evolution in the coastal dunes caused by the proposed artificial infiltration from broad channels. This work was carried out by the engineer with the Amsterdam Waterworks, J.H. Edelman, and published in his 1947 Ph.D. thesis (cf. Edelman, 1972). His work included analysis of (i) propagation into the adjacent aquifer of instantaneous water level changes in channels, (ii) transient well flow (an alternative solution to arrive at the Theis formula, based on Weber, 1928), and (iii) numerical calculations using a hexagonal finite difference network for regional groundwater flow, including density-driven flow. The finite difference approach was derived from mechanical engineering (Richardson, 1911), and Edelman used the relaxation method of Southwell (1940) for the iteration and optimization procedures.

In the course of time, many analytical and numerical studies of groundwater flow involving fresh and salt water followed in the Netherlands, initially supported by electrical resistance and capacitance-network analogons, and subsequently by computer simulation models. An example of the first category was the 5000 grid-point Electric Network Analogon for Groundwater Flow (ELNAG). This was developed in the 1960s to forecast steady-as well as transient fresh and salt groundwater flow in connection with a large-scale water management and flood protection project (the so-called Delta Works) in the south-western estuarine area of the Netherlands. This scheme, carried out from the 1950s to the 1980s, was a response to the devastating flood that struck the Netherlands in 1953. Other studies concentrated on reconstructing and predicting the long-term redistribution of fresh and salt water occurrences, caused by 1000 years of land reclamation and associated changing groundwater level topography (CHO-TNO, 1980; De Vries, 1981).

Many studies on the fresh-saltwater interface were carried out in the United States, particularly in the extensively studied coastal area of Florida. Luszynski (1961) introduced the valuable concept of the *point-water-level* to reduce head measurements in a multi-density field to the same density. Glover (1959) contributed to the influence of seepage across the interface, and Kohout (1960) from the United States as well as De Josselin de Jong (1960) from the Netherlands, and Bear (1961) from Israel, considered the multi-density interaction processes at the interface, including dispersion and diffusion. Numerous investigations followed in coastal areas on the behavior of the interface under the influence of external conditions (e.g., Verruijt, 1969). Research in this field in Europe was highly stimulated by the regularly organized Salt Water Intrusion Meetings (SWIM), which started in 1967 as a Dutch-German initiative.

1.3.3.3 Consolidation of Hydrogeology as a Scientific Discipline

Numerous solutions of the general flow equation for different schematizations of subsurface structures, liquid density differences, and the character of the boundary and initial conditions have been developed in the course of the half-century between the 1920s and 1970s. Many mathematical techniques were identified as being suitable to solve the Laplace equation, including graphical flow net analysis, separation of variables, integral transformations, conformal mapping, and numerical methods. Electric analogons were widely used to particularly study cause-and-effect relationships in complicated aquifer situations for steady- as well as transient flow (e.g., Karplus, 1958). These analogons were gradually replaced from the 1960s by the more flexible numerical solutions using computer simulation models (e.g., Fayers and Sheldon, 1962; Chun et al., 1964). Viscous parallel plate models were applied particularly for flow conditions with multi-density fluids. In the Netherlands, a unique, horizontal, parallel plate model with vertical storage was build by the National Bureau for Drinking Water Supply to simulate unsteady flow under water table conditions, and to assess the effect of groundwater extractions on the water table (Santing, 1957).

For many years, Morris Muskat's (1937) monumental book with theoretical solutions of flow problems for homogeneous and heterogeneous fluids (particularly meant for petroleum engineers) remained a reference in the English-speaking world; German-speaking countries mainly used a similar text of more limited scope by Dachler (1936). Geological aspects of groundwater behavior were emphasized in Cyrus F. Tolman's (1937) textbook. Theoreticians in search for new solutions often made use of Carslaw and Jaeger's standard text on analytical solutions of heat conduction, the first edition of which appeared in

1921. However, it was only in 1940 that Marion King Hubbert (1903–1989) discovered that the until then applied concept of the velocity potential (Kh) in the Laplace equation did not have general validity in the case of a 2D and 3D anisotropic flow field. He, therefore, proposed the generally applicable concept of the force potential (gh). He further examined Darcy's law in the light of the microscopic Navier–Stokes flow theory, and emphasized its character as a macroscopic law. Hubbert, who was familiar with earlier oil exploration research on the influence of fluid properties on percolation, (notably by R.D. Wyckhoff and others, including Muskat), further reviewed the concept of *intrinsic permeability* and the limits of the validity of Darcy's law. With a graphical solution for the pattern of flow lines between recharge areas and the associated drainage line, he explicitly illustrated the connection between water table elevation at a point and the value of the intersecting equipotential line. His well-known flow-net picture is, however, not essentially different from Pennink's case, as is depicted in Figure 1.5. It can be stated that Hubbert's rigorous treatise finally consolidated the scientific basis of groundwater hydrology within the general theory of hydrodynamics.

Information on the partly parallel developments in Eastern Europe and the former USSR, notably on the theory of groundwater flow, became available with the 1962 translation of Polubarinova-Kochina's (1952) well-known textbook *Theory of Groundwater Flow*, and subsequently through the text *Groundwater Hydraulics* by the Czechs Hálek and Sveč (1979). Until the early 1960s, the most complete volume on the theory and application of groundwater hydrology, including physical and chemical aspects, was probably Henri Schoeller's (1962) *Les Eaux Souterraines*. An accessible and popular English text on groundwater engineering, in the early 1960s, was David K. Todd's (1959) *Groundwater Hydrology*; this was followed by a more elaborate treatment by Milton E. Harr (1962). A large number of more advanced groundwater textbooks have subsequently been produced since the mid-1960s, and specialized international journals have appeared, including *Hydrologic Science Bulletin of the IASH* in 1956, *Journal of Hydrology* in 1963, *Ground Water* in 1963, and *Water Resources Research* in 1965. This reflects the increasing world wide interest in water resources management in this period, and the recognition of hydrology as a discipline in its own right.

These developments are also illustrated by the founding of the International Association of Hydrogeologists (IAH) in 1956, and the establishment in 1965 of UNESCO's International Hydrological Decade (IHD), forerunner of the present International Hydrological Programme (IHP). Another indication of emancipation of hydrology as a science was the 1971 decision by the International Association of Scientific Hydrology (IASH) to change its — somewhat defensive — name to International Association of Hydrological Sciences (IAHS). Well-known examples of broad and integrated texts on groundwater from the mid-1960s to the late 1970s include Davis and De Wiest (1966), Walton (1970), and notably Freeze and Cherry (1979). Bear et al. (1968), Verruijt (1970), and Bear (1972) produced an overview of the fundamentals of flow through porous media and theoretical approaches to the solution of groundwater flow problems. Remson et al. (1971) covered the application of numerical analysis, Kruseman and De Ridder (1970) developed a manual for analysis and interpretation of pumping test data, and Zötl (1974) wrote a comprehensive text on karst hydrology. Specialized volumes on chemical and contaminant hydrogeology, groundwater recharge, and isotope hydrogeology followed in the 1980s and 1990s.

1.3.4 Integrated Analysis of Regional Groundwater Systems

1.3.4.1 Basin-Scale Analysis and Evaluation

Regional reconnaissance studies in the early 20th century in the United States, included the delineation of recharge and discharge areas, flow pattern analysis, temperature measurements, monitoring of groundwater level fluctuations, and the determination of aquifer properties by steady-state pumping tests. Lysimeter experiments to assess elements of the water balance were already applied in the early 19th century, but their conditions were often very different from the undisturbed terrain and difficult to regionalize over larger areas. Veatch (1906) analyzed a large number of groundwater level fluctuations, particularly from Long Island, and reviewed the results of earlier lysimeter research. A first quantitative approach, based on water budget considerations, was presented by the chief of the Groundwater Branch

of the USGS, Mendenhall (1905), on an aquifer in South California. These studies were extended by Charles H. Lee (1914) into one of the first sound resource evaluations with regard to the *safe yield* concept.

The first extensive regional study in the Netherlands was carried out by the National Bureau for Drinking Water Supply in the coastal dune area. An analysis of the results from a large number of boreholes to depths of more than 100 m, with piezometers at different levels, produced a detailed 3D picture of the hydraulic head, corrected for water density, and the associated flow patterns (Van Oldenborgh, 1916). In addition, four large lysimeters (each with dimensions of 25×25 m and a depth of 2.5 m) were built in the 1930s in the dunes near Castricum to study the influence of vegetation on groundwater replenishment, in particular to assess the effect of afforestation of the dunes with pine trees. The results revealed a recharge reduction under pines of more than 50% relative to the annual 350 mm under natural dune shrub vegetation (cf. Stuyfzand, 1993).

Groundwater recharge and discharge components on a basin scale were studied during the first half of the 20th century almost exclusively by the water budget approach. Phreatic aquifer recharge was quantified by a combination of groundwater level rise and recession hydrographs, whereas river basins were analyzed using measurements of rainfall, stream runoff, and estimates of evapotranspiration. The study of base flow recession curves has been widely used to identify the hydrogeologic character of watersheds, and to separate fast (near-)surface runoff components of recent rainfall from storage prior to rainfall. This problem of hydrograph separation was extensively reviewed by Hoyt (1936), the results from an assessment of annual groundwater discharge from 22 US stream basins.

Numerous empirical studies have been carried out in the United States, as well as in Europe and the former USSR, to relate annual stream flow to rainfall. Most formulae were of the form $Q = aR - b$, where R is annual rainfall, and a and b are regional or watershed-specific parameters for average long-term conditions. In more advanced studies, the evaporation-related factors a and b are variables, expressed as functions of average temperature. Temperature-dependent annual evapotranspiration relations that have been widely used in watershed balance studies are, for example, the empirical potential evaporation formulae of Thornthwaite (1948) from the United States. In France, Turc (1954) proposed formulae for average discharge as a function of average temperature and rainfall based on a large number of watershed studies. These methods provide reasonable order of magnitude results, notably for the annual time scale. Thornthwaite also used his formulae for his well-known climate classification based on the monthly difference between rainfall and potential evaporation (Thornthwaite and Mather, 1955). More complex empirical rainfall-runoff relations, including watershed morphological characteristics, were developed for storm runoff prediction. R.E. Horton's papers on infiltration in the 1930s and 1940s, in particular, initiated numerous studies on the separation of surface runoff and groundwater discharge (cf. Hall, 1968). A well-known example of a semi-empirical runoff model with numerous parameters is the "Stanford Watershed Model," application of which only became feasible after the introduction of powerful digital computers in the late 1950s.

An analytical study of basin-scale dynamics of groundwater level fluctuations due to seasonal and inter-annual pulses of recharge was proposed by the Belgian Leon J. Tison (1951). (Tison was well-known for his leading position in the International Association of Scientific Hydrology.) Wright and Edmunds (1971) analyzed the depletion and residual flow in "fossil" groundwater basins in the Libyan Sahara on a time scale of 10,000 years (cited by Burdon, 1977, who similarly considered the whole Sahara and Arabian desert). More advanced time-series analysis of groundwater levels became available in the 1970s from application of the semi-empirical transfer function modeling procedures of Box and Jenkins (1970), originally developed to analyze economic trends. This method estimates groundwater level fluctuation as a response function of the external driving forces, on the basis of an empirical stochastic correlation and a deterministic auto-correlation (recession) function. It proved to be particularly applicable as a diagnostic tool to detect trend or to identify the influence of interfering processes. Evaluation of groundwater resources got a new perspective with the emergence in the 1960s of environmental isotopes and noble gas tracers as a tool to reconstruct paleohydrologic evolution, and to assess recharge and discharge components (cf. Section 1.3.5.2).

1.3.4.2 Topography Driven Groundwater Flow Systems

Until the 1960s emphasis was on the exploration and engineering requirements of groundwater hydrology, including the inventory of groundwater resources and groundwater balance studies. A more integrated regional approach to gain understanding of natural groundwater flow systems and associated hydrochemical process interaction with the subsurface, topography, vegetation, and climate, emerged in the 1960s from the work of Peter Meyboom and József Tóth, notably in the glacial hummocky terrain of the Canadian prairies. In these areas the water table follows the topography at a regional scale because the hydrogeology is dominated by clay-rich glacial till with low permeability. Most of the shallow water movement is therefore regulated by topography-controlled infiltration and evapotranspiration, which accordingly control the depth of the water table below ground surface.

Meyboom mapped the spatially distributed groundwater heads in the vicinity of glacial potholes, and recognized the seasonal dynamics of expanding and contracting seepage zones and shifts in groundwater flow patterns. He further identified discharge phenomena related to these “groundwater outcrops” such as springs, seeps, and salt tolerant vegetation in exfiltration zones with evaporation-induced increased salinity (Meyboom, 1966). Tóth (1962, 1963) derived an analytical solution (using a separation of variables technique) for the steady-state topography-driven flow systems with areas of recharge and discharge, the latter often characterized by seepage zones. It followed from the observations by Meyboom and the theoretical analysis of Tóth that, depending on the topography, nested flow systems of different order are generated which are characterized by shallow local systems superimposed on deep, regional systems.

Allen Freeze and Paul A. Witherspoon (1966, 1967) applied numerical analysis to examine and extend Tóth's flow systems by including subsurface heterogeneity. The concept of topography-driven and geologically transformed local and regional flow systems has subsequently been widely used in exploration, mapping, and analysis of groundwater basins at various scales. It should be noted, however, that the concept of nested flow systems was not new. For example, René d'Andrimont of Belgium, who was inspired by Pennink's work, recognized this regional flow pattern at the beginning of the 20th century and presented a picture of the phenomenon as a novelty at Brussels World Exhibition in 1910 (Figure 1.6; D'Andrimont, 1910).

There is a strong similarity between the Tóth–Meyboom approach and investigations in the Netherlands on groundwater drainage of shallow aquifers by stream systems of different order. Lodewijk F. Ernst of the Institute of Land and Water Management Research (ICW), in particular, analyzed the interaction of topography and the seasonal contraction and expansion of the drainage system caused by fluctuations in the groundwater table; he arrived at formulae, which were similar to those from Tóth (Ernst, 1962, p. 84). Both Meyboom and Tóth (who originated from the Netherlands and Hungary respectively) studied in the Netherlands, and were familiar with Ernst's work in general, but Tóth and Ernst derived their analytical formulas independently. Jacobus J. de Vries (1977) expanded Ernst's ideas to analyze the natural stream network under shallow aquifer conditions, and to explain them genetically as outcrops of groundwater flow systems of different order, driven by topography, climate, and seasonally fluctuating water tables.

1.3.4.3 Groundwater Discharge and Land Drainage

The Netherlands has more than 1000 years of tradition in land drainage, but the design of dewatering systems used to be based mainly on experience. This changed in the 1930s when a 250,000 ha land reclamation scheme in the former Zuiderzee (a North Sea embayment) was initiated, and a rational water management of this newly created land was proposed. Trail blazing theoretical analyses and experiments related to land drainage processes were carried out at laboratory, plot, and field scale by Symen B. Hooghoudt (1901–1953) at the Groningen Soil Science Institute and Experimental Station. These led to formulae for steady, horizontal flow through two-layer soils with radial converging flow components near the drainage channels (Hooghoudt, 1940). Hooghoudt simply transformed, by imaging, radial horizontal well flow theory into vertical radial flow, in order to evaluate the effective depth of drainage.

His work was further advanced theoretically by his students, the physicists Van Deemter (1950) and Ernst (1956), who included soil heterogeneity, drainage channel geometry, and nonlinear flow considerations.

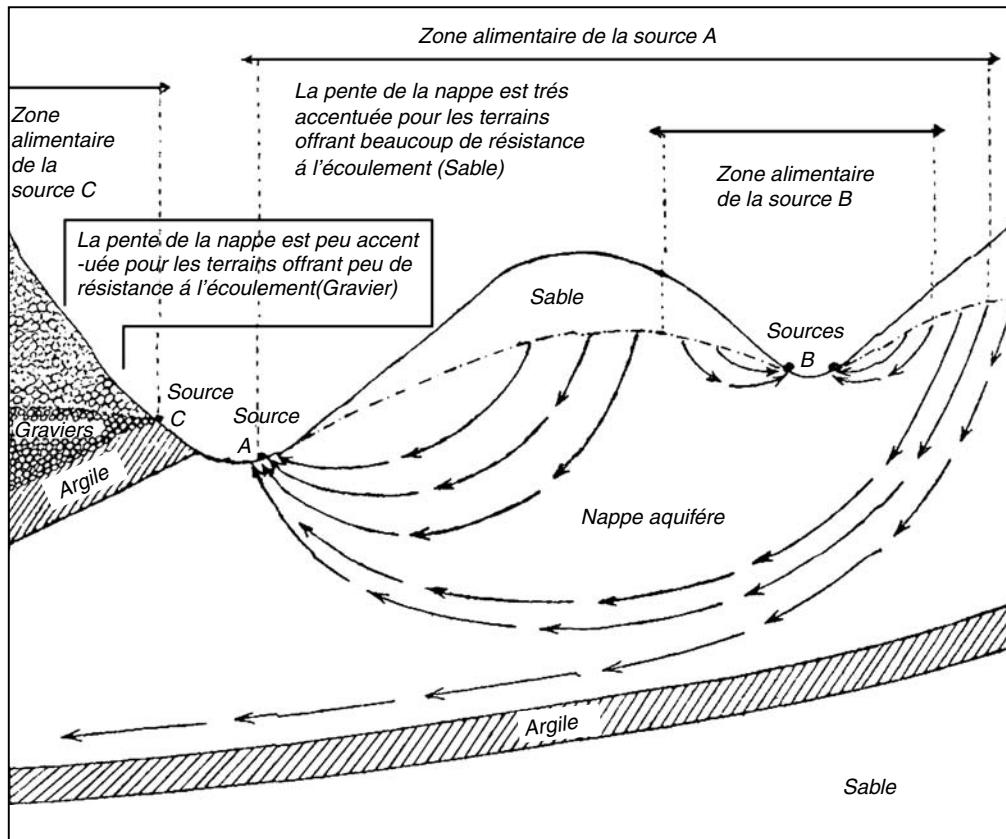

FIGURE 1.6 Groundwater flow systems; picture presented at the Brussels World Exhibition in 1910 by René d'Andrimont.

Their work was partly based on early analytical formulae by the Dutch professor of hydrodynamics, Burgers (1926) which they combined with the numerical relaxation method according to Southwell (1940). Similar situations were investigated in the United States by the soil physicist Don Kirkham and collaborators (e.g. Kirkham, 1954). Dutch-born Ph.D. students at Cornell and Iowa State Universities (notably Jan van Schilfgaarde) facilitated the export of Hooghoudt's ideas (which were published mainly in Dutch) to the United States (e.g., Van Schilfgaarde et al., 1956; cf. Raats and Van der Ploeg, 2005).

Previous to Hooghoudt's pioneering work, land drainage in Western Europe was based mainly on simple Dupuit assumptions of horizontal flow to ditches, and fed by uniform rain infiltration at the water table (cf. Section 1.3.1.1, Equation 1.4). This approach had already been applied in the second half of the 19th century by the Dane Ludvig Colding, who was in turn inspired by drainage experiments by the French engineer S.C. Delacroix in the 1850s (cf. Raats and Van der Ploeg, 2005).

Numerous studies have been carried out since the 1950s on time-dependent drainage processes from shallow flat-land aquifers with high drainage density, in connection with dewatering and groundwater table control. These processes are complex and strongly nonlinear because the shape of the water table, as well as the storage factor, are changing in time and space, and because of the influence of the drainage channel geometry on the flow resistance. An approximate, but reasonably adequate formula for the drainage process was derived by Dirk A. Kraijenhoff van de Lier (1958) in the Netherlands. He assumed a cascade of linear storage basins and combined this with the effect of the falling water table near the channel. This solution of the impulse-response process is related to the Glover-Dumm treatise of a falling groundwater table after an instantaneous delivered depth of irrigation water at the surface (Dumm, 1954),

and to Edelman's (1947) groundwater reaction following an instantaneous lowering of the water level in a drainage channel (cf. Section 1.3.3.2).

The physical processes of infiltration and the separation of shallow subsurface processes from percolation to the groundwater table are the domain of soil physics. Numerous studies by soil physicists, particularly in connection with agricultural water management and crop production, have been carried out on experimental plot scales. Many empirical formulae have been proposed for the relation between unsaturated hydraulic conductivity and soil moisture suction, based on textural properties of the soil. Well-known early formulae are those of Childs and Collis-George (1950) and Gardner (1958). Youngs' (1958) study of the vertical redistribution of moisture during and after the process of infiltration presented for the first time a coherent picture of the transient flow pattern in the unsaturated zone.

Paramount were the fundamental, physically based infiltration process studies by the Australian John R. Philip from the mid-1950s onwards (e.g., Philip, 1969). More relevant to regional hydrological processes were the numerical studies by Rubin and Steinhardt (1963) and Rubin et al. (1964) to predict infiltration from rainfall intensity and antecedent moisture conditions, as well as the integrated saturated–unsaturated modeling by Freeze (1969, 1971) to simulate the time-dependent response from steady ponding conditions resulting from constant rainfall.

Studies of capillary processes also led to a better understanding of evaporation from the soil. For example, Keen (1927) demonstrated that capillary uplift of moisture from the water table to the evaporating surface or root zone is strongly reduced if the water table is at a depth of about 35 cm for coarse sand and 85 cm for loam. More fundamental studies followed after the development of the physically-based Penman–Monteith evapotranspiration formulae (Penman, 1948; Monteith, 1965; Rijtema, 1965), which enabled to assess the actual evapotranspiration as a moisture–stress related function of the potential evapotranspiration.

Many experiments were carried out in the Netherlands from the 1950s through the 1970s to relate upward capillary flux and evapotranspiration to the depth of the groundwater table in shallow aquifers, in order to optimize groundwater depth with respect to crop yield (Wind, 1955). One of the applications was to determine crop yield reduction and damage to valuable wetlands caused by a lowering of the water table through groundwater extraction and land drainage. Similar studies have been carried out in arid areas in connection with irrigation requirements and the related hazards of salinization and clogging.

1.3.4.4 Runoff Generation on Sloping Areas

Land drainage studies are mainly connected with more or less artificially controlled conditions, often on low lying alluvial ground in more or less homogeneous situations. Under such conditions the drainage process can be characterized by lumped parameters, such as the *reservoir coefficient* of Kraijenhoff van de Leur (1958), that include the geometry of the drainage network as well as the subsurface permeability and storativity. Groundwater processes in natural watersheds and the generation of runoff, particularly on slopes and in heterogeneous areas, are much more complex. The separation of groundwater discharge from the total drainage basin runoff is a problem that is related to the distributed interaction of overland flow, saturated and unsaturated flow, and the process of infiltration.

Early investigations on infiltration of rainfall were carried out by Robert E. Horton (1933, 1945) as part of his pioneering studies on surface runoff, channel generation, and stream flow. He observed that infiltration capacity decreases rapidly over time in the course of a storm, and thus emphasized the dominance of surface processes. His work, however, referred mainly to semi arid conditions where overland flow is indeed common, especially because of the forming of infiltration-hampering salt crusts. At the same time, ideas about rapid runoff generation caused by interflow through piping, macro-pores, and perched saturated flow in stratified soils were, among others, advanced by Hursh (1936), Barnes (1939) and Hursh and Brater (1941), but their observations were probably neglected because of the authoritative concept of the so-called “Hortonian overland flow”.

It was only in the 1960s that it became evident that Horton's model did not apply to temperate areas with vegetation cover. Notably J.D. Hewlett of the US Forest Service, together with A.R Hibbert, developed

a new concept based on the observation that almost all rainwater normally infiltrates. This subsurface water subsequently runs off, partly through high permeability shallow horizons as flow in a perched saturated–unsaturated zone, and partly as deeper groundwater flow. Storm runoff is generated through converging discharge in the valley heads and other depressions with shallow groundwater tables, where the unsaturated zone becomes saturated and overland flow starts. The expanding *surface-saturated* zones develop notably along the upstream valley slopes and are responsible for the rapidly responding storm runoff (Hurst and Brater, 1941; Hewlett, 1961; Hewlett and Hibbert, 1963, 1967; Kirkby and Chorley, 1967). These so-called *partial-area* and *variable-source-area* concepts have been confirmed in later studies using tagged water and isotope tracer analysis (e.g., Fritz et al., 1976). There is a certain similarity with the previously mentioned contracting and expanding stream systems associated with shallow aquifers in level areas, where seasonal groundwater fluctuations determine the number and order of streams that participate in the groundwater drainage process (De Vries, 1977; Ernst, 1978).

Dunne and Black (1970a, 1970b) succeeded in simultaneously measuring the three components of discharge in an experimental watershed with an integrated set of instruments. The combined surface–subsurface, saturated–unsaturated flow approach has subsequently become the basis of runoff generation studies with reference to catchment morphologic conditions. Attempts in the 1960s to combine flow in saturated and unsaturated zones in numerical schemes paved the way for modeling of this saturated–unsaturated runoff system. One of the first integrated models was presented by Freeze (1972a, 1972b). Others applied environmental chemical and isotope tracers to separate the different systems, and to analyze their dynamics in field studies (e.g., Farvolden, 1963; Pinder and Jones, 1969).

These chemical tracer studies also confirmed the earlier assumptions that old water in storage is pushed out by newly recharged water. This combination of different approaches has eventually resulted in advanced physically based distributed modeling, in which the dynamic-contributed-area effect is combined with channel network topology; a well known model is TOPmodel (Bevin and Kirkby, 1979). Such catchment scale processes are evidently highly nonlinear in time and space, and subject to scaling problems.

These runoff generating processes are strongly related to slope erosion. Understanding of shallow subsurface flow and related surface runoff is essential for the understanding of the slope processes, and particularly of scarp retreat and the head wards extension of valley tributaries. Flow in a perched saturated zone can lead to seepage erosion and tunnelling by entrainment of grains in water emerging from a porous medium (Terzaghi, 1943; Buckham and Cockfield, 1950). The role of subsurface flow in stream channel initiation and development was proposed by, among others, Chorley and Morgan (1962), Dunne (1970), Jones (1971), and De Vries (1977).

These integrated analyses of runoff generation and slope erosion processes merged well with the systems approach in process-based landform evolution studies in physical geography, as proposed by Richard Chorley and Barbara Kennedy (1971). Systems analysis, and its dynamic feedback mechanisms, had evolved in the 1960s as a unifying conceptual framework in engineering as well as ecological studies to model cause–effect relationships. Patrick Domenico (1972) wrote a textbook on models in groundwater hydrology and groundwater management within the framework of this approach. It is clear that the analysis and modeling of integrated hydrological systems that comprise coupled nonlinear processes, only became feasible after the introduction of computer simulation models in the 1960s.

1.3.5 Evolution of Hydrochemistry and Isotope Hydrology

1.3.5.1 Hydrochemistry

The chemical processes in groundwater are much more complex than those studied by engineers in chemical reactors under controlled conditions. Groundwater on its way to the discharge area is normally interacting with aquifers, which are composed of different rock and soil minerals and which are subjected to the inflow of water, solutes, and gases from various origins, thus producing a new reactive mix. Equilibrium is therefore seldom reached. Until the mid-20th century, hydrochemistry was mainly restricted to groundwater inventories in order to determine its quality for use as drinking water and

for agricultural purpose. In hydrogeological exploration, chemical characteristics were attributed to petrographic rock type to enable determination of the interconnection between aquifers and origin of the waters. Classifications were developed for grouping water from a single aquifer, or from the same origin, and to identify dominant chemical processes and rock interaction, and to study chemical trends and evolution in connection with flow fields. The oldest classifications are based on Palmer's (1911) concepts of salinity and alkalinity, which are related to the contents of non-hydrolyzed salts and weak acids components, respectively.

Diagrams and graphs were developed to summarize large quantities of data, and to visually characterize water for interpretation and mapping. Well-known diagrams which are suitable to plot on maps are the 3-vector diagram of Rogers (1917), the bar diagrams according to Collins (1923), and the distinctive symbol diagrams from Stiff (1951). More genetically indicative are the triangular diagrams by Emmons and Harrington (1913), where similarity is characterized by the plot position of anion and cation ratios. Hill (1940) combined these triangular figures with a diamond-shaped diagram in which anion and cation ratios are combined into one plot; this procedure became well-known through the work of Piper (1944). Also genetically indicative are the logarithmic nomographs by Schoeller (1935), in which comparable compositions are indicated by parallel lines.

The dominant physico-chemical processes that could be identified in the early days were dissolution in connection with solubility of various minerals, sulphate reduction under anaerobic conditions, and cation exchange processes. Sulphate reduction and the role of bacteria were already known in the late 19th century, notably from groundwater in petroleum reservoirs. Exchange of sodium by calcium at the adsorption complex, as a product of freshening of originally saline aquifers, was proposed by Jan Versluys (1916) to explain sodium-bicarbonate water in the Dutch coastal area. This water type therefore became a useful tracer in reconstructing the hydrogeologic evolution in relation to coastal history. The same type of process had often been observed under the American Great Plains, and was characterized as "natural softening" because of the calcium depletion (Renick, 1924).

An important advancement for understanding the continuous dissolution of limestone along a flow path in the saturated zone was brought into perspective by discovery of the nonlinear relation between free CO₂ and the concentration of dissolved calcium. This explains the possibility of continued corrosion through inflow of new water with a different CO₂ content. If both existing and new water are in equilibrium with respect to CO₂ and calcite, the nonlinear relation causes their mixture to be undersaturated in this regard (Tillmans, 1932). Alfred Bögli (1964) applied this concept of mixing corrosion in his physically based karst-water studies. Numerous regional investigations have been carried out to explain the dynamics and development of karst systems, including the influence of geological structure on propagation of conduit systems and cave evolution.

A degree of zonation from the water table downward, and with distance from the intake area, could be recognized in the Great Plain aquifers in the United States. This zonation is dominated by a trend in which bicarbonate water is gradually converted into a mix of sulphate/chloride water and, eventually, into chloride dominated water, toward a sea water composition. This stratification was attributed to an increased ionic concentration induced by an increase in temperature and a prolonged circulation and retention, causing a relative abundance of the ions of the most soluble salts (Rogers, 1917).

Similar chemical evolution, caused by climatic zonation, was recognized by Schoeller (1941) from his studies of chemical evolution along flow trajectories in northern Africa. He observed an increase in solute concentration from the (semi-) humid to the dryer (semi-)arid regions. Schoeller explained this effect by postulating a net loss of water by evapotranspiration and lack of carbon-dioxide production in the latter areas, which had led to precipitation of calcium/magnesium carbonate and gypsum, and a concurrent enrichment of chlorides. In the USSR, with its clear climatic- and associated soil type zonation, comparable observations were made and explained in 1948 by Garmanov (Silin-Bekchurin, 1951; cf. Schoeller, 1962, Chapter VII) and Garmanov (1958). The Russian Chebotorev (1955) further included 10,000 analyses from Australia to analyze climatic zonation. The above cited Russian authors represent a large volume of literature from the USSR, including theoretical studies. Hydrochemistry in the USSR was largely based on the use of water composition in geochemical mineral exploration. This climatic zonation in chemical

character of natural waters was earlier recognized by Clark (1924) in his analysis and comparison of the average chemical composition of stream water from large river basins in various climatic belts.

Henri Schoeller of France was probably the first to carry out extensive, systematic calculations on chemical equilibrium and stability in the context of pH and redox potential (Eh) conditions for various rock types and environments (Schoeller, 1955, 1962). He applied the results in an extensive chemical facies classification, which was largely based on ion ratios, to identify chemical process and to explain observed groundwater compositions in terms of current conditions and paleo-hydrological evolution. The concept of chemical facies as a diagnostic tool to reflect the response of chemical processes within a hydrogeological framework, was also applied by Chebotarev. In addition mass-balance analysis of non-reactive solutes (notably chloride) and stable isotopes proved to be a powerful tool in groundwater budget studies, particularly to estimate groundwater recharge under arid conditions (e.g., Eriksson, 1976).

These applications of hydrochemistry in regional studies have been widely practised in the arid areas of North Africa and the Middle East in the 1950s and the 1960s, in projects, initiated by the UN-organizations, FAO and UNESCO.

In the United States, John D. Hem (1916–1994) compiled a wealth of data on the occurrence and properties of constituents from the huge number of reported water analysis, mainly from the United States (Hem, 1959, 1970). In addition, Hem and Cropper (1959) and Hem (1963) analyzed the stability of iron, manganese, and sulphur as functions of the environmental conditions characterized by the combined pH and Eh. The results were verified and confirmed from the field studies by Barnes and Back (1964) in the intensively investigated Floridian coastal aquifer. Studies on calcite solubility equilibria were carried out by William Back (1963). Around the same time, Garrels began his pioneering work on systematic application of well-known chemical principles in low-temperature aqueous solutions to study water–rock interaction. This led to the principles for a fundamental unifying understanding of hydrochemistry on the basis of chemical thermodynamics (Garrels, 1960). Back and Hanshaw (1965, 1970) applied the modern principles of equilibrium, thermodynamics, and interaction time in regional field studies. Georg Mattes (1973) wrote the first comprehensive textbook on hydrochemistry in western Europe; this German text was translated in English in 1982.

Modeling of combined transport and chemical reactions along a flow path is particularly complicated because it includes a distributed flow of water, matter, and energy, as well as physico-chemical and microbial processes in a heterogeneous environment. An integrated modeling approach only became feasible in the 1970s with the introduction of numerical simulations using powerful digital computers. Isotopic tracers proved to be invaluable tools to identify paleo-conditions and to calibrate the complex reactive-transport models. A well-known early hydrochemical transport and process model which accounts for mixing of waters is PHREEQE (Pakhurst et al., 1980), which marked the beginning of a new era in hydrochemistry. These developments were largely stimulated by pollution problems, and numerous studies on contaminant hydrochemistry have been published since the early 1980s.

1.3.5.2 Isotope Hydrology

Isotopes form a very special and powerful diagnostic tool, which has been used in groundwater studies since the 1950s. Initially, mainly short-lived radio-isotopes were added to surface water and groundwater as labels to trace pathways and to determine local parameters. However, because of the limited time and space scales of the experiments, as well as for safety reasons, this application was virtually abandoned in the 1960s and was replaced by the use of environmental isotopes. This opened the way for reconstruction of the “natural history” of water by determining its age and provenance, and to identify processes to which water had been subjected. The following outline is based mainly on reports by Letolle and Olive (2004) and Froehlich et al. (2004).

Important isotopes in hydrology, such as oxygen-18 (^{18}O) and deuterium (D), were already identified in the 1920s and 1930s, but the use of isotopes in hydrological research came into perspective only in the 1950s after the introduction of advanced mass-spectrometers. A catalogue of ^{18}O and D for waters of various origins was also established in the 1950s (Dansgaard, 1953; Epstein and Mayeda, 1953; Friedman, 1953). A further milestone was the discovery by Harmon Craig (1961) of the $^{18}\text{O}/\text{D}$ relation in precipitation, the

Global Meteorological Waterline, and his introduction of the use of *Standard Mean Ocean Water*. At the same time, analyses of thermal waters revealed their predominantly meteoric origin, and subsequent investigations showed that the juvenile component of waters associated with volcanic activity normally represents only a small fraction (Craig, 1963).

The application of radio-active tracers began in 1947 with the first radiocarbon dating by W.F. Libby (for which he was awarded the Nobel Prize in 1960); the first groundwater dating followed in 1957 by Karl-Otto Münnich and his team in Heidelberg. From 1952 to 1980 huge amounts of tritium were added to the atmosphere as a result of thermo-nuclear bomb tests. This made tritium the most important indicator to distinguish pre-1952 from post-1952 waters, with the various annual peaks in the groundwater used as markers for identifying its year of infiltration. The 1963-peak became the classical marker, when the tritium content of the atmosphere that year rose to about 3000 TU. Application of tritium, in combination with ^{18}O and D, has been particularly valuable to obtain insight to the complicated processes in the unsaturated zone. The decrease of the tritium concentration in the atmosphere after the 1980s, and the natural attenuation of the previous peaks, has reduced the value of this isotope.

Important for the stimulation of isotope hydrology was the establishment in 1958, in Vienna, of the International Atomic Energy Agency (IAEA) as an UN agency. One of its sub groups was the Isotope Hydrology Group (later changed to Section of Isotope Hydrology), initially headed by the Swede Eric Eriksson, with as mission to promote and support the development and practical application of nuclear and isotopic techniques in hydrology and related earth sciences. Of paramount importance was the establishment by IAEA of the Global Network of Isotopes in Precipitation, comprising of 150 selected WMO meteorological stations.

General application of isotopes in hydrology began in the early 1960s with, among others, Brown (1961) in Canada, Eriksson (1963) in Sweden, Münnich et al. (1967) in Germany, and Vogel (1967), and Mook (1968) in the Netherlands. Isotopes have been used worldwide from the 1970s in a variety of hydrological studies, including understanding the mechanisms of infiltration and evaporation, biodegradation, the provenance of water, the climatic conditions during infiltration, the separation of hydrograph components, salt water intrusion, hydro-geothermal processes, and dating groundwater in connection with paleohydrological evolution (notably in fossil aquifers and basins with low recharge). In addition, noble gas contents in groundwater have been used as recorders of water temperature during infiltration.

Application of environmental tracers, in combination with numerical transport modeling, particularly facilitated the direct determination of groundwater replenishment, including aspects like preferential flow paths and bypass flow. This applies specifically to (semi-)arid areas where the magnitude of recharge is far below the accuracy range of the evapotranspiration determination, so that establishing recharge as difference between rainfall and evaporation or by groundwater discharge analysis is normally not feasible (e.g., Zimmermann et al., 1967; Allison and Hughes, 1974; Dinçer et al., 1974). Several stimulating conferences on the use of isotopes in arid zone hydrology were organized by the IAEA. It was in response to this new perspective that UNESCO-IHP and the IAH launched in 1984 an international cooperation programme on groundwater recharge, targeting arid and semi arid areas. The main outcome of this initiative was a manual for understanding and estimate of natural recharge (Lerner et al., 1990).

Another very useful application of isotope tracers is in hydrochemical studies, notably for identifying physical processes and for calibrating inverse models. From the 1980s, isotope application was further boosted by the introduction of the accelerated mass spectrometer (AMS), which allows measurements of very low concentrations. This resulted in the use of, for example, ^{36}Cl for dating young as well as very old water, and a variety of “new” tracers to identify, for example, sources of contamination and biochemical degradation processes in landfill leachates.

1.4 Main Trends since the Early 1980s

The development of hydrogeological concepts and the mathematical and chemical tools to describe and analyze groundwater behavior, seem to have reached a mature stage by the early 1980s. The principal

remaining problem is the heterogeneity of the hydrogeological environment and the nonlinearity of the hydrogeological processes. Therefore, advances in the last quarter of the 20th century were dominated by the application of the numerical approach by digital computer simulation models. These made feasible the analysis of distributed transient flow problems in heterogeneous aquifers with complex boundary conditions, and to include such aspects as reactive transport, multi-phase flow, skeletal deformation, and microbial activity. This released groundwater studies from the necessity of drastic simplification and unrealistic assumptions in order to arrive at analytical solutions. Computer modeling, on the other hand, has often led to unrealistic simulation of reality by parameter generation through misleading optimization results.

The computer facilities and the shift of focus from quantity to quality and contamination studies has resulted in an explosion of transport and process models to explain present condition, to predict quality evolution, to design adequate monitoring schemes, and to develop remediation measures, including *in-situ* microbial techniques. Interest in aquifer behavior on a geologic time scale, including tectonic stress evolution and diagenetic processes on basin scale, has been stimulated by concern for the long-term behavior of radioactive waste repositories. Progress has been made in the 1980s in understanding the physical and geochemical behavior of an increasing number of environmental isotopes and other tracers, and in more refined detection techniques.

One of the main future hydrogeological challenges is to solve the problem of the geostatistical meaning of aquifer parameters and their scale dependency, including inverse modeling with its non-unique solutions (cf. Narasimhan, 1982, 1998). It is questionable however, to what detail we will be able to characterize the subsurface with its heterogeneous lithology and discontinue porous system. With respect to the interaction of groundwater and runoff generation is the challenge to develop distributed, physically based hydrological models at catchment scale. A principal problem here is the up scaling of hydrologic and geomorphologic parameters, and the synthesis of the various process components for nonlinear systems. Time-scale is another question; the need, for example, to isolate some types of waste for a very long period, requires prediction of aquifer system behavior on a time scale of hundreds of thousands of years.

Acknowledgments

The author expresses his gratitude to Ian Simmers, Peter Raats, and Garth van der Kamp for reading and amending the manuscript.

Further Information

Biswas (1970) gives an extensive account on the history of hydrology from ancient times to the end of the 19th century. A historical sketch on the evolution of theories about the hydrological cycle is presented by Brutsaert (2005). Recent trends in historical perspective on several aspects of hydrogeology, notably from North America, are reviewed in Narasimhan (1982); Narasimhan (1998) gives an explanatory overview of the developments in determination and characterization of hydraulic subsurface parameters. Recent trends are also found in a Special of the *Hydrogeology Journal* on the future of hydrogeology (Voss, 2005). See *References* for complete citations.

2.1 Introduction

Subsurface water is generally divided into two major types: phreatic water or soil moisture in the unsaturated zone, and groundwater in the saturated zone. This division is made mainly because of the differences in the physics of flow of water in the saturated vs. the unsaturated zone; these differences are discussed later in this chapter.

To understand the increasing importance of groundwater and the science explaining it in a modern, industrialized nation and economy, it is well to consider the experience of the United States of America. In the 18th century, when the United States was being formed into a new nation, little emphasis was given to groundwater because in the humid East, where most of the population was located, surface water met nearly all water needs. In the 19th century and into the first half of the 20th, groundwater was investigated as a water source, especially as the population moved westward and new farms, ranches, mines, and cities were created in the semiarid West. Lack of water caused intense competition among the various uses and users, which continues to this day at an even greater pace.

Anticipating a need for natural resource evaluation of all kinds, the U.S. Government in the waning years of the last century sponsored a number of exploratory and investigative studies of water resources, especially in the West. These studies continued until well into this century. Notable were the field efforts of Chamberlin (1885), Darton (1909), Lee (1915), Mendenhall (1905), and others.

In addition, laboratory studies and theoretical studies added to our understanding of the physics and chemistry of groundwater. Important breakthroughs in physical understanding were made by several investigators who are listed with representative significant references: Hazen (1911), King (1899), Theis (1935), Jacob (1940), Hantush (1956), Hubbert (1940), and many others.

The work of Meinzer (1923, 1939) of the U.S. Geological Survey is significant in that he was the prime motivator for many government-sponsored investigations.

The work of these scientists was built upon a solid foundation of theory developed in Europe during the 19th and early 20th centuries by such luminaries as Darcy (1856), Boussinesq (1904), DuPuit (1863), Forcheimer (1914), and Theim (1906).

In the latter half of this century, several refinements of physical groundwater concepts have been made, and there has been a considerable body of knowledge built up as the result of efforts to more safely dispose of hazardous and radioactive wastes. Numerous advances in remote sensing by satellites have helped in delineating water-bearing entities such as fracture zones, springs, and to a lesser extent, aquifers. Geophysical techniques and methods have improved significantly in their use for groundwater exploration tools. Pumping tests and other hydraulic tests have been developed that greatly improve our understanding of the hydraulics of aquifers and their potential for groundwater supplies.

Perhaps the most significant tool developed in this century for the study of groundwater has been the digital computer. As a consequence, numerical modeling of groundwater flow and contaminant transport has become a commonplace effort in nearly all groundwater studies.

Problems of quality and quantity of data, in quantitative assessment of groundwater properties are mainly related to the functions of the heterogeneity of most geologic formations and their hydraulic properties, and the difficulty and expense of drilling for good data. With the recent advent of stochastic methods for analyzing hydrogeologic data, there are now better ways of interpolating, extrapolating, and predicting trends in hydraulic parameters.

With all the advances, both theoretical and technical, there is still one overriding fact in hydrogeologic analysis and modeling that must not be forgotten. Equations of flow and transport are differential in nature and require boundary conditions for their complete solution. The goodness of the solution to a partial differential equation of groundwater flow or transport is directly dependent upon the accuracy of the boundary conditions used. Boundary conditions are geological in nature and are only as accurate as the knowledge of the geology of the area being investigated.

This may appear simplistic to some, but the facts stand, not only from theory, but from the experience of thousands of investigators working on this problem for the past several decades. A thorough understanding of groundwater hydrology, correct interpretations of the results of hydraulic tests and resulting model predictions can only be made after a thorough understanding of the geology.

Still, high accuracy is often difficult to obtain in the quest for hydraulic parameter values of aquifers. There are variations in geologic structure that are often too small to be determined, but do affect hydraulic conductivity on a significant scale. Even in fairly homogeneous systems, this problem still frustrates the analyst and the modeler, and much more research is needed. Recent work by Eggleston et al. (1996) gives an example of this problem in glacial outwash of Cape Cod.

Perhaps the most crucial area of groundwater research today is the search for new and improved methods to acquire, quantify, and properly utilize good subsurface hydrogeological data with minimal expenditures of time and money.

2.2 Importance of Groundwater

2.2.1 Groundwater and World's Available Fresh Water

The amount of water on, under, and above the earth's surface remains essentially constant. Although a minor amount of water vapor may escape into space, additional new water is constantly created as *juvenile* water by chemical reactions during volcanic emanations. Table 2.1 shows estimates of the volumes of various kinds of water on, above, and under the surface of the earth as reported by Maidment (1993). Examination of the figures reveals that fresh water of all kinds comprises only 35,029,210 km³ in contrast to the 1,338,000,000 km³ sea water. Thus, fresh water makes up only 2.5% of all the water on earth, but not all of this water is available for human use. The water in polar ice caps, other forms of ice and snow, soil moisture, marshes, biological systems and the atmosphere are not readily available. As a result, only the 10,530,000 km³ of groundwater, 91,000 km³ of freshwater in lakes, and the 2,120 km³ of water in rivers are considered attainable for use and comprise a total of 10,623,120 km³. Consequently, groundwater comprises 99% of the earth's available fresh water.

2.2.2 Groundwater Availability in North America

Heath (1984) describes the groundwater regions of the United States. Heath (1988) has made a thorough compilation of groundwater areas in all of North America, including the United States, Canada, and Mexico. Figure 2.1 shows the major ground water regions of the conterminous United States.

The United States, because of its size and varied and complex geology, contains groundwater in many different kinds of rocks and unconsolidated materials. Table 2.2 summarizes the hydraulic characteristics of each of the regions in Figure 2.1. A major aquifer system in the United States is worth a brief discussion because of its importance in supplying water for major agricultural uses and because of problems associated with heavy pumping from it.

TABLE 2.1 Estimates of Relative Volumes of Water of Various Kinds on Earth

Item	Area 10^6 km^2	Volume km^3	Percent of total water	Percent of fresh water
Oceans	361.3	1,338,000,000	96.50	
Groundwater:				
Fresh	1,34.8	10,530,000	0.76	30.10
Saline	134.8	12,870,000	0.93	
Soil moisture	82.0	16,500	0.0012	0.05
Polar ice	16.0	24,023,500	1.7	68.6
Other ice and snow	0.3	340,600	0.025	1.0
Lakes:				
Fresh	1.2	91,000	0.007	0.26
Saline	0.8	85,400	0.006	
Marshes	2.7	11,470	0.0008	0.03
Rivers	148.8	2,120	0.0002	0.006
Biological water	510.0	1,120	0.0001	0.003
Atmospheric water	510.0	12,900	0.001	0.04
Total water	510.0	1,385,984,610	100	
Fresh water	148.8	35,029,210	2.5	100

The High Plains Aquifer occupies the area marked as "High Plains" in Figure 2.1. It is composed of several hundred feet of Tertiary sediments that were laid down by streams flowing eastward from the present site of the Rocky Mountains as they were being uplifted. Sandy layers in the present aquifer provide irrigation water for several states in the High Plains.

Although there are a number of separate geological formations present, the Ogallala formation, consisting of alluvium, is the principal water-yielding unit and thus, is the one most often tapped by wells. Gutentag et al. (1984) reported that in 1978 there were 170,000 wells extracting water from this aquifer, and the pumping rate was from 2 to 100 times the recharge rate.

As a result, the water table has dropped 100 ft or more causing an increase in pumping expense. Careful management practices are now being put into place to better manage the resource. This is a significant example of ground-water mining and shows the effects of overuse of water resources.

Detailed descriptions of the hydrogeology of each region and in all of North America can be found in Heath (1988). In addition, the U.S. Geological Survey has performed detailed studies on several major aquifer systems in the United States through a major investigative effort known as the Regional Aquifer Systems Analysis (RASA). Specific reports of these studies are available from the U.S. Geological Survey National Headquarters in Reston, Virginia. Summaries of results of the RASA studies can be found in Bennet (1979), Sun (1986), and Chapters 25, 26, and 27 of Back et al. (1988).

2.2.3 Brief History of Groundwater Usage

The following paragraphs give only a brief synopsis of the history of groundwater usage, but a more complete history can be found in Chapter 1 of, "*History of Scientific Developments in Groundwater Hydrology*" by Jacobus J. de Vries.

It is uncertain when mankind first started extracting groundwater by artificial means such as wells or infiltration galleries. Early humans most likely drank from surface streams. They may also have discovered groundwater through the discharge of natural springs and in some parts of the world, used this source in addition to surface streams. As streams dried up in hot weather, people learned to dig into the alluvium to find water below the surface.

There was much speculation about the origin of water emanating from springs, and early theories proposed a hollow earth filled with water. The ancient Greeks were the first people to record their theories,

germinated no doubt from their observation of disappearing rivers and emerging springs in the limestone *karst* areas of the Greece and the rest of the Balkan Peninsula. Davis and DeWiest (1966) summarize the history of groundwater use and the development of the body of knowledge now surrounding it.

The earliest recorded use of groundwater is found in the 16th chapter of the Book of Genesis where it tells of a spring in the desert. In Chapter 26, mention is made of the digging of wells.

Egyptians are reported to have perfected core drilling by 3,000 b.c. Ancient Chinese invented the churn drill (similar to the modern cable-tool drill) and drilled to a depth of 1500 m (Tolman, 1937).

Western Europe did not engage in drilling until the 12th century when churn drilling was developed there. Much of the impetus for development of drilling methods was generated in the area around Artois, France, where artesian water was in demand.

In the latter part of the 19th century, the rotary drilling technique was developed, and by 1890 the *hydraulic rotary method* had been perfected. This was probably the single most significant advance in drilling technology (Davis and DeWiest, 1966).

As the water-well and oil-well drilling businesses grew in various parts of the world, rotary drilling methods were continuously improved and introduced worldwide. Today, it is the most widely used method and has been the primary reason that groundwater is now available to even primitive tribes. Present groundwater availability to people on every continent has been a prime reason for increasing the health and standard of living for untold millions.

Groundwater is now recognized as a national treasure and a most important natural resource. For example, approximately half the water used in the United States of America is groundwater. In some areas, groundwater is the sole water supply for all purposes.

2.3 Earth Materials

2.3.1 Minerals and Rocks

The inorganic part of the earth is made up of rocks and their weathering products. A rock, by definition, contains one or more *minerals*, and a mineral is defined by Hurlburt (1970) as follows:

"In addition to being natural and inorganic, a mineral must meet another requirement: it must be a chemical element or compound. It cannot be a random mixture of elements; the atoms that make it up must have definite ratios to each other, so that its composition can be expressed by a chemical formula. Not only are the proportions of the various atoms of a given mineral fixed, but so are their relative positions. These attributes give to each mineral a set of properties that characterize it so uniquely that one can distinguish it from all other minerals."

A *rock* can be composed of one mineral or a mixture of several. For example, sandstone may contain grains of the mineral, quartz (silica or SiO_2), and a cement between the quartz grains composed of the mineral, calcite (CaCO_3). Granite is normally composed of crystals of the minerals, feldspar, quartz, mica, and others. By definition then, frozen water (ice) is both a mineral and a mono-mineralic rock.

The most fundamental of the three classes of rocks are *igneous rocks* that are formed as cooling products from the molten state. Igneous rocks are primordial in many parts of the world and are some of the world's oldest, exceeding three billion years in age. One way they can be formed is when molten rock is intruded into other rock formations and then cooled to the solid state. If the cooling is slow enough, various minerals will crystallize out into an interlocking solid mass that is characteristic of particular rocks such as granite.

Extrusive igneous rocks like dense basalt are forced from fissures in the earth's crust and harden into vast sheets of solid material, usually containing very small crystals (due to the rapid cooling), or perhaps no crystals at all (obsidian glass). Other extrusives like lighter lava or pumice are ejected during volcanic eruptions and are highly charged with gases to form very porous and even frothy glasses resembling a

sponge. Some of the ejecta may fall from the air to settle as a sediment. This particular kind of deposit is known as a *pyroclastic* rock, that is, part igneous and part sedimentary.

A *sedimentary rock*, the second class, is deposited from either air or water as grains of rocks and minerals. These sediments in turn, may have been derived from the weathering of igneous, metamorphic, or other sedimentary rocks.

If any kind of rock, igneous, metamorphic, or sedimentary, is subjected to intense heat and pressure, such as exists at great depths in the earth's crust, at the edge of tectonic plates, or in rising mountain ranges, the parent rock will be transformed into the third class of rock — a *metamorphic rock*. A metamorphic rock may contain the same chemical composition as the parent rock, but the mineral composition and structure may be changed drastically from the parent. For example, limestone containing amorphous or cryptocrystalline calcite (CaCO_3) is often metamorphosed into marble that has a definite crystal structure and is much harder than the original limestone. Granite may be metamorphosed into gneiss with the same overall chemical composition as the original granite, but with new minerals and mineral structures.

Groundwater can be found in all three classes of rocks, but in general, the sedimentary rocks contain by far the greatest amounts of water due to their greater *porosity*.

2.3.2 Unconsolidated Materials

Unconsolidated materials are those earth materials that have not been indurated. That is, the grains have not been fused together by heat and pressure, as in the cases of igneous granite or metamorphic gneiss; or by cement, as in the case of sedimentary rocks. Unconsolidated materials can be the non-indurated products of weathering of all three classes of rocks, or sediments laid down by running water, ponded water, the sea, or ejecta from volcanoes.

Most unconsolidated materials are young, geologically speaking, and are at or near the earth's surface. Thus, they have not been exposed to pressure, heat, and migrating cementing fluids long enough to become consolidated or hard. Hence, they generally contain high porosity and are the sources for much groundwater.

A common unconsolidated deposit in glaciated areas of the world is *glacial drift*. It is any kind of earth material that was deposited directly by glaciers or by meltwater from glaciers. As such, it can range in size from the finest silt or clay to the largest boulders, and can be mixtures of all sizes. The name "drift" was given to this material when it was believed that it was depositional material, or "drift," from the great Noachian Flood, described in the Book of Genesis. Drift can generally be subdivided into the more specific lithologies such as *till* and *outwash*.

Glacial till is a generally a heterogeneous mixture of many different lithologies and particle sizes. Typically, in the midwestern United States, till contains a preponderance of clay and silt with additional amounts of ground-up rocks and boulders that may vary in size from small pebbles to erratics the size of a house or larger. On rare occasions, geologists find tills composed of one lithology indicating local sources of material. Glacial till is not generally utilized as a source of groundwater because of its low permeability.

Glacial outwash is material deposited from high-energy streams of water that originated from melting glaciers. This process can be seen today at the toe of any mountain glacier on different continents.

Glacial ice, more often than not, contains entrained rock and soil material which it has eroded from the surrounding valley sides or ground beneath it. This material varies widely in size from clay to large boulders. As the ice melts and leaves the toe of the glacier, normally in great flow rates and very turbulent, this material is moved with the flowing water.

As the stream loses energy, materials settle out with larger sizes coming out first, followed by gradually lessening sizes. Therefore, along a stretch of an outwash stream one may find coarse gravel and boulders settling out first, followed by finer gravel, then sand and gravel mixtures, then sand, silt, and finally clay (in still water).

Many present-day stream courses were glacial spillways for outwash water and sediment during the Pleistocene Epoch (Ice Age). For example, the Wabash River Valley in Indiana contains outwash sand and gravel deposits in excess of 300 ft in thickness, which were deposited by the melting of two and possibly

three different ice sheets. The Big Sioux River valley in South Dakota and Iowa is another example. A very extensive deposit of outwash sand is the Cape Cod peninsula, which was deposited in an interlobate outwash between two lobes of ice – one to the east and one to the west of the site.

Outwash sand and gravel deposits are frequently exploited for groundwater because of their high porosity and permeability. Well yields in many of these deposits often exceed 5500 m³/d.

Other water-lain deposits not directly deposited from glacial meltwater may be comprised of reworked glacial detritus (glacially-transported material), or they may be found in areas where glaciers never occurred. The most common example of such deposits is *alluvium*. Flood plains along large streams are created of this material as the streams flood over their banks and deposit the material. Stream beds also contain alluvium.

In fast-flowing streams with high gradients, as in mountainous areas, alluvium may be absent because the stream is eroding rather than depositing material. If alluvium is found in and along such streams, it is generally very coarse-grained gravel with large boulders. On the other hand, mature streams such as the Ohio, Missouri, and Mississippi Rivers deposit their loads of fine silt and clay over broad flood plains.

Alluvium deposits may serve as important groundwater sources, but in large river valleys, the yield of such deposits may be low to moderate, depending on the grain size and the resulting permeability and porosity.

Lacustrine materials are silts and clays that are deposited from relatively still bodies of water such as lakes and lagoons. These materials, being so fine-grained, are not utilized for groundwater supplies because of their low permeability.

Peat is the remains of mostly water plants that die and accumulate in ponded water and marshes over long periods of time. The top part of a peat deposit is very porous and permeable, but it becomes more compact with depth. The lower layers of peat are often sticky masses of black organic material with little resemblance to the original plant material.

Peat is not generally utilized as a groundwater source, but it can serve, under the right conditions, as a natural cleansing agent to remove organics and heavy metals from water that passes through it — the large and complex organic molecules in the peat attract such contaminants.

Chemical precipitates of most importance include limestone and marl that precipitate directly from sea water or even from fresh water bodies. Major deposits of limestone were deposited in many parts of the world during the Cretaceous Period (the “Chalk Period”) of the Mesozoic Era. Examples include the Chalk Beds of Dover, England; the limestones of the Balkan Peninsula; and limestones of the High Plains in the United States. Other vast limestone deposits were formed in earlier times and are found across most of the Midwestern United States and the Appalachians.

Limestone is composed primarily of calcite. Entrained silt and clay and other materials may also be present. After deposition, a process known as *diagenesis* often takes place in which the rock incorporates magnesium to become dolostone, or CaMg(CO₃)₂; this is also the formula for the mineral, dolomite. Pure MgCO₃ is the mineral, magnesite.

Collectively, limestone and dolostone are called “carbonate rocks”, or “carbonates.” Carbonates, especially limestone, often undergo solution along bedding planes and fractures to form caves and sinkholes, which in an interconnected system is known as *karst* terrane, after the Karst region in Yugoslavia. Networks of such caves and tunnels may exceed hundreds of miles in length and may contain large streams that emanate from springs in the rock.

Examples of such systems are found in the Balkan Peninsula, the Mediterranean area, France, Kentucky (Mammoth Caves), New Mexico (Carlsbad Caverns), to name just a few. Karst systems are often sources of very large quantities of groundwater, and due to the very high permeability, can be productive aquifers. A drawback, though, is the ease with which water in karst systems can be contaminated by surface sources. Thus, care must be taken to protect such sources.

Aeolian deposits are fine-grained materials, such as silt and sand, which may have been deposited originally from water, but which have been reworked and redeposited by wind. Examples of such active deposits today can be found in sand-dune areas of the Sahara, the Middle East, New Mexico, Nevada, and many other places.

Ancient dunes from the geological past are often found as sandstone bodies and may have some potential for groundwater extraction if coarse enough to allow sufficient porosity and permeability. Generally, wind-blown deposits are fine-grained, and when cemented with precipitates from circulating groundwater, may possess low porosity and permeability. The finest grained aeolian deposits are composed of silt or "rock flour" known as *loess*. The silt source is usually a wide river bed with braided channels where large dry areas of fine-grained materials are exposed to the wind. In most cases, the silt was deposited in such rivers as the end product in the long chain of deposition of glacial outwash. Prevailing winds then pick up the silt and transport it downwind where it is deposited on the lee sides of river valleys.

Significant loess deposits are found on the east side of the Missouri River, which acted as a glacial spillway during the Pleistocene. North of Sioux City, Iowa, this material forms bluffs that are ten meters high. Other noteworthy deposits are found along the Mississippi River (another spillway) and in the Gobi Desert of China.

Loess, after deposition, will often be reworked by frost action to form columnar structures with vertical fractures. The grains of silt are then oriented with their long axes vertically to form such features. With this alteration, it will allow fast vertical movement and drainage of water, and is fairly solid material to build upon, but its permeability is too low to utilize it for groundwater supply.

2.4 Important Hydraulic Properties of Earth Materials and Groundwater, with Examples

2.4.1 Porosity

Porosity (n) is defined as the volume of the pores of a rock or soil sample (V_p) divided by the total volume (V_t) of both pores and solid material, that is,

$$n = V_p/V_t \quad (2.1)$$

When a rock is first formed by precipitation, cooling from an igneous melt induration from loose sediments; or when a soil is first formed by weathering of rock materials and possibly subsequent biological action, the new entity will contain a certain inherent porosity known as *primary porosity*. This porosity may later be reduced by cementation from precipitates from circulating groundwater, or from compaction accompanying burial by later sediments. However, fractures or solution cavities formed in the rock, or root tubes or animal burrows in soils may later form and are known as *secondary porosity*. Thus, the total porosity of a sample will be the sum of the primary and secondary porosities.

Porosity of a consolidated sample can be determined quite simply by first cutting the sample to a known dimension such as a cylinder or cube and measuring the total volume. Next, the sample is submerged in a known volume of water and allowed to saturate. After saturation, the volume of water displaced will be the volume of solids in the sample. The volume of voids is simply the difference between the total volume and the volume of solids, and porosity can be calculated by the above formula. More accurate and more sophisticated methods for testing earth materials for various properties are given in various publications of the American Society for Testing and Materials (ASTM).

If all the pores in a rock are not connected, only a certain fraction of the pores will allow the passage of water, and this fraction is known as the *effective porosity*. An example is pumice, a glassy volcanic ejecta (a solidified froth) which may float on water because the total porosity is so high and it contains so much entrained gas that its bulk density is less than water. It may take some days to sink because the effective porosity is so low that water cannot easily pass through it.

Coarse gravel may contain a porosity of only 25%, but that porosity will practically be effective. Thus, gravel is an excellent conductor of water.

Porosity of a rock or soil is determined largely by the packing arrangement of its grains and the uniformity of the grain-size distribution. The greatest ideal porosity that could be attained in a material

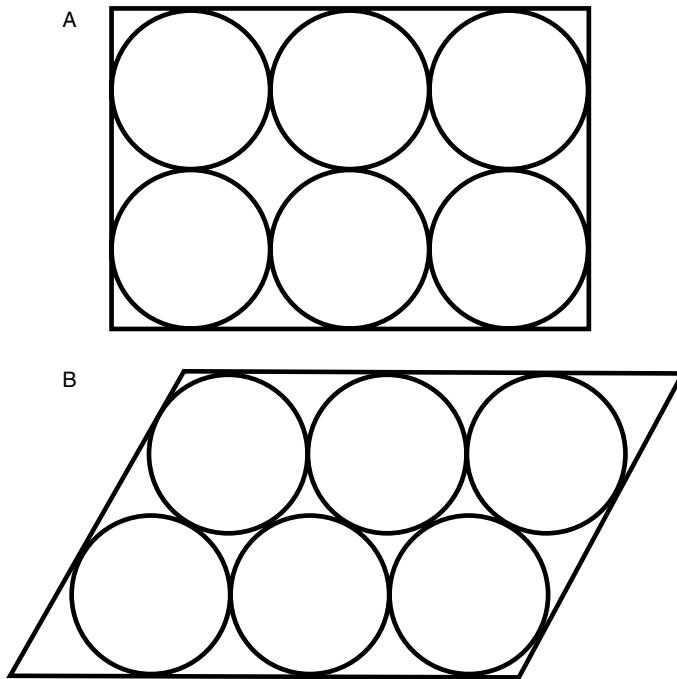

FIGURE 2.2 (A) Cubic packing; (B) Rhombohedral packing.

with uniform spherical grains is 47.65%; this is known as *cubic packing* (Figure 2.2A) because the centers of eight such grains form the vertices of a cube. The least porosity that can be attained with the same grains is found in *rhombohedral packing* with a value of 25.95% (Figure 2.2B). The centers of the eight adjacent spheres form the vertices of a rhombus.

These are ideal extremes because no natural sediment or rock contains spherical grains nor are the grains of uniform size. If small grains are situated in the spaces between large grains, the porosity will be reduced below that for the large grains only. This is demonstrated by the *uniformity coefficient* (C_u) which is a measure of how well or how poorly the sample grains are sorted:

$$C_u = D_{60}/D_{10} \quad (2.2)$$

where D_{60} is the grain diameter below which 60% of the grains are finer, and D_{10} (the effective grain size) is the diameter below which 10% of the grains are finer. If the C_u is less than four, the sample is well sorted; if it is greater than six, it is poorly sorted and will have a lower porosity than the first sample.

The *void ratio*, e , used in soil mechanics, is defined as

$$e = V_p/V_s \quad (2.3)$$

where V_s is the volume of solids, so that

$$n = 1/(1 + 1/e) \quad (2.4)$$

Typical values of porosity are given in Table 2.3.

TABLE 2.3 Important Physical Properties of Soil and Rock

Lithology	Porosity (percent)	Hydraulic conductivity (cm/sec)	Compressibility, $\alpha(m^2/N \text{ or } Pa^{-1})$
Unconsolidated			
Gravel	25–40	10^{-2} – 10^2	10^{-8} – 10^{-10}
Sand	25–50	10^{-4} –1	10^{-7} – 10^{-9}
Silt	35–50	10^{-7} – 10^{-3}	no data
Clay	40–70	10^{-10} – 10^{-7}	10^{-6} – 10^{-8}
Glacial Till	10–20	10^{-10} – 10^{-4}	10^{-6} – 10^{-8}
Indurated			
Fractured Basalt	5–50	10^{-5} –1	10^{-8} – 10^{-9}
Karst Limestone	5–50	10^{-4} –10	not applicable
Sandstone	5–30	10^{-8} – 10^{-4}	10^{-11} – 10^{-10}
Limestone, Dolomite	0–20	10^{-7} – 10^{-4}	$< 10^{-10}$
Shale	0–10	10^{-11} – 10^{-7}	10^{-7} – 10^{-8}
Fractured Crystalline Rock	0–10	10^{-7} – 10^{-2}	$—10^{-10}—$
Dense Crystalline Rock	0–5	10^{-12} – 10^{-8}	10^{-9} – 10^{-11}

2.4.2 Moisture Content

Moisture content (ϕ) can be measured and described either *gravimetrically* or *volumetrically*. The gravimetric equation is

$$\phi = W_w/W_t \quad (2.5)$$

where W_w is the weight of the water contained in a sample and W_t is the total weight of the solids and water in the sample. This definition, although useful for some purposes, does not indicate the degree of saturation of the rock or soil. Thus, the volumetric definition is more widely used:

$$\phi = V_w/V_t, \quad (2.6)$$

where V_w = volume of water in the sample, and V_t = total volume of water and solids. Closely related terms are the *saturation ratio* which is the volume of contained water divided by the volume of voids; and the *degree of saturation*, which is the saturation ratio times 100 (V_w/V_v) \times 100. If the saturation ratio is less than unity, or the degree of saturation is less than 100%, the sample is unsaturated and the pores are then partially filled with air.

Gravimetric moisture content can be determined by weighing a sample to obtain the total weight and then drying it in an oven to drive out the moisture. The dry sample is weighed to obtain the weight of the solids. The difference is the weight of the entrained water.

2.4.3 Capillarity

Capillary forces play a major role in the movement of water through unsaturated materials. Water is attracted to solid grains by *adhesion*. The familiar example of water rising in a soda straw is also a good example for capillary rise, h_c , in a small tube of radius, r , (Figure 2.3) and the rise is calculated as

$$h_c = 2\sigma \cos \alpha / \gamma_w r \quad (2.7)$$

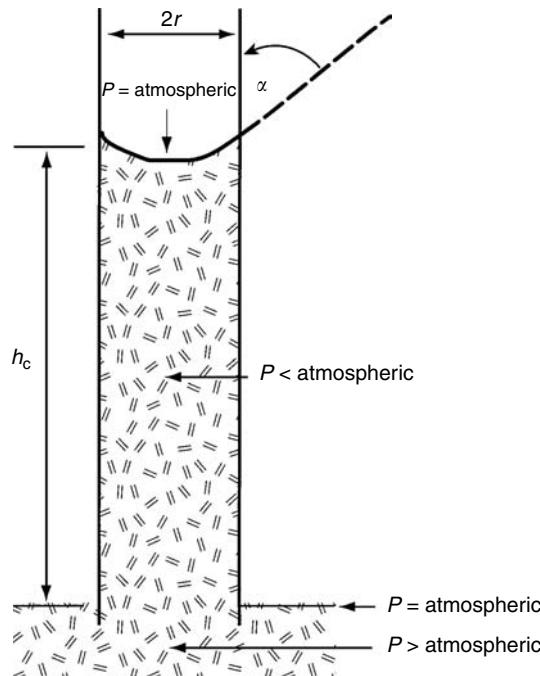

FIGURE 2.3 Capillary rise in a tube. (Adapted from Lohman, S.W. 1972. *Ground-Water Hydraulics*. U.S. Geological Survey Prof. Paper 708, U.S. Government Printing Office, Washington, DC.)

where σ is the surface tension of water (0.0756 N/m at 0°C), γ_w is the specific weight of water (9.805 kN/m³ at 0°C), $\alpha = 0^\circ$ for water. Thus, for water at 0°C in a clean tube, Domenico and Schwartz (1990) give the formula for capillary rise in cm as

$$h_c = 0.153/r. \quad (2.8)$$

Mavis and Tsui (1939) developed the following equation to estimate the height of capillary rise in millimeters in soils,

$$h_c = (2.2/d_H)[(1 - n)/n]^{2/3} \quad (2.9)$$

where d_H is the harmonic mean grain diameter in millimeters and n is the porosity. Capillary rise in coarse gravels may be only a few millimeters, but in clay it may be as much as three or four meters (Davis and DeWiest, 1966; Lohman, 1972).

In the root zone, normally in the upper part of an unsaturated soil, there is a natural competition for water between capillary forces in the soil and osmotic suction in the plant roots. The moisture content at which the capillary forces become greater than osmotic forces is known as the *wilting point*, that is, the moisture content at which the plants will cease to take in water and will start to wilt.

Due to the fact that capillary forces in coarse-grained materials are not as great as those in fine-grained materials, the wilting point in sand is only about 5% whereas in clay it is around 25 to 30% (USDA, 1955).

The wilting point will be reached more rapidly during hot, dry weather, especially if rainfall is insufficient, because capillarity causes water in the soil to rise where evapotranspiration from the surface will accelerate the loss of water from the soil.

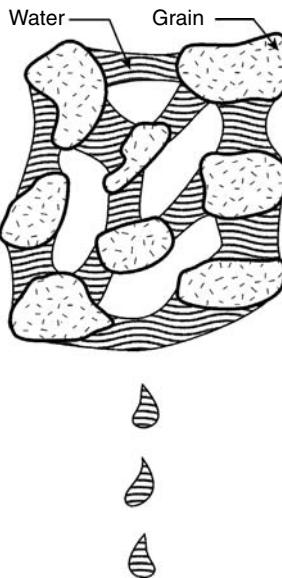

FIGURE 2.4 Porous medium under drainage.

2.4.4 Electrostatic Forces of Attraction and States of Water in Pores

Capillarity is caused by a combination of two forces: (1) *molecular attraction*, which is responsible for water adhering to soil or rock particle surfaces, and (2) *surface tension*, which is due to cohesion of water molecules toward each other when water is exposed to air. In saturated systems, the first force is balanced in all directions and thus, canceled out, and surface tension is also balanced.

An unsaturated rock or soil, if allowed to drain under the force of gravity, will not lose all its water by this means (Figure 2.4). Instead, some water will be held inside the pores by these forces. The drained water is known as *gravitational water* and the retained water as *capillary water* (Todd, 1980). Earlier literature may refer to the latter as *pellicular water*. The capillary or pellicular water will stay in the pores unless it is subjected to additional stresses such as centrifugation in the laboratory, or excessive heat as during a hot dry period.

If moisture reduction continues, the minimal water that will be held will exist as thin films around grains and will be held there by adhesive forces of molecular attraction; this water is known as *hygroscopic water* and is unavailable to plants. The wilting point is always a higher moisture content than the hygroscopic water content.

Often, initially dry soils near the surface will first attract and hold hygroscopic water if the air humidity increases significantly. It is only after the hygroscopic moisture content exceeds the *hygroscopic coefficient* (the maximum water content that can be held hygroscopically) that any additional water from precipitation or irrigation travel through the soil. Adhesion and cohesion are strongly affected by the mineralogy of soil or rock and chemical content of soil and water.

2.4.5 Compressibility of Water

Water is only very slightly compressible. At conditions of constant temperature and mass, Domenico and Schwartz (1990) define the *isothermal compressibility* of water as

$$\beta_w = 1/K_w = -(1/V_w)(\partial V_w / \partial P) \quad (2.10)$$

where β_w is the fluid compressibility in units of reciprocal of pressure, K_w is the bulk modulus of compression for water, V_w is the bulk volume of water, and P is the pressure. At 25°C, groundwater possesses a β_w of $4.8 \times 10^{-10} \text{ m}^2/\text{N}$ or $2.3 \times 10^{-8} \text{ ft}^2/\text{lb}$.

2.4.6 Compressibility of Solid Earth Materials

The compressibility of water-bearing rock and soil at some internal point is affected by both external and internal stresses and pressure of entrained water within the pores. The stress-balance equation is given as

$$\sigma_t = \sigma_e + P_p \quad (2.11)$$

where σ_t is the total vertical stress acting downward on the point of interest and includes the pressure of overlying soil or rock and its contained water as well as that from buildings, trees, and the like on the surface. The effective stress or resisting stress from the skeleton of the solid grains, that is, the matrix, is σ_e , and P_p is the pore pressure of the water in the pores. Figure 2.5 illustrates this relationship.

Any increase in total vertical stress must be balanced by the same increase on the right side of the equation; this occurs when depth increases because total vertical stress naturally increases with depth. If a well is pumped, the extraction of water will suddenly decrease the pore pressure and the porosity with an attendant increase in the effective stress exerted by the matrix. As a result, the matrix will compress. If water is injected into the well, the reverse occurs.

Such expansion and compression of the matrix, at constant temperature and assuming incompressible grains, can be quantified as shown by Domenico and Schwartz (1990) as

$$\beta_b = 1/K_b \quad (2.12)$$

$$= -(1/V_b)(\partial V_b / \partial \sigma_t) \quad (2.13)$$

$$= -1/V_b(\partial V_p / \partial \sigma_t) \quad (2.14)$$

$$= \beta_p = 1/H_p \quad (2.15)$$

where β_b is the bulk matrix compressibility in units of the reciprocal of pressure, K_b is the rock bulk modulus of compression, β_p is the vertical compressibility, H_p is a modulus of vertical compression related only to pores, V_b is the bulk volume, and V_p is the pore volume. The negative sign in the equation refers to the fact that volume decreases with increasing pressure. Equation 2.9–2.12 show that if the grains are incompressible then β_b is equivalent to β_p . Table 2.3 lists the compressibility of several lithologies.

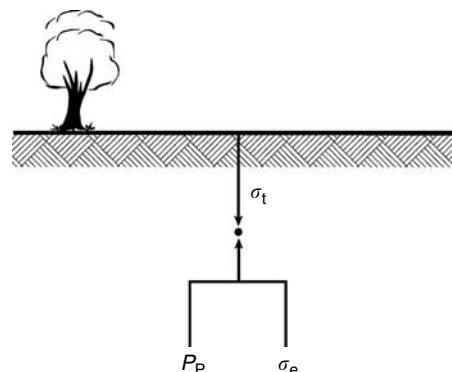

FIGURE 2.5 Stress-balance diagram.

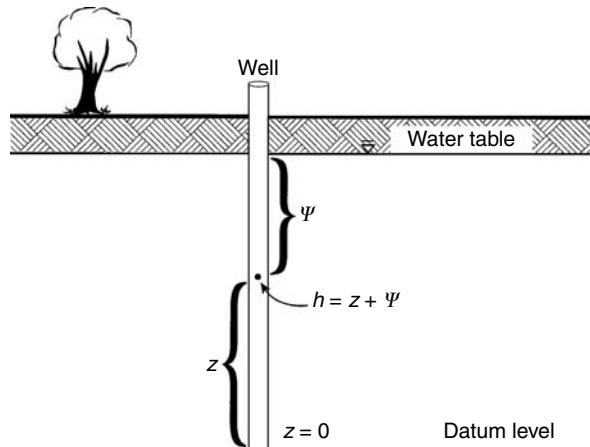

FIGURE 2.6 Illustration of hydraulic head.

2.4.7 Hydraulic Head

Hydraulic head at a point in a groundwater system (Figure 2.6) is expressed as

$$h = Z + P/\rho g \quad (2.16)$$

where Z is the elevation head or the distance of the reference point above a datum plane (normally mean sea level), P is fluid pressure at the point exerted by the column of water above the point, and ρg is the specific weight of water, γ , or more simply stated

$$h = Z + \Psi \quad (2.17)$$

where Ψ is also called the pressure head. The relationship has the dimension of length.

Development of this relationship can be found in Chapter 3 by J.W. Delleur and in Hubbert (1940).

Thus, hydraulic head has the dimension of length that makes it convenient for calculations based on the elevation of water above sea level, the generally accepted zero datum. Fluid potential and hydraulic head are equivalent and both are used, except that the head is the most popular entity for groundwater studies. It can be shown, often to the surprise of the unsuspecting, that water can flow from a region of lower pressure to a region of higher pressure if the total head at the starting point is greater than at the ending point.

In the field of petroleum and natural gas engineering, pressure is generally used in place of the head because pressures at great depths are normally so great that elevation heads are often insignificant.

2.4.8 Storage

A simple mass balance equation for groundwater flow through a unit volume of porous medium is given as

$$Q_{\text{out}} \Delta t = Q_{\text{in}} \Delta t \pm \Delta S \Delta t \quad (2.18)$$

where Q is the total flow rate in volume per unit time, and ΔS is the volume per unit of time going into or coming out of storage in time, t .

In a saturated porous medium that is confined between two transmissive layers of rock or clay, water will be stored in the pores of the medium by a combination of two phenomena: these are water compression and aquifer expansion. As water is forced into the system at a rate greater than that it is being extracted, the

water will compress and the matrix will expand to accommodate the excess. In a unit volume of saturated porous matrix, the volume of water that will be taken into storage under a unit increase in head, or the volume that will be released under a unit decrease in head is called *specific storage*, and is shown as

$$S_s = \rho g(\alpha + n\beta) \quad (2.19)$$

where α is aquifer compressibility, ρ is fluid density, g is gravitational acceleration, n is porosity, and β is water compressibility. This unit has the dimension of $1/L$ and is quite small, usually 0.0001 or less.

The storage coefficient of an aquifer, or simply, the storativity, S , is given as

$$S = S_s b \quad (2.20)$$

where b is the saturated thickness of the aquifer. Storativity is defined as the volume of water per unit aquifer surface area taken into or released from storage per unit increase or decrease in head respectively (Figure 2.7). It is a dimensionless quantity. In confined aquifers the value of storativity ranges from 0.005 to 0.00005.

In unconfined porous media, that is, where there is no overlying confining cover, storage of water in its upper part is defined as specific yield, S_y . This is the ratio of the volume of water that drains from a saturated porous matrix under the influence of gravity to the total volume of the matrix, per unit drop in the water table.

Specific yield is normally much greater than specific storage, as water released from elastic storage leaves the pores still saturated. Specific yield is often in the range of 0.2 to 0.3, or three to four orders of magnitude greater than elastic storage.

Gravity drainage will proceed until the forces of surface tension and molecular attraction to the matrix grains become equal to the force of gravity. The ratio of the volume of water retained in the pores to the total matrix volume is known as *specific retention*, or S_r . In the upper parts of an unconfined porous

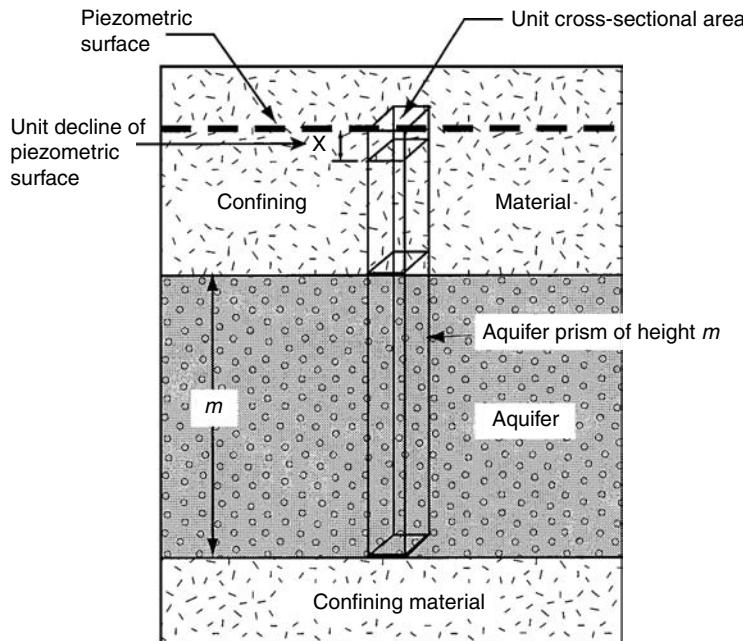

FIGURE 2.7 Illustration of specific storage and storativity. (Adapted from Ferris, J.G., Knowles, D.B., Browne, R.H., and Stallman, R.W., 1962. *Theory of Aquifer Test*. U.S. Geological Survey Water-Supply Paper 1536E.)

medium, where elastic storage is not significant, the sum of specific yield and specific retention equals porosity,

$$S_y + S_r = n \quad (2.21)$$

When an unconfined porous medium is very thick, the lower parts of the medium may also contain water under elastic storage, owing to the increase of pressure and consequent water compressibility and matrix expansion with increasing depth. In this case the total storativity of the medium is expressed as

$$S = S_y + bS_s \quad (2.22)$$

where b is the saturated medium thickness.

Field capacity is used to describe essentially the same phenomena as specific retention, but it is normally used in agricultural soil-moisture studies. It is a function not only of specific retention, but also of the evaporation depth and the unsaturated permeability of the soil (discussed below). A good discussion of all the above relationships can be found in de Marsily (1986).

2.4.9 Intrinsic Permeability

There are several basic properties of both porous media and fluid that will determine the ease with which the medium will transmit a fluid. The most fundamental of all these properties is known as *intrinsic permeability*, k . It is simply a function of the average pore size of the medium and is related to this property as follows,

$$k = Cd^2 \quad (2.23)$$

where d is the average pore diameter, and C is an empirical constant which depends upon packing, sorting, and other factors.

Intrinsic permeability is strictly a function of the medium and has nothing to do with the temperature, pressure, or fluid properties of a particular fluid passing through the medium. It is commonly measured in terms of the *darcy*, after Henri Darcy who developed the relationship known today as Darcy's Law (discussed later). The millidarcy is the commonly used unit, but many authors also use the units of cm^2 .

Although independent of the fluid, the darcy is defined with a fluid standard in order to quantify it as the area through which a fluid with a dynamic viscosity of one centipoise will flow at a rate equivalent to one cubic centimeter per second per square centimeter under a pressure gradient of one atmosphere per centimeter; or

$$1 \text{ darcy} = [(1 \text{ centipoise} \times 1 \text{ cm}^3/\text{sec})/1 \text{ cm}^2]/(1 \text{ atmosphere}/1 \text{ cm}) \quad (2.24)$$

One centipoise is $0.01 \text{ dyne}\cdot\text{sec}/\text{cm}^2$, and one atmosphere is $1.0132 \times 10^6 \text{ dynes}/\text{cm}^2$. If these values are substituted in to the above equation, the result is that

$$1 \text{ darcy} = 9.87 \times 10^{-9} \text{ cm}^2 \quad (2.25)$$

and the same value will apply to the flow of Newtonian liquids or gases of any kind through the medium.

2.4.10 Viscosity

The resistance of a flowing fluid to shear is known as *dynamic viscosity*. Figure 2.8 shows the conceptual and mathematical relationships in the development of the term. Note that a liquid fills the space between two plates; the bottom plate is stationary and the top plate moves unidirectionally at a velocity, U . The

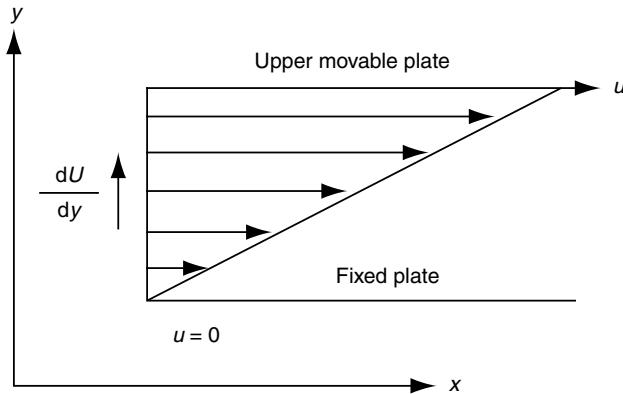

FIGURE 2.8 Illustration of dynamic viscosity as a resistance of a fluid to shear.

liquid is undergoing laminar flow and thus there is a linear change of velocity upward from zero on the bottom plate to U on the top plate. The rate of change of velocity with vertical direction is then dU/dy which is also called the vertical rate of strain. This is caused by the shearing stress, τ , which is

$$\tau = F/A \quad (2.26)$$

where F is the force that pulls the upper plate along at the velocity, U , and A is the surface area of the upper plate.

From these observations it is apparent that

$$\tau \propto dU/dy \quad (2.27)$$

and we assume that there is a constant, μ , that will convert this proportionality into an equation, namely

$$\tau = \mu(dU/dy) \quad (2.28)$$

and

$$\mu = \tau/(dU/dy) \quad (2.29)$$

where the constant μ , is known as the dynamic viscosity. It is specific to the fluid and to temperature, generally decreasing with increasing temperature. The dynamic viscosity has the units of $[FT/L^2]$.

Dynamic viscosity is defined in terms of the *poise* (0.1 Nsec/m^2), after the French mathematician and fluid dynamicist, Poiseuille. The centipoise (0.001 Nsec/m^2) is the most commonly used unit. At 15°C , water possesses a dynamic viscosity of 0.011404 poise, or $1.1404 \times 10^{-3} \text{ Nsec/m}^2$, or approximately one centipoise. In contrast, the dynamic viscosity of the earth's mantle is estimated at 10^{23} centipoise.

Dynamic viscosity is not to be confused with *kinematic viscosity*, η , which is dynamic viscosity divided by fluid density,

$$\eta = \mu/\rho \quad (2.30)$$

The kinematic viscosity has the units of L^2/T . The stoke, named after G.G. Stoke, the British physicist, has the units of cm^2/sec , but the centistoke ($0.01 \text{ cm}^2/\text{sec}$) is a more convenient unit. Water at 15°C has a kinematic viscosity of $1.139 \times 10^{-6} \text{ m}^2/\text{sec}$ or 1.139 centistokes.

2.4.11 Hydraulic Gradient

The hydraulic gradient is simply the loss of head per unit length of flow along a stream line, and is given as

$$I = dh/dl \quad (2.31)$$

a dimensionless number. Development of this relationship can be found in Chapter 3 by J.W. Delleur of this publication and in Hubbert (1940).

2.4.12 Hydraulic Conductivity of Saturated Media

Although the intrinsic permeability describes the water-transmitting property of a porous medium, it does not completely describe the relative ease with which a particular liquid will flow through the medium. The complete description is given by the *hydraulic conductivity*, K , which combines both medium and fluid properties,

$$K = k\rho g/\mu. \quad (2.32)$$

This parameter has the dimension of velocity, generally cm/sec or feet per day, and is a second-order tensor quantity. Its physical meaning is stated as, "The volume of liquid flowing perpendicular to a unit area of porous medium per unit time under the influence of a hydraulic gradient of unity." Earlier literature described this phenomenon as *field coefficient of permeability* with units of gallons per day per square foot. This name and definition are now only rarely used. Table 2.3 lists the hydraulic conductivities of several lithologies.

In the mid-19th century, a French engineer, Henri Darcy, was experimenting with sand filters for a water supply system for the city of Dijon, France. Through a series of experiments with sand-filled tubes (Figure 2.9), he was able to determine the factors that controlled the flow rate of water through the sand (Darcy, 1856).

He discovered one of the most important physical relationships in the science of porous-media hydrodynamics which became known as *Darcy's Law*,

$$q = -K(dh/dL) \quad (2.33)$$

where q is the *specific discharge* or volumetric flow rate per unit area of porous medium perpendicular to the direction of flow, and dh/dL is the hydraulic gradient along the flow path, L . By convention, the negative sign implies that flow is along the direction of decreasing gradient.

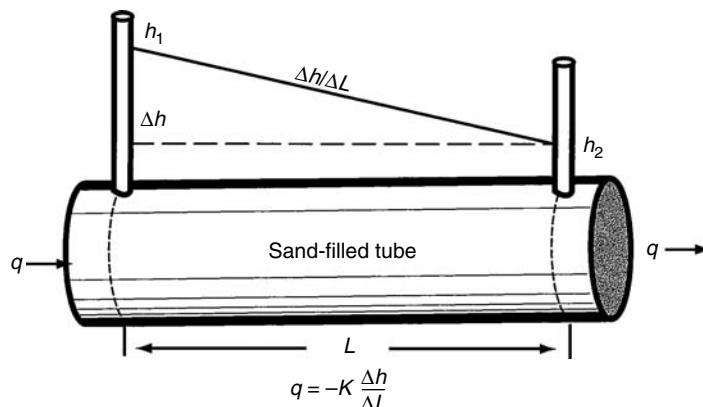

FIGURE 2.9 Figure illustrating tube experiments of Henri Darcy.

It should be noted that q has the dimension of velocity and is called *Darcian velocity*. This term or its usage is not the same as the true *average linear velocity* or *average pore velocity* or *seepage velocity* of flow through a porous medium; the latter property is given as

$$v = q/n_e \quad (2.34)$$

where n_e is the effective porosity. This difference should always be kept in mind when estimating the true velocity of groundwater flow and solute transport.

Although it is common to employ hydraulic conductivity in a general sense in studying or describing the hydraulic properties of a porous medium, it is more advantageous to use the term, *transmissivity* (defined below) to describe the ease with which water moves through a large porous medium body such as a horizontal or layered aquifer. Transmissivity, T (sometimes called transmissibility) is simply the product of hydraulic conductivity and saturated thickness of the aquifer,

$$T = Kb \quad (2.35)$$

and has the dimensions of L^2/T . This dimensional characteristic derives from the definition of transmissivity is “the volume of water per unit time passing through a unit width area of aquifer perpendicular to flow integrated over the thickness of the aquifer,” or $[L^3/(TL^2)]L$ (Figure 2.10).

Transmissivity is usually reported in units of square feet per day or square meters per day. The total rate of flow (Q) through any area (A) of the aquifer perpendicular to the flow direction under the gradient (I)

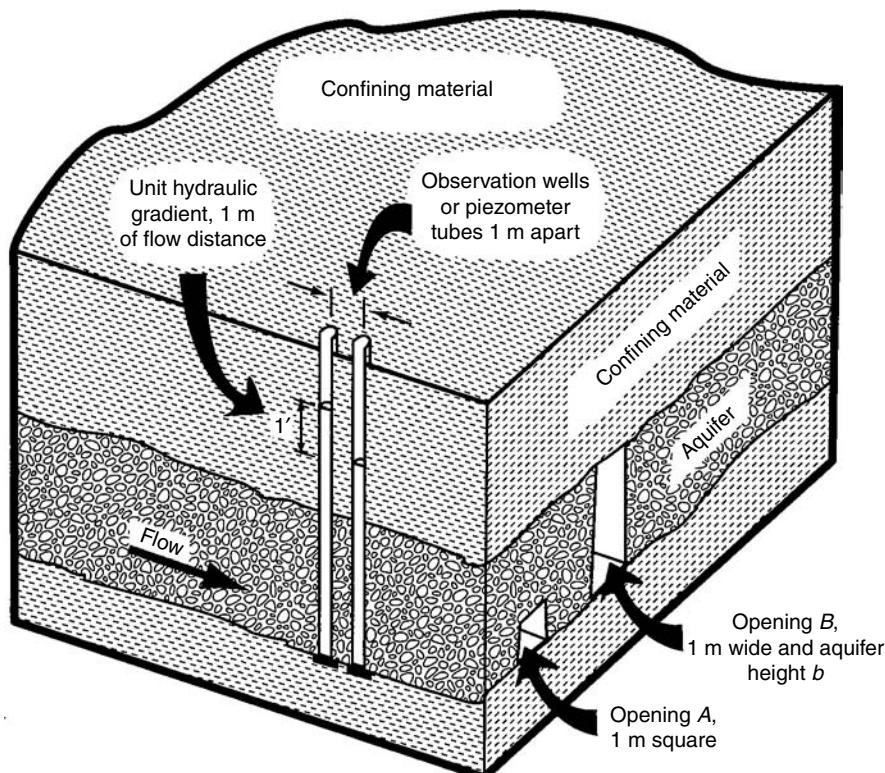

FIGURE 2.10 Illustration of the concept of transmissivity. (Adapted from Ferris, J.G., Knowles, D.B., Browne, R.H., and Stallman, R.W., 1962. *Theory of Aquifer Tests*. U.S. Geological Survey. Water-Supply Paper 1536E.)

is then given as

$$Q = TIA \quad (2.36)$$

2.4.13 Hydraulic Conductivity of Unsaturated Media

Water in unsaturated media is subject to the influences of not only the hydraulic gradient, but also of molecular attraction and surface tension, as described previously. Therefore, the unsaturated hydraulic conductivity is a function of the pressure head (Ψ), which, in unsaturated media will always be negative. Consequently, we write unsaturated hydraulic conductivity as $K(\Psi)$. This is discussed later in the section on the unsaturated zone.

2.4.14 Anisotropy and Heterogeneity

The discussion to this point has assumed that the porous media is *isotropic*, that is, the permeability and hence, the hydraulic conductivity and transmissivity, are equal in all directions at any point in the porous medium. If the parameters differ in value directionally at a point, the medium is then said to be *anisotropic*.

These directional properties are described three-dimensionally in cartesian tensor notation using nine general terms, a_{ij} , which can represent permeability, hydraulic conductivity or transmissivity, but transmissivity is a two-dimensional term that is applied only in a horizontal sense.

$$A_{ij} = \begin{matrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33}, \end{matrix} \quad (2.37)$$

If the principal directions of the tensor coincide with the major cartesian axes, the off-diagonal terms will cancel out and the only terms of interest will be a_{11} , a_{22} , and a_{33} . Specific discharge, velocity, and hydraulic conductivity are vectors. Thus, for example, in a three-dimensional porous medium with anisotropic hydraulic conductivity, specific discharge will be given as

$$\mathbf{q} = q_1 \mathbf{i} + q_2 \mathbf{j} + q_3 \mathbf{k}, \quad (2.38)$$

where \mathbf{i} , \mathbf{j} , and \mathbf{k} are unit vectors in the x , y , and z directions respectively, and q_1 , q_2 , and q_3 are specific discharge components in the x , y , and z directions respectively.

Expansion of this equation using, K_{xx} , K_{yy} , and K_{zz} to represent the main diagonal terms of the hydraulic conductivity tensor, the above equation can be expanded to the following form,

$$\mathbf{q} = K_{xx}(\partial \mathbf{h}/\partial x)\mathbf{i} + K_{yy}(\partial \mathbf{h}/\partial y)\mathbf{j} + K_{zz}(\partial \mathbf{h}/\partial z)\mathbf{k} \quad (2.39)$$

If the principal directions are along the cartesian directions, it is also common to express anisotropy graphically by use of the equation and figure for an ellipsoid in three dimensions, and an ellipse in two dimensions. Using a two-dimensional example, the semi-axes of an ellipse represent the square root of the property along those axes, and the length in any given direction, r , is the square root of the property in that direction (Figure 2.11).

The equation for an ellipsoid is

$$(x^2/a^2) + (y^2/b^2) + (z^2/c^2) = 1 \quad (2.40)$$

where a , b , and c are the semi-axes. If the medium is isotropic, the ellipsoid degenerates into a sphere for which the equation is

$$x^2 + y^2 + z^2 = r^2 \quad (2.41)$$

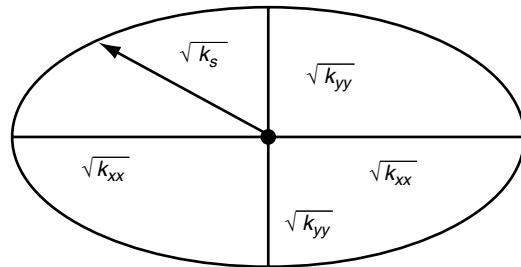

FIGURE 2.11 Elliptical representation of permeability and hydraulic conductivity.

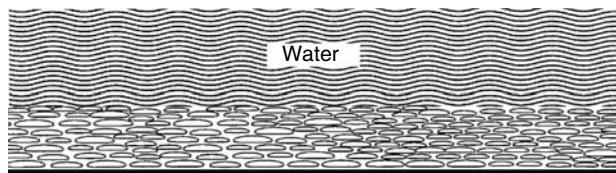

FIGURE 2.12 Natural hydraulic anisotropy in water-lain sediments.

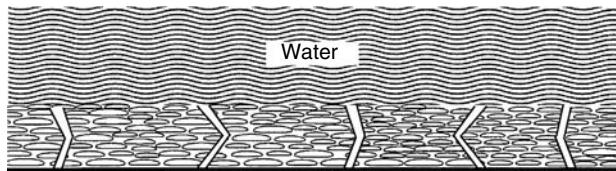

FIGURE 2.13 Anisotropy due to generation of secondary porosity by fracturing.

Isotropy or anisotropy of hydraulic conductivity and transmissivity is controlled specifically by the isotropy or anisotropy of the intrinsic permeability. The latter parameter, being a function strictly of the porous medium, is usually determined by the medium structure, which in turn, is the result of the medium's geological origin and subsequent alterations.

For example, sedimentary deposits almost always possess a lower permeability in the vertical direction than in the horizontal. This is due to the fact that as sediments are laid down from water, they assume a more stable position if possible where the longer axes of the grains and pebbles are oriented horizontally (Figure 2.12).

Subsequent fracturing by tectonic forces in a given direction will add a secondary permeability to the medium that is oriented by the forces and may result in greater vertical permeability than horizontal (Figure 2.13).

If the condition of directional equality of properties is the same from point to point anywhere in the medium, the medium is termed *homogeneous*. If the condition of either isotropy or anisotropy varies from point to point, the medium is then said to be *heterogeneous*. Figure 2.14 demonstrates these four possible descriptions of a medium – (1) homogeneous and isotropic, (2) homogeneous and anisotropic, (3) heterogeneous and isotropic, and (4) heterogeneous and anisotropic.

The average hydraulic conductivity (K_p) perpendicular to a layered sequence of m beds (Figure 2.15a), each of which is either isotropic or anisotropic, can be determined using a weighted harmonic average as

$$K_p = d \left/ \sum_1^m d_m / K_{pm} \right. \quad (2.42)$$

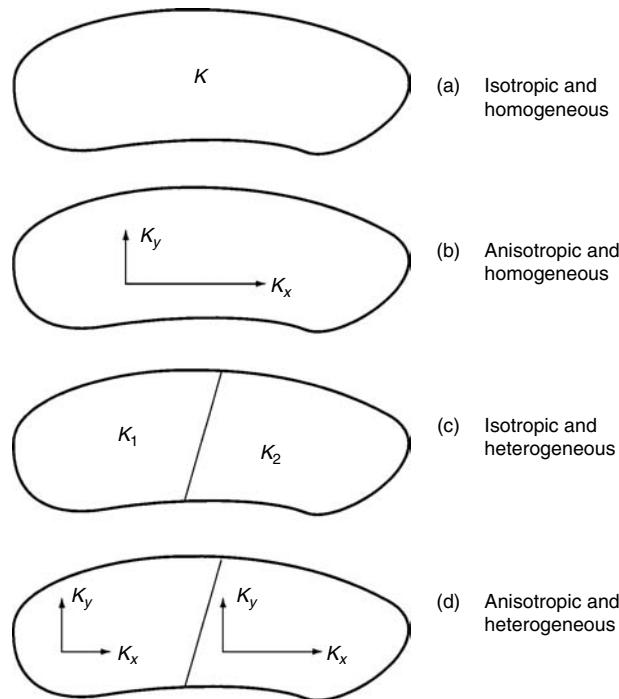

FIGURE 2.14 Summary of possible combinations of isotropy, anisotropy, homogeneity, and heterogeneity.

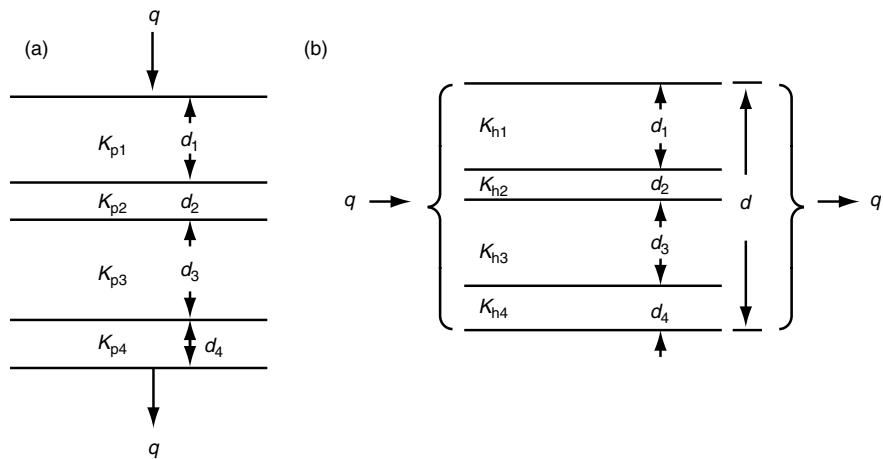

FIGURE 2.15 Hydraulic conductivity of layered systems. (a) flow perpendicular to layers; (b) flow parallel to layers.

where d is the total thickness, d_m is the thickness of each layer, and K_{pm} is the perpendicular hydraulic conductivity of each bed.

The average horizontal hydraulic conductivity parallel to the beds is given as a weighted linear average (Figure 2.15b)

$$K_h = \sum_1^m K_{hm} d_m / d \quad (2.43)$$

where K_{hm} is the horizontal hydraulic conductivity of each bed.

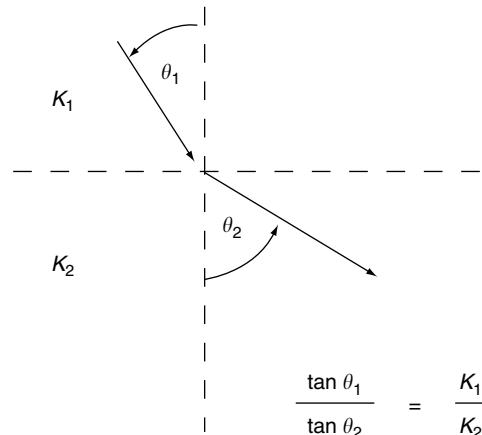

FIGURE 2.16 The Law of Tangents.

If two isotropic beds of porous media of differing hydraulic conductivities are separated by a plane surface, then a particle of water traveling through one bed will refract upon entering the other (Figure 2.16) according to the *Law of Tangents*,

$$\tan \theta_1 / \tan \theta_2 = K_1 / K_2 \quad (2.44)$$

This phenomenon occurs because of the laws of conservation of energy and mass, that is, one side of a particle will move faster or slower than the other at the interface, depending upon whether or not a more permeable or less permeable medium respectively is encountered. This phenomenon is discussed in Bear (1972).

2.4.15 Aquifers

An *aquifer* is defined by Davis and DeWiest (1966) as "... natural zone (geological formation) below the surface that yields water in sufficiently large amounts to be important economically." This definition is very relative and subjective, for a thin bed of sandstone may economically yield water to a well at a rate of $5.5 \text{ m}^3/\text{d}$ for a home but would not be sufficient to supply an irrigation well that required $2700 \text{ m}^3/\text{d}$. Yet, it could be called a aquifer by strict definition.

The most productive aquifers are generally deposits of glacial outwash, karstic carbonates, permeable sandstones, and highly-fractured rocks of all kinds.

An aquifer that is sandwiched in between two impermeable layers or formations that are impermeable is called a *confined aquifer* if it is totally saturated from top to bottom (Figure 2.17a).

If the recharge area for the aquifer is located at a higher elevation than the top of the aquifer, and a well is drilled into the aquifer, the water level will rise above the top as shown. Such an aquifer is known as an *artesian* aquifer; it is named after Artois, France where such wells are common. It should be noted, however, that the well does not have to be flowing to be termed "artesian," although that is the popular conception. A flowing well is known as a "flowing artesian well."

The water level above the top is known as the *piezometric surface* (pressure surface) which is the locus of the piezometric head, and it is not to be confused with the water table discussed below. The piezometric surface occurs above the ground surface because the higher elevation of the recharge area causes the pressure head to rise to such an elevation. The water within the aquifer will be partly under elastic storage. Pumping a well or allowing it to flow will release the water from storage.

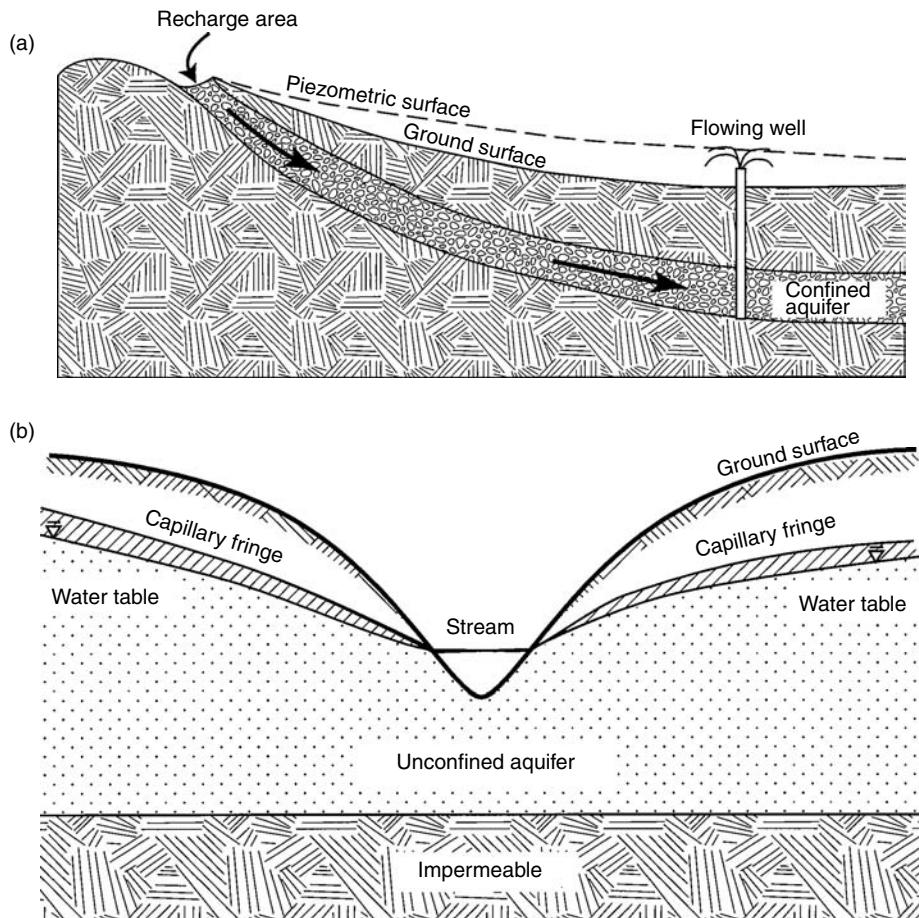

FIGURE 2.17 Kinds of aquifers. (a) Confined aquifer; (b) unconfined aquifer.

Artesian or confined aquifers are common in glaciated regions of the world where a body of outwash sand and gravel may have been covered by clay-rich till or lacustrine sediments from a subsequent glaciation. They may also occur in layered bedrock such as the famous Dakota aquifer of Cretaceous age which rises in the west to lap onto the crystalline rocks of the Black Hills in South Dakota and Wyoming where it is recharged by rain and snowmelt, and extends for a few hundred miles east to Minnesota. Along the way, it is sandwiched between impermeable or slightly permeable shales which maintain its confined and artesian condition. Wells drilled into this aquifer, even hundreds of miles from its recharge area, often flow from the pressure within the aquifer.

An *unconfined aquifer* possesses no overlying confining layer, but may sit upon an impermeable or slightly permeable bed. Therefore, the top of the unsaturated zone of an unconfined aquifer is most often the ground surface, and the top of the saturated zone is usually under negative pressure or tension. This latter property gives rise to the definition of the *water table* which is simply the surface where the relative pressure is zero, that is, the absolute pressure is atmospheric (Figure 2.17b). Immediately above the water table, the medium is still saturated but the water is held by capillary forces, thus creating a negative pressure head, or tension. This tension can exist even though the pores may be saturated between the water table and the top of the capillary fringe. Below the water table, the water pressure increases with depth.

Figure 2.18 shows the cross section of a perched aquifer. These are pockets of sand or gravel or other material that sit on top of impermeable materials such as clay. During periods of high recharge rates, these

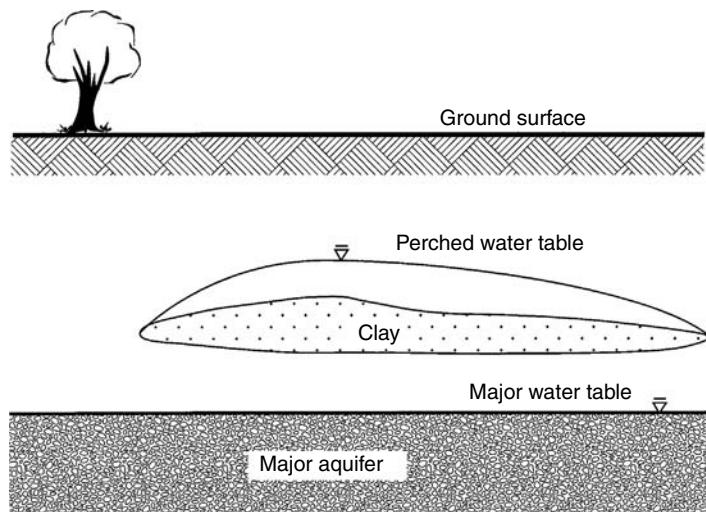

FIGURE 2.18 A perched aquifer.

aquifers may become saturated and actually contain enough water for usage on a temporary basis. Often though, after the onset of dry weather, and after pumping, the perched aquifers will become dry.

Many people make the mistake of finishing a well in a perched aquifer, thinking they are saving money by not having to drill deeper for water, but end up running out of water when the perched aquifer is depleted. Perched aquifers are common in glaciated regions because a till sheet may contain numerous sand and gravel deposits at various depths that are actually perched aquifers.

A map of the water table in a region can be constructed from water levels measured in wells in the region. In most cases the water table will be a subdued replica of the surface topography. Although the term, “piezometric surface,” is generally reserved for confined aquifers with a high pressure head, both water table and piezometric surface can be grouped into the term, *potentiometric surface*.

There is yet another kind of unit between the permeable and the impermeable, known as an *aquitard*, which is semi-permeable. A totally impermeable bed is termed an *aquiclude*. An aquifer sandwiched in between an aquitard and an aquiclude, or between two aquitards, is called a *semi-confined* or *leaky* aquifer. It usually possesses properties common to a confined aquifer, such as a high piezometric surface, but some water will flow into or out of the aquifer through the aquitard(s) (Figure 2.19).

In reality, few rocks or formations are entirely impermeable and the above definitions may be relative to the time period and intensity of pumping stresses imposed on the aquifer. For example, a low-permeability stratum overlying an aquifer may indeed serve as a confining layer under normal and natural pressures. However, when the added stress of heavy pumping is added to the aquifer, the change in head within the aquifer may be great enough to cause some water to move through the overlying bed and the system will then be semi-confined.

Pumping a well in an confined aquifer will release water from elastic storage determined by the elastic specific storage, as discussed above. Pumping from an unconfined aquifer releases water from gravity drainage of the actual media itself, and this is controlled by the specific yield. Recalling that specific yield may be as much as three or four orders of magnitude greater than the elastic storage coefficient implies that much more water can be obtained from an unconfined aquifer per unit of energy expended than from a confined aquifer, providing that the permeability and thickness of the two different aquifers is the same.

Well yields of a semi-confined aquifer with the same properties as the confined and unconfined aquifers will generally yield more water per unit of energy expended than the confined aquifer, but less than the unconfined, because the semi-confined will yield water from elastic storage plus some from leakage through the semi-confining bed(s), but neither sources are as great as the yield from an unconfined aquifer in most cases.

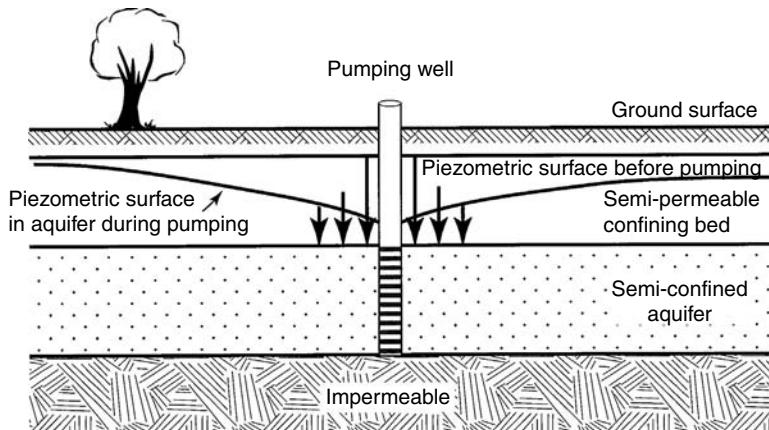

FIGURE 2.19 A semiconfined or leaky aquifer. Vertical arrows indicate relative rates of leakage into aquifer as a function of the distance from the well.

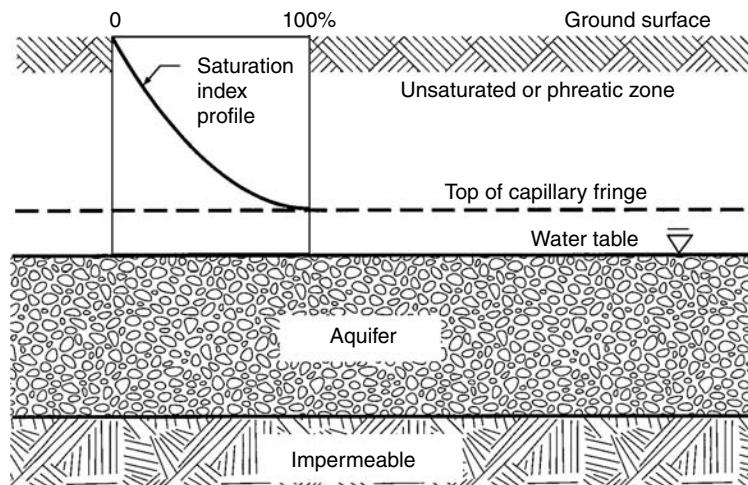

FIGURE 2.20 Saturation index profile vs. depth in an unsaturated soil.

Although more water can be obtained from unconfined aquifers than the other types, they are more vulnerable to contamination from surface sources than the others because of the lack of a protective confining bed above them. It is for this reason that special care must be taken to insure the removal and/or remediation of contamination sources above an unconfined aquifer in use or being considered for use as a water supply. This is discussed further under the subject, *Well-Head Protection Programs* below.

2.5 Water in the Unsaturated Zone

2.5.1 Moisture Content vs. Depth

Figure 2.20 shows the general profile of the saturation index from the surface to the water table in an ideal homogeneous and isotropic aquifer. For purposes of discussion, this figure assumes that there have been no recent rains or snowmelt events and that at the surface the moisture content is zero.

From the ground surface to the top of the capillary fringe, the saturation ratio increases from zero to unity and will remain so to the bottom of the aquifer. Below the capillary fringe is the water table at

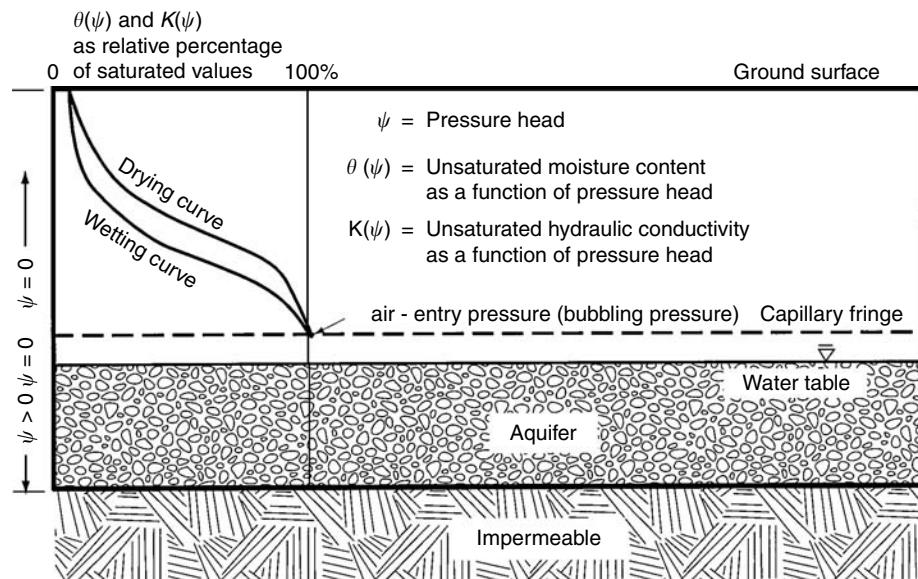

FIGURE 2.21 Soil moisture characteristic curves.

atmospheric pressure which marks the surface delineating the tension zone above from the pressure zone below. The relationships are all the result of a dynamic equilibrium of several forces and conditions — capillary attraction, porosity, initial moisture recharge at the surface, gravitational acceleration, vertical permeability, and evapotranspiration from the surface.

The functional relationship of the moisture content and hydraulic conductivity of the unsaturated profile can be demonstrated by the use of *characteristic curves* as shown in Figure 2.21.

At very low (negative) values of the pressure head, ψ , both the moisture content and hydraulic conductivity are at minimal values for the system. With increasing values of ψ , they increase to become constant at the top of the capillary fringe where the saturation ration is unity, indicating full saturation. Here also, the hydraulic conductivity is no longer a function of the pressure or moisture content, but attains a maximum value at which it remains, providing no changes in the porous media occur. The pressure head at this point is called the *bubbling pressure* or the *air-entry pressure*; at a lower pressure, air will enter the system causing loss of saturation. As the pressure increases with increasing depth in the system, it will become atmospheric, or zero relative to positive and negative extremes of the pressure range, marking the water table. With still increasing pressure, both moisture content and hydraulic conductivity remain constant.

The lag between the wetting and drying curve shapes is called *hysteresis*. This is due to the fact that initial wetting of the porous medium is enhanced by strong capillary and adhesive forces, but these same forces tend to hold water in the unsaturated pores and it requires more suction or greater negative pressures to drain the pores, as illustrated by the offset of the drying curve from the wetting curve.

It should be noted that characteristic curves of fine-grained materials such as silt and clay will be much steeper in shape than those of coarse sand and gravel. This is due to the fact that in the coarse-grained material with relatively large pore diameters, the effects of capillarity and adhesion are not as great as in the fine-grained material. It is for this reason that the capillary fringe in clay is much thicker (one or two meters) than in coarse materials (a few centimeters at most).

In reality, soil moisture is not distributed evenly in the unsaturated zone, but varies both vertically and horizontally due to variations in soil types, crop types, infiltration rates, etc. Recently, new work has been done in expressing the variability of soil moisture in unsaturated chalk with electrical tomography (Andrews et al., 1995). This method, although in the experimental stage, does allow visual imaging of soil moisture contents based on subsurface electrical resistivity of various zones.

2.5.2 Recharge and Infiltration Capacity

Recharge is the actual entering of water into an aquifer, whereas *infiltration* is movement of water from the surface into the ground. Usually, the recharge source is surface water from precipitation and to a lesser degree, irrigation or artificially constructed recharge pits or losing streams (discussed below). The actual recharge rate is controlled by several factors: (1) the amount and rate of precipitation not lost to surface runoff and evapotranspiration, (2) the initial soil moisture content or saturation ratio of the soil, (3) the elevation of the recharge surface relative to the discharge area, (4) the horizontal hydraulic conductivity of the aquifer being recharged and its hydraulic gradient which determine the rate at which recharged water will be carried out of the recharge area, (5) the vertical hydraulic conductivity of the soil being recharged, and (6) the presence of man-made alterations to the subsurface such as drainage tiles that carry water away to run off in surface streams.

People are often surprised to learn how little precipitation is actually recharged in even moist climatic zones. For example, the state of Indiana receives approximately 91.4 cm of precipitation water per year. Yet, a statewide average of only about 10% (9.14 cm) is actually recharged into the groundwater system, the rest being lost to evapotranspiration, surface runoff, and subsurface drainage tiles. Recharge is not evenly distributed with perhaps eight to ten times the amount going into more permeable sands and gravels than into till.

Figure 2.22 shows a hypothetical cross section of a recharge/discharge system with recharge taking place in the higher elevation and discharge in the lower. The stream lines are perpendicular to the equipotential lines. Discharge areas are often seen on the ground as wet spots with seeps or springs and often with lush vegetation.

Recharge rates are not easy to determine due to the variability of soils and the necessity of extensive field instrumentation. One very effective method has been the actual tracking of infiltrating water by analyzing the concentrations of atmospheric tritium at depth in the soil. This procedure was very successful in Indiana (Daniels et al., 1991), and in Minnesota (Kanivetsky and Rumynin, 1993). Tritium in the atmosphere, due to atmospheric nuclear weapons tests in the 1950s and 1960s, is incorporated into precipitation which is eventually recharged into the ground. The concentration of tritium in a vertical drill core can be used to estimate the rate of recharge.

In addition to elevation and soil type and its variability, recharge is controlled by the *infiltration capacity* of the soil. This phenomenon was studied by Horton (1933) and is the maximum rate at which a soil will permit the entry of water. It is generally a time-dependent parameter because it depends upon the rate of change of the saturation ratio and hence, the moisture content.

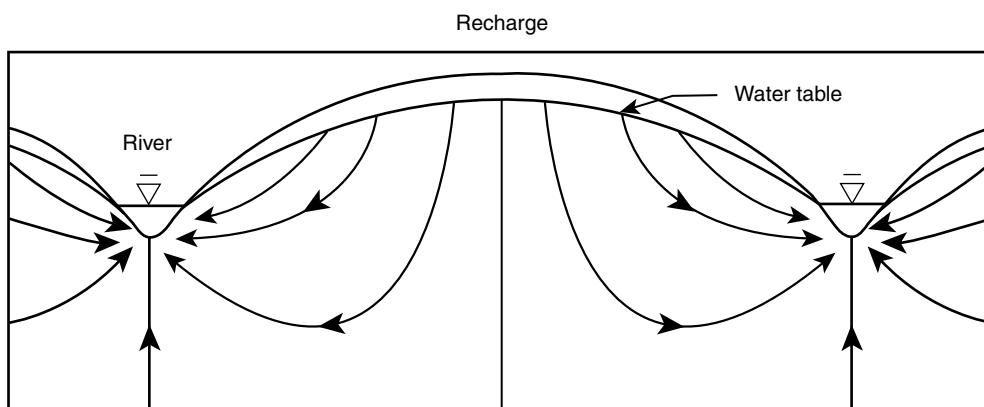

FIGURE 2.22 Hypothetical recharge/discharge system. (Adapted from Lohman, S.W. 1972. *Ground-Water Hydraulics*. U.S. Geological Survey Prof. Paper 708, U.S. Government Printing Office, Washington, DC.)

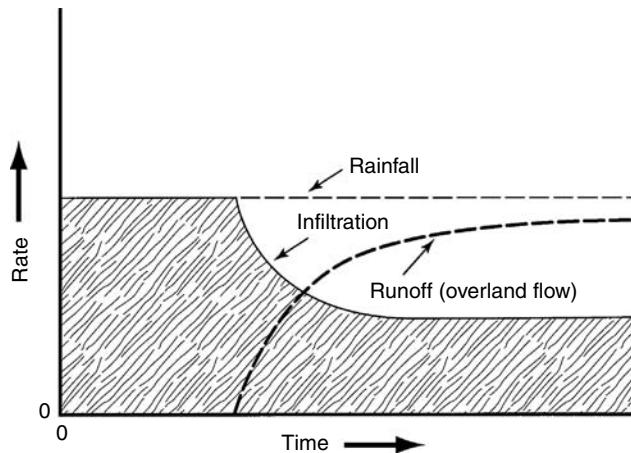

FIGURE 2.23 Illustration of infiltration capacity.

This relationship is illustrated with Figure 2.23. Here, an initially dry soil is rained upon at a constant rate. Initial infiltration into the soil is rapid as the empty pores begin filling. As infiltration continues, the pores gradually lose capacity for additional water at the initial rate. As a result, the infiltration capacity decreases to an eventual steady-state rate where the infiltrating water enters as the same rate that it is transported downward by porous media flow.

Once the infiltration rate falls below the precipitation rate (or snowmelt rate), the excess water will become runoff known as *overland flow*. Generally, this will happen after all surface storage requirements are met, for example, leaf storage in trees, crops, and grasses; and depression storage in hollows in the ground. From these considerations, it is obvious that the most effective rain for watering plants and recharging groundwater supplies is the slow steady kind, and not the intense, high-rate storm, most of which runs off and does not infiltrate.

2.5.3 Hydraulic Conductivity and Specific Discharge through the Unsaturated Zone

When the infiltration capacity is reached, the unsaturated hydraulic conductivity is then at its maximum. When the soil is initially dry, water will not flow any significant distance until the water content in the soil is sufficient and the pressure head becomes less negative, as demonstrated with the characteristic curves above. The specific discharge is then given as

$$q = -K(\psi) \quad \partial h / \partial l, \quad (2.45)$$

or

$$q = -K(\theta) \quad \partial h / \partial l \quad (2.46)$$

where θ is the water content of the soil. Three methods for computing unsaturated hydraulic conductivity as a function of water content are given below and are summarized in Rawls et al. (1993). The equations below are dimensionless making them applicable to any consistent set of units.

Brooks and Corey (1964) give the formula for hydraulic conductivity as

$$K(\theta)/K_s = [(\theta - \theta_r)/(n - \theta_r)]^m \quad (2.47)$$

where K_s is saturated hydraulic conductivity, θ_r is residual water content, n is porosity, and

$$m = 3 + 2/\lambda \quad (2.48)$$

where λ is the pore-size index (Brooks and Corey, 1964).

Campbell (1974) presents the following formula:

$$K(\theta)/K_s = (\theta/n)^m \quad (2.49)$$

where

$$m = 3 + 2/\lambda \quad (2.50)$$

Van Genuchten (1980) presents the formula:

$$K(\theta)/K_s = [(\theta - \theta_r)/(n - \theta_r)]^{1/2} \{1 - [((\theta - \theta_r)/(n - \theta_r))^{1/m}]^m\}^2 \quad (2.51)$$

where

$$m = \lambda/(\lambda + 1) \quad (2.52)$$

2.5.4 Residence Time

Water exists in different forms and in different places and for widely varying times in the hydrologic cycle. Freeze and Cherry (1979) state that soil moisture may stay in place for two weeks to one year. This rate is an average and depends on a wide variety of conditions such as permeability, infiltration rate, plant use, hydraulic gradient, and anthropogenic withdrawal rates.

2.5.5 Subsurface Stormflow or Interflow Zone

In many regions of the world, especially in tilled crop land and forest litter on sloping ground, infiltration into the upper one or two meters of soil will be quite rapid, but continued infiltration into the substratum will be much lower. The upper part often possesses much greater permeability than the lower part due to tilling, root activity, and movement of soil by worms, insects, and small mammals.

If the hydraulic conductivity of the lower part is less than the upper, then subsurface runoff will occur in the upper part, or the *subsurface stormflow or interflow zone*, as it is called. This zone may carry water all the way to a stream or it may discharge it along the way at a lower elevation. Figure 2.24 illustrates the interflow zone.

2.5.6 Atmospheric Discharge and Seepage Face

In a discharge area, at the juncture point where groundwater enters a stream or lake, the water table will coincide with the elevation of the surface water. Beyond this point, the hydraulic gradient is zero and groundwater has completed its journey from recharge to discharge.

Also at this point, there will generally be a zone of wet soil extending above the juncture point (Figure 2.25). This zone, called the *seepage face*, is wetted by capillary attraction of the water above the water table and it is essentially the surface exposure of the capillary fringe. A small fraction of the discharge from the groundwater system will escape into the atmosphere at this point. The height of the seepage face will depend upon the grain size of the soil – greater in fine-grained and lesser in coarse-grained sediments.

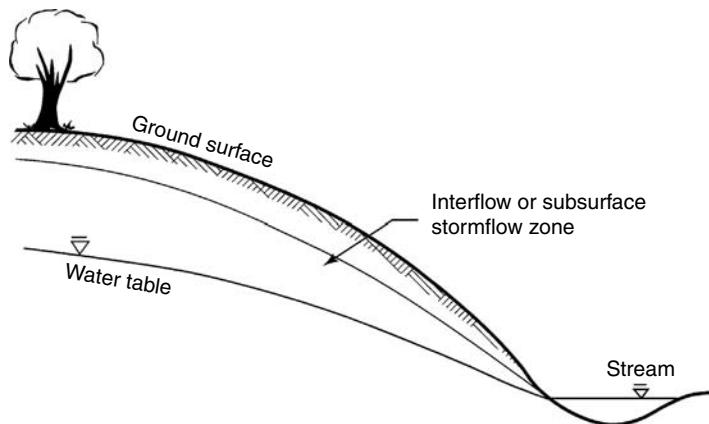

FIGURE 2.24 The interflow or subsurface stormflow zone.

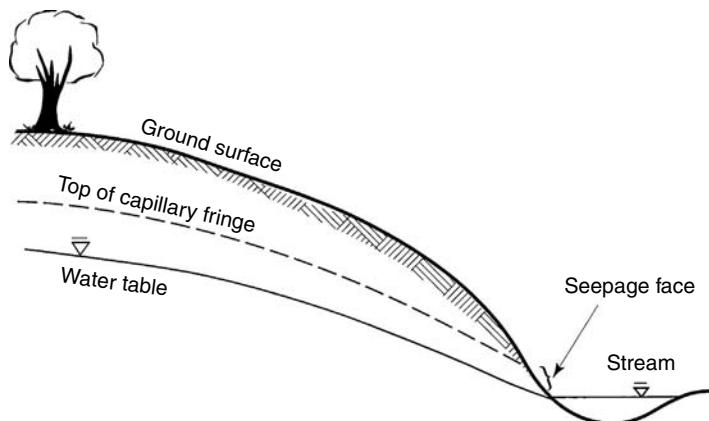

FIGURE 2.25 The seepage face.

2.5.7 Discharge to the Saturated Zone

Water in the unsaturated zone will percolate downward from the surface and gradually increase in content to a maximum, where the saturation ratio is unity at the top of the capillary fringe. At this point, it will flow downward to the water table under saturated flow conditions. The rate of flow to the saturated zone will depend to a large degree on the vertical permeability and the rate at which the groundwater in the saturated zone is being carried away by lateral Groundwater flow.

2.6 Water in the Saturated Zone

In saturated pores, the forces of adhesion are equal in all directions, so there is no directional attraction. The only dynamic or motive forces in action are gravity and the force represented by the gradient of the fluid potential. Resistive forces due to viscosity (resistance to shear) work in opposition to the dynamic forces.

Darcy's Law is assumed to be in effect in porous media flow and the flow is assumed to be laminar, that is, the *Reynold's number*

$$R_e = \rho v d / \mu, \quad (2.53)$$

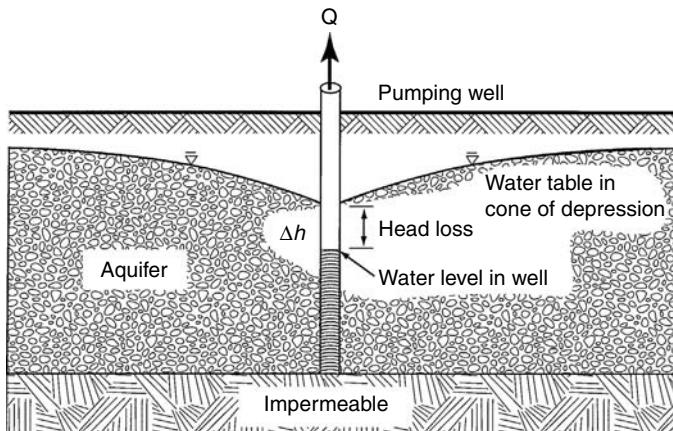

FIGURE 2.26 Flow to pumping well with head loss.

has a value from 1 to 10, where ρ is water density, v is average pore velocity, d is average pore diameter, and μ is dynamic viscosity of water at a given temperature.

The average pore diameter is probably the best estimate of pore properties that can be attained on a large scale. However, the pore size in a medium can range over even a few orders of magnitude in very heterogeneous media with high uniformity coefficients (greater than 4). Therefore, it is unlikely that laminar flow occurs in all pores at the same time. Large pores (including fractures and karst conduits) may allow passage of water at velocities high enough to be non-linear laminar or transitional ($4 \leq R_e \leq 100$), and in some cases, turbulent ($R_e > 100$). In small pores, the frictional resistance may be too great to allow flow faster than laminar. In spite of these uncertainties, hydrogeologists generally accept the assumption of laminar flow throughout a granular porous media with $R_e < 100$ for the sake of simplifying the mathematics of flow.

Groundwater may flow for some distance over a wide area in the laminar state, but as it approaches a discharge point (e.g., a spring or well) much narrower than its upgradient flow field, the streamlines will crowd together and the flow velocity will increase to maintain the same volumetric discharge rate. Near or at the point of discharge the velocity will often be great enough to be actually turbulent.

Under such conditions, the specific discharge will be expressed as

$$q = -K(\partial h/\partial l)^m, \quad (2.54)$$

where $m > 1$.

Figure 2.26 illustrates a situation where flow can change from laminar to turbulent as it approaches a pumping well. Assuming that the aquifer is homogeneous and isotropic and that the flow is steady-state, the flow lines converge as they approach the well.

At some distance from the well the equation of steady-state flow is given as

$$q = -K(dh/dr) \quad (2.55)$$

where r is the radial distance from the well center. At or near the well, the equation becomes

$$q = -K(dh/dr)^m \quad (2.56)$$

where $m > 1$ and generally closer to 2.

Steady-state laminar flow into the well will require a gradient such that the water level in the well casing is the same elevation as that immediately outside the well casing in the aquifer. Turbulent flow into the

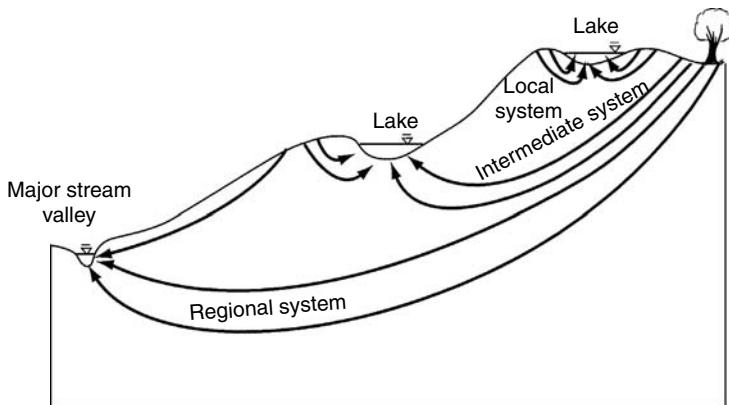

FIGURE 2.27 Local, intermediate, and regional flow systems.

well requires more energy and thus a steeper gradient than laminar flow. To accomplish this, the water level in the well will have to drop below the level required for laminar flow as demonstrated in Figure 2.26.

This extra head drop is known as head loss or *well loss*, and is undesirable. Well loss means extra energy is needed which reduces the efficiency of the pumping system and drives up the cost of pumping water. In addition, because a greater pressure drop occurs with head loss, gasses will be more likely to come out of solution and cause precipitation of lime (CaCO_3) and iron and manganese oxides (Fe_2O_3 and MnO_2 respectively) onto the well screen which causes clogging of the screen and further reduces the efficiency of the well. For further discussion, see chapter on *Well Hydraulics*.

2.6.1 Residence Time

Groundwater occurs over a wide range of depths, from near the surface to even thousands of meters below. It has been estimated that the residence time of groundwater can vary from as little as two weeks to more than 10,000 years (Freeze and Cherry, 1979). Some water presently being extracted from aquifers in the north central United States is believed to have been recharged during the Pleistocene Epoch, more than 10,000 years ago.

Tóth (1962) introduced the concept of flow system lengths and applied it to the prairie pothole regions of the Canadian high plains. The same concept (the "Prairie Profile") applies in many other regions and to many other Groundwater regimes. Tóth's three systems are the (1) local systems, (2) intermediate systems, and (3) regional systems, as demonstrated by Figure 2.27.

The local flow system consists of relatively short cells with discharge a few tens to a few hundreds of meters from the recharge areas. Such systems generally contain water of the best quality, that is, the lowest concentration of total dissolved solids, because of its short residence time and the short flow paths. Residence times may be only a few months or a few years. Such systems are commonly recharged on the interfluvial high ground between glacially-created ponds, and they discharge to the ponds a few tens or hundreds of meters away.

Intermediate systems cover a larger area of perhaps a few hundred to a few thousand meters and residence time may be tens of years. Dissolved solids concentrations are greater than in the local systems.

Regional systems may cover many kilometers and be as large as a state. A typical example is the Dakota Aquifer which is recharged in the Black Hills of South Dakota and yet extends for a few hundred miles eastward.

Most regional systems discharge into major rivers or large lakes, such as the Mississippi or the Great Lakes, respectively. In regional systems, the total dissolved solids can be quite high. For example, it is not uncommon to find as much as 2,500 to 3,000 mg/l of TDS in the Dakota Aquifer. Residence times can exceed several thousands of years.

Fossil water is that water trapped deep in the earth and incorporated with original sediments. Generally, it is of geologic time in age and contains such high concentrations of dissolved minerals that it is often considered a brine.

Connate water is groundwater which has circulated so deeply in the flow system that it too is excessively old, approaching geologic time in many cases. It also is briny in most cases.

Both kinds of water may contain large concentrations of magnesium, calcium, sodium, potassium, chloride, sulfate, carbonate, and bicarbonate. Often these brines contain dissolved matter in concentrations exceeding 100,000 mg/l, and as such are known as *bittern brines* (Hem, 1985).

2.6.2 Surface Discharge

When streams are incised into aquifers, or even into saturated soil or rocks which cannot be classified as aquifers, the streams normally serve as discharge lines or sinks for groundwater as it leaves the groundwater system. Groundwater is seldom static and streams carry water back to lakes and oceans where it is naturally recycled by evaporation.

Between storms and runoff events, stream flow is maintained by groundwater discharge known as *baseflow*, as long as the water table remains above the stream bottom. After a storm or snowmelt event, the stream will flow at its highest rate and will continue to flow at an ever decreasing rate until the next precipitation event. During dry weather, the water table may even drop below the stream bottom which will cause stream flow to cease. The history of these events and relationships is shown in a *hydrograph* in Figure 2.28.

The falling limb of the hydrograph is a record of both overland flow and baseflow. Over a period of many years, such falling-limb records of a particular stretch of stream can be analyzed by regression analysis to derive a number unique to that particular stretch and its upstream contributing basin. This number, a , the *base flow recession constant*, is used in the following equation to compute flow rates,

$$Q = Q_0 e^{-at}, \quad (2.57)$$

where Q is the flow rate at any time, t , Q_0 is the initial flow rate, and t is elapsed time since time of the initial flow rate. The reader may note that this equation, a decay-curve equation, is of the same form as the classical decay curve equation which is also applicable to radioactive decay, using different units.

The baseflow recession constant of a stream or a certain stretch of a stream may change only slightly over a long period of time if neither the environment nor the climate does not change appreciably. However,

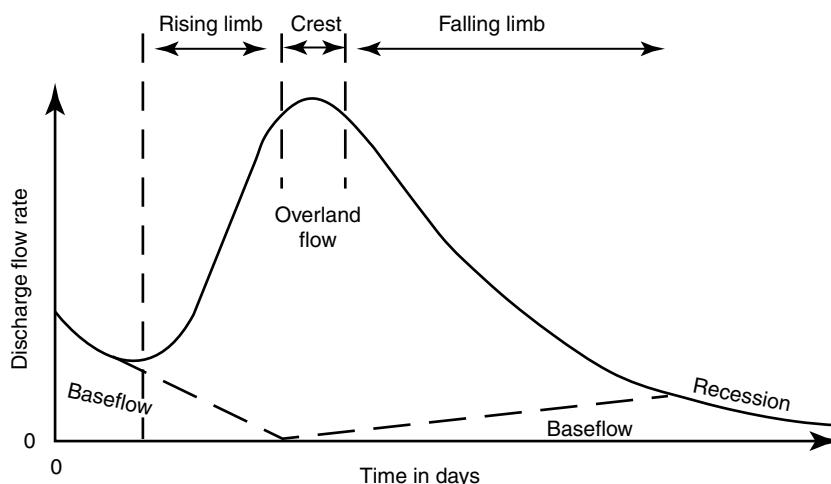

FIGURE 2.28 Hydrograph of stream flow.

anthropogenic alterations such as timbering, farming, tiling of fields, construction of roofs and pavements, and damming of the stream or diversion of its water can drastically change the recession constant in a fairly short time.

In water-management and water-budget studies, it is often necessary to separate out the various components of the hydrograph to determine the contribution of groundwater, surface water, etc. This is not an easy task, but four commonly-employed methods are described in the following paragraphs:

- (1) *Direct-measurement method:* Accurate knowledge of the groundwater hydraulic gradient on both sides of the stream and an accurate estimate of the hydraulic conductivity must be known beforehand. The first can be gotten by installation of piezometers, in which the water levels are regularly measured. Hydraulic conductivity can be determined with pumping tests or from laboratory determinations from grain-size distributions. Direct measurement of stream flow is taken carefully, and evapotranspiration is estimated by proper formulas. Direct precipitation is also recorded.

Using Darcy's law, the specific discharge from groundwater can be calculated to yield an estimate of groundwater contribution to total stream flow. The groundwater discharge, precipitation, and evapotranspiration are then known, they can be subtracted from total stream flow at various times in the time period of the hydrograph to determine the overland flow component during these times.

- (2) *The curve tangent method:* Pilgrim and Cordery (1993) describe a graphical estimation method in which tangents are drawn to recession curves at point where overland flow starts and is assumed to end (breaks in the hydrograph slopes). Under conditions where maximum baseflow discharge is below 10% of the maximum discharge, a straight line can be drawn between the two tangent points which will be an acceptable estimate of the baseflow discharge component.
- (3) *The basin-area method:* Linsley et al. (1975) gives the formula for calculating D , the number of days between the storm peak of a hydrograph and the end of overland flow, for a basin of area, A (in square kilometers), as,

$$D = 0.827A^{(0.2)} \quad (2.58)$$

The hydrograph recession limb that existed before the storm is extended until it is under the hydrograph peak. A straight line drawn from this point to the point on the hydrograph corresponding to D is then considered to be the graph of the baseflow component.

- (4) *The chemical and isotope method:* Stream water and groundwater supplying the stream's base flow can be analyzed for a variety of chemicals and isotopes during periods of normal flow to obtain normal background levels. Typical analytes include ^2H , ^3H , ^{18}O , Na^+ , Ca^{2+} , Mg^{2+} , Cl^- , SO_4^{2-} , and HCO_3^- . Electrical conductance has also been used. During periods of high flow, the stream water is sampled again and analyzed for the same isotopes (Freeze and Cherry, 1979).

If the chemicals or isotopes that were high in concentration in the groundwater are also high in the stream water, then it can be assumed that a significant percentage of the surface flow is actually being contributed by groundwater. On the other hand, if the groundwater isotopes are low in the stream water, then it can be assumed that most flow originates from surface runoff.

Highly permeable soils will contribute significantly to surface flow during precipitation. Low-permeability soils will contribute less, and the isotope analyses will show these differences.

A *spring* is a natural discharge point for groundwater to the surface and the atmosphere. Several geological factors can cause springs of various types to occur, as listed below:

- (1) *Geological contact springs:* When a saturated permeable formation sits on a stratum of low permeability, it will often result in a spring at the contact. This is a common occurrence in glaciated regions where saturated sand and gravel sits on till. If the water has not been contaminated by surface sources, the water from such springs is often of good quality because it has not traveled far before discharge and therefore, little mineral matter has been dissolved.

- (2) *Karst springs:* In limestone and dolomite formations, springs will often discharge from the points on a valley side where caves have been intersected by incising stream valleys. These are common in areas of the world where the valleys are deep enough and precipitation and recharge are great enough to allow a water table to exist well above the streams.

The Fontaine de Vaucluse in southern France discharges between 8 and 150 m³/sec and is one of the largest springs in the world. It is supplied by precipitation on the fissured carbonates of the Vaucluse Plateau. The extensive network of karst conduits ends at the point of discharge. Another kind of karst spring is the sinkhole spring. This feature is simply a spring where a sinkhole intersects karst conduits. Springs of this kind are very common in the limestone of the state of Florida, with names like Silver Springs, Tarpon Springs and others. Many large lakes in central Florida are actually large sinkhole springs.

- (3) *Structural springs:* When there is significant movement along faults such that permeable and water-bearing formations are juxtaposed against impermeable rocks; or fracturing opens pathways into aquifers, water can emanate from these features to discharge at the surface. Such springs are not uncommon in the Great Basin of the United States of America where tension in the earth's crust has produced a large area of block faulting Nevada, Utah, and parts of Arizona and Idaho. One such example is the Ash Meadows Springs in the Amargosa Desert of Nevada, just east of Death Valley, where discharge along a fault spring in carbonates is approximately 2.1×10^7 cubic meters per year.
- (4) *Depression springs:* If the land surface is lowered below the water table, a depression spring will form and will actually create a small local flow system with the spring being the discharge point. Such depressions can be created by wind in areas of fine sand, or by land slides, or tectonic activity, or even the collapse of land into underlying sinkholes or mine tunnels.

Many springs are known for their size and have been utilized for water supplies, spas, and tourist attractions. Examples are Steamboat Springs, Colorado; Hot Springs, Arkansas; Big Springs, Texas; White Sulfur Springs, West Virginia; and many others.

Ponds and lakes can form in many ways. Commonly in glaciated regions like the Midwestern United States, Canada, and northern Europe, present-day lakes and ponds are the results of ice blocks that were covered with drift and later melted to form permanent depressions in the new landscape. Glaciers in mountain valleys may leave large debris dams at their termini which cause ponding of water. Sinkhole lakes are common in Florida, Kentucky, Indiana, and other karst areas. Landslides can dam up rivers. Tectonic forces can cause certain areas, as in the Basin and Range areas of the United States, to subside relative to the surrounding areas, for example, Death Valley which contained a large lake during the Pleistocene Epoch. Volcanic craters may contain ponded water like Crater Lake, Oregon. Oxbow lakes can form when large rivers meander and eventually, a meander loop is cut off from the main stream.

Surface bodies of water are nearly always groundwater discharge areas. Very large lakes, for example the Great Lakes in North America, serve as discharge areas for regional, intermediate and local systems upgradient from them. The smallest ponds of few acres in area discharge water from local systems.

The dynamic role of lakes and ponds in the movement of groundwater is most significant for two reasons. In the first place, the generally low topographic positions of these bodies in relation to the upgradient flow system feeding them cause water to flow toward them under the force of gravity, and the size of the lake and its elevation relative to other bodies of water in the area can determine the relative size of the groundwater system feeding it; that is, very large and low-elevation lake surfaces can be sinks for regional systems, whereas small ponds at relatively high elevations will generally serve only local systems.

Second, lakes, especially those with large surface areas, can allow significant evaporation to take discharge water out of the system and put it back into the atmosphere. This process is especially important in hot summer months when actual evapotranspiration can equal potential evapotranspiration. For example, Leap (1988) discusses an area on the Coteau Des Prairies in northeastern South Dakota where 6% of the surface area is covered with glacially-derived ponds and lakes, ranging from a few hundred

meters to a few kilometers in diameter, that drive local and intermediate systems respectively. The potential evapotranspiration rate from May through September, when transpiration is highest, was calculated to be 0.61 m.

Assuming, for example, that in one square kilometer of the area, 6% of the area, or $60,000 \text{ m}^2$ is covered with water, then the total amount lost from the lakes is approximated as $60,000 \text{ m}^2 \times 0.61 \text{ m}$ or 36,600 cubic meters of water during the period from the first of May through the last of September. This is a conservative estimate because minimal evapotranspiration occurs before and after this time before the winter freeze sets in.

For illustrative purposes, assume that the one square kilometer area is underlain by an aquifer five meters thick with a porosity of 25% (characteristic of this area). If fully saturated, this aquifer would then contain $1,250,000 \text{ m}^3$ of water. Thus, the $36,600 \text{ m}^3$ of water lost by evapotranspiration would equal 3% of the total water contained in the aquifer.

This amount does not seem like much over the entire one-square-kilometer area, but the lowering of the water surface of many ponds by even a small amount by evapotranspiration sets up gradients sufficient to drive many local flow systems. The same amount of loss in one large lake of the same area can cause gradients sufficient to drive even intermediate systems.

Meyboom (1967) discusses the role of evapotranspiration in prairie pothole lakes in western Canada. His study showed that the role of vegetation, especially water-using phreatophytes like willow, around the edge of a lake can be quite significant. In many areas, the water table will actually be depressed beneath these trees.

The depression of the water table below the root zone can be studied quantitatively with a method by White (1932). Using his equation, one can estimate the amount of water removed from the groundwater system per day by evapotranspiration. An example is given in Todd (1959).

Thus, it is the interaction of the dynamics of gravity pulling rain and snow to the surface and then moving groundwater to the lakes (and streams), and evapotranspiration removing it from the earth's surface that maintains the circulation of groundwater. If this were not so the residence time in the ground would be so long that groundwater would dissolve so much mineral matter that it would become unpotable. Through this interactive process, water on earth is constantly cleansed before being re-introduced into the system.

Definitive modeling studies of the three-dimensional physical dynamics of groundwater flow to and from lakes were made by Winter (1976). Two contrasting examples of several modeled scenarios are shown in Figure 2.29a and b in order to illustrate the importance of permeability contrasts in the subsurface below lakes.

In Figure 2.29a, the subsurface is anisotropic, but homogeneous. Figure 2.29b shows the case where the subsurface is anisotropic and heterogeneous. Given that there is an ample supply of recharge, a high-permeability layer at depth can be great enough to divert much of the flow toward the lower layer. Thus, high-permeability layers at depth are significant in causing water from the surface to recharge the subsurface. Knowledge of the positions and hydraulic characteristics of such layers are critical to estimating recharge rates for water-management purposes, and for estimating the potential for contaminants from the surface to reach potable groundwater supplies.

Ideally, there will be a point beneath a lake undergoing both recharge and discharge, to and from the subsurface respectively, where the hydraulic gradients will be in opposition to the extent that flow does not take place. This is called the *stagnation point* and it is shown in Figure 2.29a. The stagnation point is in dynamic equilibrium with the head and gradients that exist at any one time, but will change position with changes in recharge rates from the surface, or discharge from the subsurface. Therefore, any attempts to dispose of waste at a stagnation point, as has been suggested in the past, would not be wise due to the fact that the location will change under most circumstances and soluble waste will then migrate.

An additional factor that can greatly affect the inflow/outflow characteristics of lakes is the presence low-permeability sediments on the bottom. This is often a problem in artificial recharge pits where such sediments can lower the infiltration rate of water from the pits to the subsurface. The influence of the

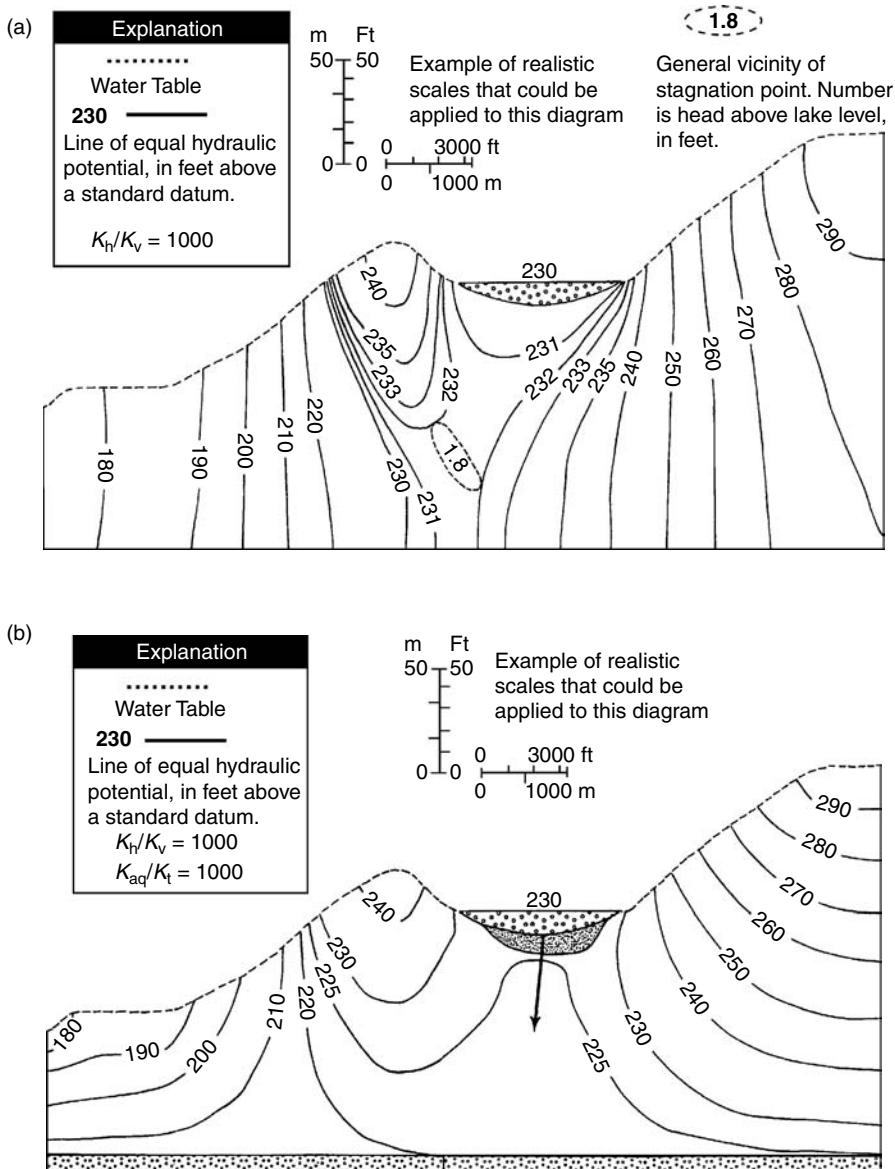

FIGURE 2.29 Cross section showing lake/aquifer interactions. (a) Anisotropic and homogeneous aquifer; (b) Anisotropic and heterogeneous aquifer. (Adapted from Winter, T.C. 1976. *Numerical Simulation Analysis of the Interaction of Lakes and Ground Water*. U.S. Geological Survey Prof. Paper 1001. U.S. Government Printing Office, Washington, DC.)

sediments can be quantified by Equation 2.42, from which it can be shown that even a thin layer of low-permeability sediments can make a very large difference in the infiltration rate.

2.6.3 Gaining and Losing Streams

Streams also gain and lose water in the same manner as lakes and ponds (Figure 2.30a and b). *Perennial streams*, that is, streams that flow year-round, are usually *gaining streams*. They gain water from base flow through the sides of the streams as it flows through from the groundwater system. This kind of stream is situated such that the water table is always above the stream surface.

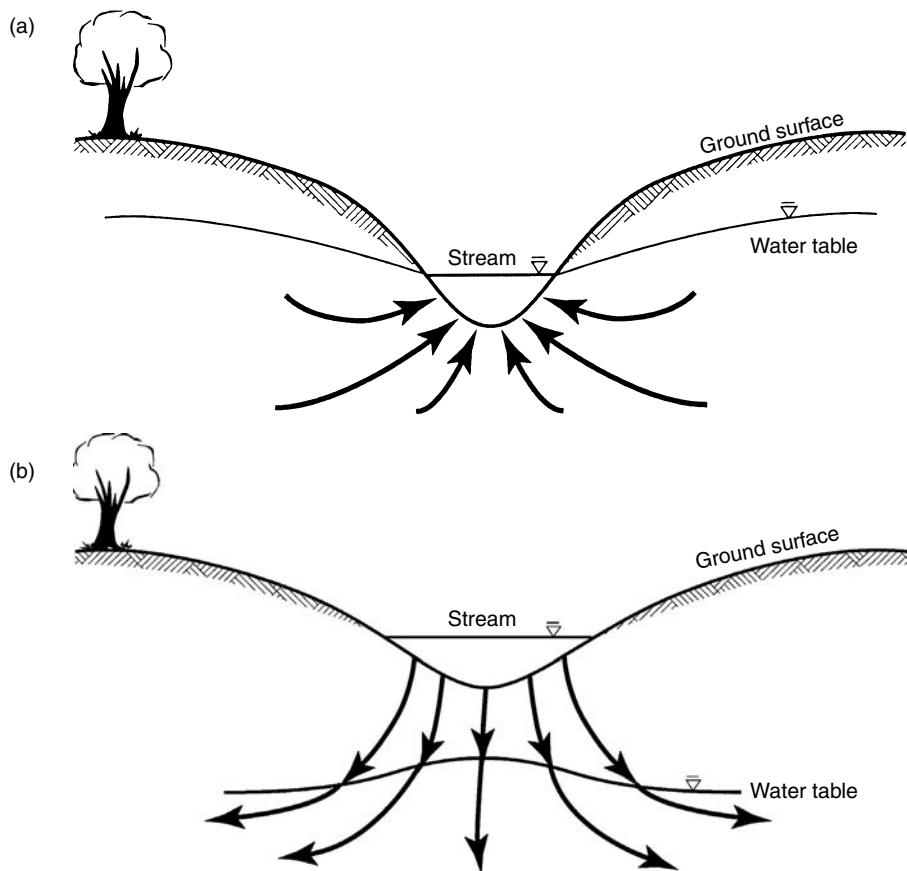

FIGURE 2.30 Gaining and losing streams. (a) Gaining stream; (b) losing stream.

Gaining streams in the cross section (Figure 2.30a) will usually show a stagnation point in the subsurface similar to that of lakes. However, in three dimensions, it is in reality a stagnation line that runs under the stream along its length.

Most streams are gaining streams; losing streams (Figure 2.30b) are generally those *intermittent streams* which flow only after significant precipitation and during runoff periods. They lose water to the subsurface because the water table is below the stream surface. Therefore, losing streams are generally found in mountainous areas on alluvial fans debouching onto pediments, on sand and gravel surfaces where the water table is low, or on steep slopes. In nearly all cases, the precipitation rate is insufficient and/or the subsurface is too permeable to maintain a water table high enough to support gaining streams.

Streams in certain geological settings may contain stretches which are gaining for some distance where the water table is above the stream surface, and then become losing stretches when they flow over a low-water-table area; or vice-versa. These streams are common in karst terraines where a stream may be losing in its upstream reaches, and may even disappear beneath the ground surface into a cave; downstream, it may later emerge to flow on the surface as a gaining stream. In glaciated areas of the Midwestern United States, streams may flow over till with high water tables as gaining streams, but after crossing a contact between till and outwash sand and gravel, the streams may become losing streams as their water infiltrates downward into the permeable outwash.

In areas where there are heavy demands for water for irrigation, industry, and large cities, damming of streams and pumping of aquifers has dramatically altered natural stream/groundwater interactions. Damming often raises the water table upstream of the dam, causing some losing streams to become

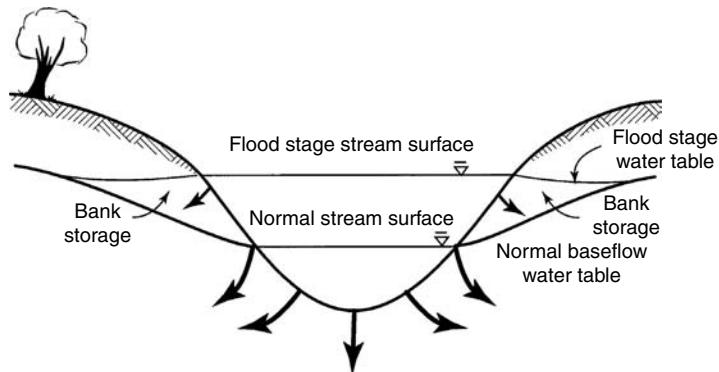

FIGURE 2.31 Bank storage.

gaining streams; and lowers the water table downstream, causing gaining streams to become losing. Heavy pumping has caused some small gaining streams to become losing because of drastic lowering of the water table. When a gaining stream does become losing, it can introduce surface contaminants into the groundwater system.

2.6.4 Bank Storage

Figure 2.30a shows a gaining stream during normal baseflow when the water table slopes toward the stream, and Figure 2.31 shows the same stream after a sudden rise in the surface elevation following an intense precipitation event. In the latter case, the water table near the stream has risen above the normal water-surface elevation and now slopes away from the stream to force water to move from the stream into the banks and beyond.

After the stream stage falls back to its normal position, the water table near the stream may not fall as fast and may remain unusually higher than the stream surface for several days or hours, depending on the permeability of the ground and the amount of water that was forced into the banks. This excess water in the stream banks is known as *bank storage*, and is common along rivers that flood.

In bottom lands along alluvial stretches, bank storage can slow natural drainage back into the stream, and thus, can cause farm fields along the stream to remain soggy for extended periods. If the stream is contaminated, the contaminants can be forced into the surrounding soil and they may not be flushed out for some time, depending on the soil permeability, the amount of precipitation, and the frequency of flooding.

2.7 Protection of Groundwater Supplies

With ever-increasing demands on our groundwater supplies, more and more thought is being given to their protection, but water demands of growing populations, especially in large cities, are often in conflict with established and traditional uses such as farming, ranching, and industrial uses. In the eastern United States where the precipitation may approach 180 cm/year, the problem is not as great as in the west where cities have been built in arid areas with precipitation of perhaps 15 cm/year. In these areas, not only has water from rivers in distant states been diverted (e.g., the Colorado River), but also, extensive pumpage of groundwater has been taking place that withdraws water faster than it can be replenished by inflow or natural recharge; this is known as *groundwater mining*.

The concept of *safe yield* was evidently suggested early in this century (Lee, 1915). The definition put forward by Todd (1959) is "... the basin draft on a groundwater supply which can be continued indefinitely without harming the supply or basin landowners." This definition is basically the same as that given by most hydrologists, but the concept of "harm" has changed over the years.

Early in this century, harm meant overdraft of the aquifer and adverse effects on the supplies of adjacent landowners who tapped the same aquifer. It came to include the breaking of water laws eventually. In the last twenty years, it has included adverse effects on ecosystems, especially if pumping would cause a lake or wetland to lose water and thereby endanger certain species, or if profitable and popular recreational sites and activities were adversely affected.

The added concerns complicate the “safe yield” definition beyond the rather simple concern of overdraft which can be calculated with the Equation of Hydrologic Equilibrium (Todd, 1959), which is given as

$$\begin{aligned}
 & [\text{Surface inflow} + \text{Subsurface inflow} + \text{Precipitation} + \text{Imported water} \\
 & \quad + \text{Decrease in surface storage} + \text{Decrease in groundwater storage}] \\
 = & [\text{Surface outflow} + \text{Subsurface outflow} + \text{Consumptive use} + \text{Exported water} \\
 & \quad + \text{Increase in surface storage} + \text{Increase in groundwater storage}]. \tag{2.59}
 \end{aligned}$$

Another complicating factor is that the added concerns above are subject to temporal and locational interpretations and values; what may be politically and socially acceptable definition today may change in ten years with changes in demographics and land use. An example is a recent problem in Park County, Colorado where a proposed *conjunctive use* plan by the city of Aurora, Colorado met stiff opposition from residents of the county.

Conjunctive use is defined simply as the use of both groundwater and surface water conjunctively. The city of Aurora, approximately 100 miles (150 km) east of Park County, bought water rights from several ranchers in the county some years ago when ranching started to become less profitable. The City is expanding and now has proposed to recharge aquifers with surface water during periods of higher runoff, and then to pump the water out later and use it conjunctively with surface water from the same area. It appears that the amount to be pumped would exceed the recharge and groundwater mining will occur. Although the greater population of Aurora was in favor of the plan, the much smaller population of Park County was opposed.

This situation is only one of many such conflicts that have occurred and are still occurring in the western United States. Similar plans have been put forward by Colorado Springs, Colorado and Las Vegas, Nevada. Again, the mining of vast quantities of water from remote areas would be necessary, even with conjunctive use to supply ever expanding cities with no practical limits to growth. Therefore, safe yield may be defined differently by developers and city planners than by landowners from whose area the water is to be taken.

2.7.1 Water Laws

The brief discussion of the subject in the following paragraphs can be supplemented by the information in Chapter 32, *Legal Framework for Groundwater Protection in the United States* by Veil, Elcock, Ranek, and Puder.

Numerous laws have been passed since the founding of the United States of America that regulate the actual use of water. These vary from state to state and from east to west. A good overview of these laws can be found in Domenico and Schwartz (1990), Fetter (1994), Todd (1959), and Walton (1991).

Within the past two decades, the U.S. Congress has passed several laws aimed at protecting water supplies, making them safer to drink and more available to everyone; they include the *National Environmental Policy Act of 1969* [P.L. 91–190], *Federal Water Pollution Control Act of 1972* [P.L. 92–500], *Clean Water Act Amendments of 1977* [P.L. 95–217], *Safe Drinking Water Act of 1974* [P.L. 93–523] and Amendments, *Resource Conservation and Recovery Act of 1976* [RCA — P.L. 94–580], *Comprehensive Environmental Response, Compensation and Liability Act of 1980* [CERCLA — P.L. 96–510], *Superfund Amendments and Reauthorization Act of 1986* [SARA], *Surface Mining Control and Reclamation Act* [SMCRA — P.L. 95–87], *Uranium Mill Tailings and Control Act of 1978* [UMTRCA — P.L. 95–604 and later amendments], *Toxic*

Substances Control Act [TOSCA — P.L. 94–469 and amendment], and Federal Insecticide, Fungicide and Rodenticide Act [FIFRA — P.L. 92–516 and later amendments].

To many individuals and industries, this number of recently-passed environmental laws seems onerous and restrictive. Yet, the lack of such laws earlier in the history of the United States resulted in severe contamination of both surface and groundwater from mining, industry, agriculture, and municipal and domestic sewage. For the most part, the laws are accomplishing a good deal of the protection and remediation for which they were written. For further details see the Chapter 32 on Legal Framework.

2.7.2 Natural Protective Barriers and Waste Disposal

Groundwater contamination is now a world-wide problem, especially in rapidly urbanizing areas, not only from trash and other wastes, but also from fertilization of lawns and gardens. For example, Cox et al. (1996) discuss the effects of urban growth on groundwater supplies of Australia; and Howard et al. (1996) discuss similar problems in Canada.

Much progress is being made today in the ability to map land for groundwater pollution vulnerability, and also to determine the areas that are protected by natural barriers, such as till and clay (Vrband and Zaporozec, 1994).

Today, there is a greater emphasis on utilization of natural protective barriers for groundwater protection than ever before. Impermeable or low-permeability natural barriers are normally clay (glacial till and lacustrine sediments), shale, salt deposits, and unfractured granitic rocks and basalt.

If waste, hazardous or otherwise, can be placed in proper containers and placed so that a natural barrier is between it and a groundwater supply, the chances are good that the water will be protected, providing proper engineering methods are followed. Unfortunately, such practices have not always been the case. In the past, abandoned gravel pits and rock quarries were often used as disposal places of convenience. Today, many of them leak and have seriously contaminated groundwater resources under and around them.

An example is the Tippecanoe County Landfill north of Lafayette, Indiana which was constructed approximately 35 years ago in a gravel pit in the glacial outwash sand and gravel bordering the Wabash River. A 3 m thick layer of clay on the bottom of the pit was removed to deepen the depression to allow more volume for refuse. Thus, the natural barrier was removed and leachate seeped into the aquifer below.

The landfill was used to dispose of not only domestic trash, but also industrial chemicals, including polychlorinated biphenyls (PCBs). The EPA and the Indiana Department of Environmental Management forced the landfill to close and cease operations and declared it a CERCLA (Superfund) site. Remediation was expected to cost the Principally Responsible Parties (PRPs) and perhaps the citizens of the county at least \$8-million, but it finally cost about \$18 million.

Another example in the same county, also on the outwash along the Wabash River, is the disposal of waste on the permeable surface. Sludge from municipal sewage processing combined with substrate sludge from mycin drug manufacturing has been disposed of for many years on the surface of the outwash. The outwash is perhaps 30 m thick and possesses a hydraulic conductivity of more than 200 m per day. The applied mixture is exceedingly rich in nitrate, phosphate, and potassium, which is welcomed by farmers as free fertilizer.

Since the soil is very permeable and retains little water, leachate from the sludge not only rapidly enters the soil, but also, center-pivot irrigation from wells in the outwash is necessary to maintain adequate soil moisture. As a result, the nitrate level in the groundwater below the site and downgradient from the site is high, exceeding by a factor of four or five the maximum permissible concentration (MPC) of 45 mg/l for drinking water set by the EPA. Not only is this water unhealthy to drink, but in addition, the property values of homes in the immediate area have dropped significantly, and perhaps as much as eight square kilometers of valuable and productive aquifer area is now seriously contaminated.

If the sludge were spread a few kilometers away on till 10 m thick with a hydraulic conductivity of 10^{-7} cm/sec, not only would it serve as inexpensive fertilizer, but the natural barrier properties of the till would prevent groundwater contamination.

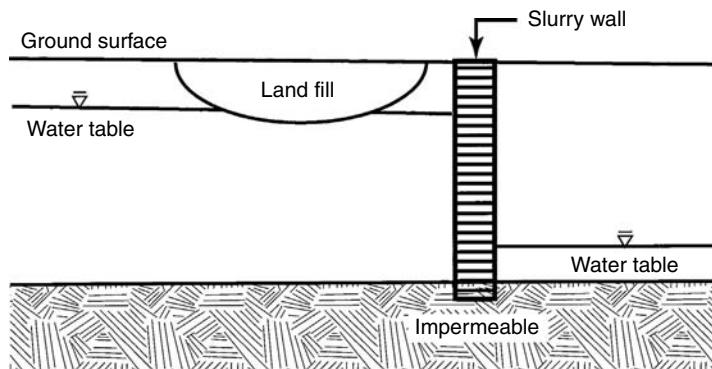

FIGURE 2.32 Slurry wall to prevent contaminant migration.

2.7.3 Artificial Protective Barriers

When natural barriers are not present, two kinds of artificial barriers can be constructed — solid and hydraulic. Extensive information about the use of such barriers can be found in EPA (1977, 1984).

Solid barriers may consist of grout curtains, slurry walls, or sheet piles constructed around a contaminated site such as a landfill to prevent the spread of contaminants to the surrounding groundwater. Figure 2.32 shows a slurry wall downgradient from a landfill which is blocking the movement of contaminants from moving downgradient at that location. This same figure can also demonstrate the utility of a sheet pile with interlocking pieces, or a grout curtain constructed at the same location.

A slurry wall is constructed by digging a trench down to an impermeable stratum and then filling it with a mixture of water, clay, and *bentonite*. The latter material is a clay mineral formed from the chemical alteration of volcanic ash and is often used as a sealant because when wet, it will expand eight to ten times its dry volume and is quite impermeable. If the depth to an impermeable stratum is too deep for construction of a slurry wall, a grout curtain can be constructed by drilling several wells close together in a line and then injecting a variety of sealing compounds into them which will infiltrate the soil pores to form an impermeable wall around the source of contamination.

A hydraulic barrier can be implemented by injecting water from a line of wells as illustrated in Figure 2.33. This kind of barrier is utilized to prevent the encroachment of saline water into fresh water aquifers along a seacoast and has been used successfully in Los Angeles, California and in Long Island, New York. It is also employed to prevent the downgradient migration of contaminants from landfills.

2.7.4 Well-Head Protection Programs

Several state environmental agencies have implemented Well-Head Protection Programs under directives from the U.S. EPA. These programs are designed to protect the recharge areas of municipal and public wells from surface contamination by limiting the kinds of activities that can take place within a certain distance from a well or well field within the *well-head protection zone*. Generally, this zone is the same as the *capture zone* for a well or well field in an unconfined aquifer. The distance is computed as the distance of travel of water to the well within a given time limit. For example, the Indiana Well-Head Protection Program, currently under revision, requires that the minimum distance limit be set for a travel time of five years, but strongly encourages a ten-year limit.

The argument for setting travel-time limits is two-fold. In the first place, an arbitrary distance limit would not make much sense without taking into account the geology, conductivity, and gradients specific to each site. Second, it is assumed that a five- or ten-year travel time will more likely guarantee that under most situations, any contaminants will have traveled far enough through the aquifer and enough water from outside the contaminated zone will have been pumped that sorption and dilution, respectively, will have rendered them innocuous.

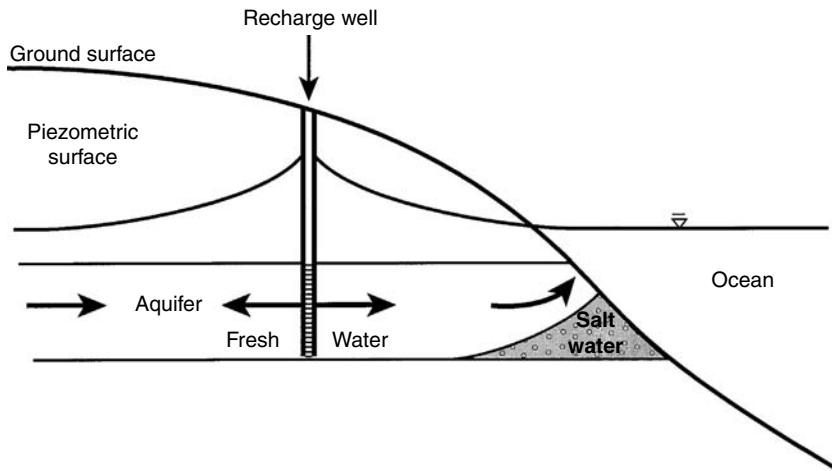

FIGURE 2.33 A hydraulic barrier.

The consequence of this law will be restriction from the recharge areas, or at least the strong regulation, of many activities that generate waste or require chemical applications. These will include livestock feedlots, fertilization of farm fields and golf courses, spreading of sludge or nitrate-rich water from sewage processing, landfills, oil refineries, chemical plants, and others.

A simple capture zone is illustrated in Figure 2.34 and is computed analytically as (Todd, 1959),

$$x = -y / \tan[2\pi Kbiy/Q] \quad (2.60)$$

where x and y are coordinate directions, Q is the pumping rate, K is the hydraulic conductivity, b is the initial saturated thickness of the unconfined aquifer, i is the hydraulic gradient, and the argument of the tangent is in radians. The units have been chosen so that the argument is dimensionless.

Bakker and Strack (1996) present a sophisticated analytical-element modeling approach to determining the capture zone under conditions of irregular and more complicated geology and boundary conditions.

Well-head protection plans have been in effect in The Netherlands for several years. The implementation of such rules in the United States has met with considerable opposition from some municipalities and well owners who realize that it will necessitate an extra expense. In order to adequately define the capture zone, there may be a need in some cases to perform test drilling and surface geophysical studies to determine the geology of the area. In addition, modeling studies may be necessary to completely understand the hydraulics of the aquifer. Small public water operations may find these studies to be financially burdensome. However, well-head protection plans, when implemented, are expected to provide a high level of protection for public water supplies as the population grows and more demands are put on groundwater resources.

For further details see the chapters on Site Remediation and Geosynthetics.

2.8 Groundwater and Modern Environmental Concerns

2.8.1 Possible Effects of Climate Change on Groundwater Flow

It is known that the world's climate has changed significantly over geologic time. Evidence from fossil plants, pollen, rodent middens, tree rings, and even clay-mineral formation has shown that precipitation and temperature have varied widely (Rasmussen et al., 1993). For example, near the end of the Pleistocene Epoch (the "Ice Age"), the climate was much wetter in the American southwest than now, and the water table in southern Nevada was 100 m higher than present (Winograd and Doty, 1980). It is not entirely clear

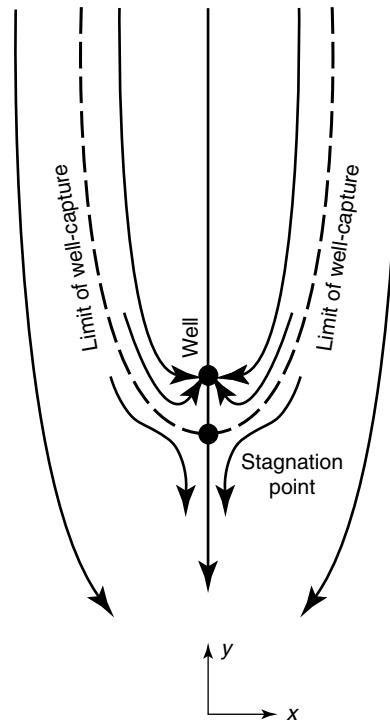

FIGURE 2.34 A capture zone around a pumping well.

what caused climate change in the past, although volcanic eruptions and tilting of the earth's rotational axis have been suggested.

Many climatologists believe that anthropogenic factors are now effecting a slow, but perceptible change in the atmosphere that is causing gradually warming temperatures. These factors include changes in land use with overgrazing and burning of forests, and the introduction into the atmosphere of abnormal amounts of certain gasses.

These gases, commonly known as *greenhouse gases*, include carbon dioxide (CO_2), and methane (CH_4) as the prime suspects in maintaining the *greenhouse effect*. This effect is the atmospheric entrapment of heat from the sun which, in turn, is expected to cause greater evapotranspiration in some areas and greater precipitation in others. As a result, the climate is expected to change significantly within the next century causing a reduction of precipitation in the Midwest and a great increase of precipitation in the southwestern United States.

Although much research has been accomplished in estimating the potential effects of climate change on surface water supplies, little attention has been directed toward the possible effects on groundwater except to estimate the increase or decrease in recharge rates and amounts that can be expected. Recent work by Leap and Belmonte (1992), Leap (1993), Reichard (1995), and Reichard and Leap (1995) illustrate the role of increased pore pressure in the opening of fractures in rocks with consequent increase in hydraulic conductivity.

It has been known for some time that a slight increase in fracture width (aperture) can cause the flow rate through a fracture to increase by a power of three; this is known as the "*Cubic Law*" (Witherspoon et al., 1980), and is given as

$$Q = (\rho g b^2 / 12\mu)(bw)(\partial h / \partial l) \quad (2.61)$$

where Q is the volumetric flow rate, ρ is the density of water, g is acceleration of gravity, b is aperture width, μ is dynamic viscosity of water, w is fracture width perpendicular to flow direction, h is the hydraulic head, and l is the length of the flow path through the fracture. The fracture is assumed to possess smooth sides and laminar flow exists. A consistent set of units must be used.

Most rocks of aquifer quality may contain tens, hundreds, or even thousands of fractures per cubic meter, and in order to quantify flow through such rocks for practical purposes, it is more convenient to assume that the fracture density is great enough that the flow system can be treated as a porous medium. Jones (1975) performed a series of experiments measuring flow through cores of fractured carbonate rocks under different pressures in order to discover the relationship between intrinsic permeability and effective stress. The rock contained enough fractures that an equivalent porous medium could be assumed and the relationship sought was determined to be

$$k/k_i = \{[\log S_e - 4.602]/[\log S_{ei} - 4.602]\}^3 \quad (2.62)$$

where k is intrinsic permeability at any pressure, k_i is initial intrinsic permeability, S_e is effective stress at any pressure, and S_{ei} is initial effective stress.

Leap (1993) postulated that these relationships between permeability, pore pressure, and effective stress could be significant in understanding and predicting changes in permeability if the water table rose during a period of increased recharge consequent to increased precipitation.

Reichard (1995) and Reichard and Leap (1995) used this equation as a basis for a modeling study to determine what the effect of a significant recharge-induced water-table rise would be on the hydraulic conductivity of an aquifer after a climate change which would cause significantly-increased recharge. Their research showed that under such conditions, the hydraulic conductivity of fractured aquifers could increase as much as 15 to 20%. More research is needed in this area, but the results thus far are significant because it suggests that not only will flow rates be expected to increase, but transport rates of contaminants could also increase as well.

Finally, changes in precipitation consequent to climate change can be expected to produce significant changes in the chemical quality of groundwater. At present, the total dissolved solids (TDS) content of groundwater generally increases from east to west across the United States as the result of two primary factors – precipitation and evapotranspiration.

In areas where precipitation amounts are large, infiltration from the surface to the subsurface is generally higher in permeable soils. The greater precipitation causes the formation of higher vertical hydraulic gradients and higher vertical groundwater flow rates than in areas of lower precipitation. As a result, increased amounts of fresher water are recharged to the groundwater system and the groundwater does not remain in place for as long as it does in areas with lower precipitation and lower infiltration rates.

If future climatic changes produce increased precipitation in certain areas, then it can be expected that groundwater quality should improve. In areas where precipitation will decrease, the TDS in groundwater should increase with a consequent decrease in quality.

2.8.2 Groundwater and Wetlands

“Wetlands consist of areas that are inundated or saturated by surface or ground water at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions” (USCIR, 1987).

Wetlands are important for intercepting and filtering surface water and groundwater as it discharges to the surface. Intense microbial activity and the uptake of nutrients by wetland plants significantly cleans the water of contaminants. For example, in the Atlantic Coastal Plain of South Carolina, the Congaree Bottomland Hardwood Swamp along the Congaree River, now the Congaree National Park, is a very old wetland of 22,200 acres (AAA, 2004). It was determined in 1990 that this wetland’s natural filtering and nutrient absorbing capabilities made it unnecessary to build a \$5-million waste-water treatment plant

for a nearby community (USEPA, 2005). Today, wetlands are being created artificially for treating waste water. Hammer (1989) thoroughly discusses this subject.

Wetlands are being reclaimed today, as in the Kankakee River Valley of northwestern Indiana. The main purpose of this project is for flood control by slowing runoff to main streams. Additionally, such reclamation greatly enhances aquatic species and water fowl.

In turn, water recharged through wetlands to groundwater systems generally tends to be cleaner and less contaminated than that recharged from non-wetland areas.

2.8.3 Groundwater and Land Subsidence

With increasing population and consequently, increasing numbers of domestic wells, irrigation wells and public water-supply wells, land subsidence is a serious problem. This phenomenon is primarily due to (1) lowering of the unconfined water table with resulting lowering of pore pressure and consequent soil compaction, and (2) lowering of the confined piezometric head which in turn reduces the upward pressure and buoyant force on overlying rocks and soil causing subsidence.

A thorough discussion of subsidence is given by J. Delleur in this handbook in Chapter 3, "Elementary Groundwater Flow and Transport Processes". In addition, Holzer et al. (1984) discuss many aspects of land subsidence with several examples.

Narasimhan and Goyal (1984) discuss land subsidence due to geothermal fluid withdrawal.

2.8.4 Groundwater and Soil Liquefaction

Liquefaction is the process by which normally solid and stable porous media becomes so saturated with water that it flows like a thick liquid or slurry like wet cement. The soil and water mixture is then called a thixotropic system.

Rearranging Equation 2.11 gives

$$\sigma_e = \sigma_t - P_p \quad (2.63)$$

which shows that if pore pressure (P_p) is equal to the total vertical stress (σ_t) then the effective stress (σ_e), that is, the stress exerted by the grains of the aquifer skeleton becomes zero and the soil then loses its strength. This condition is often created when there is excessive precipitation and infiltration that saturates the soil so much that pore pressure is equal to or exceeds total vertical stress and a mass of soil liquifies and flows like a slurry.

Liquefaction can also occur when the pore pressure is very high, but not equal to the vertical stress. The soil is then in a metastable condition and an earthquake can disturb the soil so much that the grains begin to move and slide over each other and the mass then flows.

Although such failures are often natural geological processes, their impact on society have historically been enormous. Homes and other buildings that have been built on filled land around bays and fiords have often been carried away and destroyed by such flows with significant loss of life and property.

Such disasters have been recorded around San Francisco Bay where there are large areas of fill deposited from dredging operations. Naturally-deposited silt and fine sand where rivers join fiords in Norway have also been the sites of such disasters. The Good Friday earthquake in the vicinity of Anchorage, Alaska in 1964 produced liquefaction of soil that destroyed many homes and caused significant loss of life due to liquefaction and flowage of soils around the edge of the bay. Coates (1990) discusses an approximate mobility index (AMI) that is given as

$$AMI = \theta_w / L_L \quad (2.64)$$

where θ_w is the saturated water content of in-place or undisturbed soil and L_L is its Atterberg liquid limit. At an AMI value of 0.85 debris flows may occur and liquification takes place at higher values.

2.8.5 Excess Evaporation of Groundwater and Consequent Salt Buildup

Although evaporation is commonly thought to be a surface phenomenon where heat and wind cause evaporation from surface water bodies such as lakes, water below the surface can also evaporate after it has been moved to the surface by capillary attraction. If the water table or the top of the tension-saturated capillary fringe are close enough to the ground surface, capillarity can attract the water to the surface and as it is evaporated, water continues to rise until the top of the capillary fringe or the water table drops to a low enough elevation that capillary attraction to the surface ceases. This will eventually happen unless precipitation and infiltration again raises the capillary fringe or the water table.

When ground water evaporates in this way, it usually leaves behind solid salts on and slightly beneath the ground surface. A classic example of this is found in the San Joaquin Valley of California where irrigation has been heavily used for many years to water many vegetable crops and orchards. Here, many acres of formerly arable land are covered with salt that causes these acres to be unsuitable for farming.

2.8.6 Artesian Pressure and Surface Effects

Artesian pressure in confined aquifers is in the vast majority of cases, natural. Water recharged at higher elevations flows to lower elevations beneath a confining layer of impermeable or semi-permeable rock or soil. This natural process can present problems for an expanding population that requires a greater number of new homes, wells, office buildings factories, schools, bridges, etc.

When excavating impermeable soils, engineers have to know beforehand the pore pressure beneath the material and this is generally accomplished by installing piezometers. If the pore pressure is too high, then the area must be dewatered before excavation can proceed. Otherwise, dangerous "blowouts" can occur because as excavation decreases the vertical confining stress, the pore pressure may cause the floor of the excavation fail and blow out. This has occurred in the past with loss of life and equipment.

Natural artesian pressure can force water of inferior quality from depth to the surface or to the areas of influence of pumping wells within which wells can pump it out. Such a scenario is not uncommon in the Appalachian Plateau or in the deeper river valleys of the Midwest where fractures in Paleozoic rocks can extend downward for several hundreds of feet. Saline water will often migrate upward to where they can be pumped out by municipal or irrigation wells.

On the other hand, high-quality artesian water is in demand as bottled drinking water. Artesian pressure in an aquifer also helps greatly to prevent or retard contamination from entering an aquifer from the surface, especially if the confining layer is leaky.

2.8.7 Groundwater Overdraft and Its Consequences

Overdraft simply means that (1) water is pumped out of aquifers faster than they are replenished (ground-water mining) or (2) pumped out at a rate that results in deterioration of the aquifer or causes undesirable effects on land (e.g., subsidence or dewatering of streams, lakes, and wetlands). Increasing population with consequent increasing groundwater withdrawals can result in overdraft and undesirable consequences.

The reader is encouraged to also read Chapter 27 entitled "Determining Groundwater Sustainability" by J. Bredehoeft for an in-depth discussion of the subject of overdraft.

2.8.8 Effects of Mining

Surface mining (strip mining) and deep mining (tunnel mining) both cause drastic changes to both surface water and groundwater. Surface mining can change the recharge process and produce vast chemical changes such as the production of acid-mine drainage that can run off to streams and infiltrate to groundwater systems.

Deep surface pit mining can create groundwater discharge areas that cause lowering of water tables around the pits. Deep tunnel mining also causes lowering of water tables above the tunnels because they constantly drain water or have to be pumped out to rid them of water. With the released water there is

also released to the environment acid from both coal and metals mining because of the conversion of iron sulfides to iron oxides and sulfuric acid. Metals mining also releases metal salts and some of them are toxic—especially heavy metals such as lead.

In the Appalachian Plateau of West Virginia, coal-mine tunnels are often dug into the sides of hills or deep valley walls and often these are below the water tables. As water from the mines flows or is pumped into the valleys and streams below, the water tables above the tunnels are drastically lowered and in some cases, wells go dry.

Keller (2002) presents a very good discussion of mining and its environmental and health consequences.

2.8.9 Effects of Artificial Drainage

Artificial drainage of soils for agriculture and/or buildings generally results in the lowering of water tables with often undesirable results. A good example is the drainage of natural wetlands. Construction of drainage ditches generally destroys their natural functions of wildlife production and flooding reduction. In certain types of soils, the lowering of water tables with consequent drying of the surface and the destruction of natural vegetation leaves the soil vulnerable to wind erosion.

Artificial drainage of sandy soils for farming can create additional problems. After the water table is lowered and the sandy soil is drained, maintaining adequate soil moisture for agriculture is difficult because of the low specific retention of the sand. In order to grow adequate crops, the soil must be irrigated heavily and this can result in drainage problems and contamination by fertilizers and pesticides applied to the crops directly or added to the irrigation water (e.g., “fertigation”). In addition, pumping enough water to properly irrigate can result in the lowering of water tables of productive aquifers.

2.8.10 Chemical Changes due to Groundwater and Surface-Water Interactions

In Section 2.6.2, surface discharge of groundwater to streams and lakes is discussed. There are also certain chemical reactions and processes that take place at the interface of groundwater and surface water. Winter et al. (1998) list the following: (1) acid-base reactions, (2) precipitation and dissolution of minerals, (3) sorption and ion exchange, (4) oxidation-reduction reactions, (5) biodegradation, and (6) dissolution and exsolution of gases.

As precipitation falls it dissolves from the atmosphere oxygen (O_2) and carbon dioxide (CO_2). The latter combines with water to form carbonic acid (H_2CO_3). As surface water is recharged into a groundwater system, it carries these two chemical species with it. Oxygen is used up to oxidize minerals such as iron and manganese and organic material in the near-surface soil. Consequently there is little if any dissolved oxygen in ground water. Carbon dioxide is increased in ground water. The carbon dioxide in turn, dissolves a variety of minerals (especially carbonates).

When ground water discharges to a stream valley there will often be precipitated at the unsaturated seepage face above the surface water level a variety of salts that attract wildlife. These areas are known as “salt licks.” Exsolution of carbon dioxide results in the deposition of calcium carbonate and other minerals. Iron and manganese are often precipitated in such situations as well. When ferrous iron is carried by groundwater to swamps iron hydroxides often form that are called bog iron ore. This material is used in certain undeveloped countries and societies as a source of iron for smelting and making tools. The reader is encouraged to examine Winter et al. (1998) for a more complete discussion.

2.8.11 Anthropogenic Changes in Recharge Areas

Increasing urbanization is causing significant changes to recharge areas. In large housing developments or cities, large area of pavement such as streets, sidewalks, playgrounds, and parking lots are increasing surface runoff that before development would be added to groundwater recharge. This runoff in turn contributes to increased flooding frequency and intensity. It is believed that severe flooding along the southern part of the Mississippi River has been exacerbated by increased runoff from pavement and roofs of growing urban centers over its entire drainage basin.

The use of pesticides, fertilizers, and sewage sludge causes problems of contamination of groundwater recharge areas. This is especially true in areas of sandy and therefore permeable soils as in Nebraska and northwestern Indiana. In areas where low-permeability materials such as clay-rich glacial till overlie aquifers, this problem is usually minimal or non-existent. Potentially contaminating activities are generally forbidden in well-head protection areas.

2.8.12 Groundwater Influence on Construction

Groundwater can present major challenges to construction. All too often, these potential effects are overlooked or ignored in the haste to construct homes and other buildings. Engineering soil tests are often not performed or performed in a cursory manner at best.

Soil tests for construction are generally concerned mostly with (1) water content and liquid and plastic limits (Atterberg tests), and (2) unconfined compressive strength which also is affected by the water content of soil.

The liquid limit of a soil is the water content at which the soil–water mixture will flow like a slurry such as wet cement. A soil with a water content lower than this will not flow, but will deform plastically.

The plastic limit is the water content of a soil above which a soil will deform plastically but not flow like a liquid. At still lower water contents, the soil will not even behave plastically, but will remain solid.

The unconfined compressive strength of a soil is the strength determined by compressive testing procedures and indicates the amount of soil deformation that can be expected for a given load of a building resting on footings.

Another very important consideration is selection of the correct kind of earth materials at first. Many disasters have occurred when houses were built on unstable soil close to a steep hill that resulted in landslides when the water content became too high. Swampy soils are not acceptable due to poor engineering properties and lack of sufficient support for buildings.

Descriptions of the engineering quality of specific soils are found in county soils reports published by the U.S. Soil Conservation Service.

2.8.13 Effects of Irrigation

In addition to an abundance of fertile soil, two other attributes help to make the United States and Canada major producers of grains, fruits, and vegetable crops. They are plentiful groundwater and modern irrigation equipment and methods. However, irrigation with groundwater is causing some undesirable side effects. Most notable among these are (1) groundwater overdraft and (2) contamination of groundwater and surface water.

Overdraft from pumping of irrigation water is very significant in Nebraska and in the High Plains Aquifer that stretches from Texas to South Dakota and includes nearly all of Nebraska, the western half of Kansas, parts of eastern Colorado, the panhandle of Oklahoma, the panhandle of Texas and parts of western Texas, and the extreme eastern part of New Mexico. The greatest area of this aquifer is composed of the Tertiary Ogallala Formation and the aquifer is therefore often referred to as the Ogallala Aquifer. Drawdowns in this aquifer as of 1980 exceeded 100 ft in parts of northwestern Texas and southwestern Kansas. In large parts of this aquifer in Nebraska, Colorado, Kansas, Oklahoma, Texas, and New Mexico, the drawdown has been as much as 50 ft (Gutentag et al., 1984).

Large drawdowns such as these not only deplete groundwater supplies, but also increase the vertical lift distance for pumps resulting in greater costs for pumping. In addition, Nebraska is the second of all the states in the number of acres irrigated and heavy irrigation with well water along the Platte River in Nebraska has reduced the depth of water in the stream (Winter et al., 1998).

Irrigation can cause contamination from over-pumping that causes deep water of inferior chemical quality to migrate into the area of influence of a pumping well. Contamination also results from “fertilization” where fertilizer is added to irrigation water. Additionally, pesticides added can cause contamination.

The additional hydraulic head at the surface from irrigation water causes contaminated water to migrate downward faster than clean water under natural conditions.

Contamination of soil and groundwater by salts can result from irrigation using groundwater. Overhead sprinkling and spraying can leave behind salts due to evaporation of some of the applied water. These salts can be introduced into groundwater systems by continued application of irrigation water.

Often, in order to prevent excess buildup of unwanted chemicals in the soil zone and in shallow aquifers, irrigation with clean water in excess of that required to support plant growth is employed to flush out the chemicals. This causes additional pumping and often depletion of groundwater (Winter et al., 1998).

Glossary

Adhesion: The attraction of water to solid grains by electrostatic forces.

Aeolian Deposits: Materials deposited from the air and moved about by wind (e.g., dune sand).

Alluvium: Any lithology or grains size of sediment deposited by flowing streams.

Anisotropy: The condition of a porous medium where the permeability is different in different directions.

Aquiclude: An impermeable geological formation or body that will prevent the flow of water through it.

Aquifer: A permeable geological formation or body that will yield water in economical amounts.

Aquitard: A semi-permeable geological formation or body that will retard the flow of water through it.

Artesian Aquifer: A confined aquifer in which the piezometric surface rises above the top of the aquifer.

Bank Storage: Water stored in a stream bank when the stream water level is higher than the adjacent water table, as during a period of high water.

Baseflow: The flow of water from the groundwater system to a surface stream or lake that maintains water in the surface body, even between precipitation events.

Blowout: A failure of overlying soil or rock due to high water pressure below that causes cratering of the soil by rapid expulsion of soil or rock from a site.

Cable-Tool or Churn Drilling: Drilling with a bit like a large chisel on the end of a cable. It is rapidly raised and lowered to chip a hole in the ground or in rock.

Carbonic Acid: H_2CO_3 that is formed when carbon dioxide (CO_2) is dissolved in water.

Capillary Fringe: A zone above the water table where the soil is saturated but under tension (pressure less than atmospheric), as opposed to the zone below the water table where water is under pressure.

Capillary Water or Pellecular Water: The water actually held in the soil or rock pores after drainage.

Capture Zone: The area around a well or well field from which water will move to the discharge point(s).

Characteristic Curves: Curves showing hydraulic conductivity and soil moisture content as functions of the soil pressure head; a set of such curves is "characteristic" of a particular soil.

Confined Aquifer: An aquifer overlain by an impermeable layer such that the piezometric head rises above the top of the aquifer.

Darcy's Law: The relationship discovered by Henri Darcy between flow rate, hydraulic conductivity, and gradient in a porous medium.

Dynamic Viscosity: The measure of the resistance of a fluid to shear.

Effective Porosity: The porosity of a rock or soil that is actually connected to provide flow through the rock or soil.

Fertigation: Irrigation with water that has soluble fertilizer added to it.

Fluid Potential: The potential energy per unit mass of water.

Gaining Stream: A stream in which the water surface is lower than the adjacent water table, thus causing water to flow from the groundwater system into the stream.

Glacial Drift: The general term for any and all earth materials deposited from the action of glacial ice or their meltwaters.

Glacial Outwash: Material deposited from meltwater from glaciers.

Glacial Spillway: Generally a river valley which served as a major outlet for sediment-laden water from melting glaciers (e.g., the Mississippi, Missouri, Big Sioux, and Wabash River valleys).

Glacial Till: A mixture of clay, silt, sand, gravel, and boulders deposited in a heterogeneous mass directly from glacial ice through melting or plastering.

Gravitational Water: In draining soil, it is the water that acutally drains out.

Greenhouse Gases: Gases that are believed to trap the escape of heat from the earth and therefore cause warming of the world's climate. The most important of these is carbon dioxide (CO_2), but methane (CH_4) is also of concern.

Groundwater: Water at or below the water table in earth materials.

Groundwater Mining: Removal of groundwater at a rate exceeding recharge.

Heterogeneous: The condition of a porous medium where the isotropic or anisotropic permeability is different in different parts of the medium.

Homogeneous: The condition of a porous medium where the isotropic or anisotropic permeability is the same in all parts of the medium.

Hydraulic Conductivity: The ease with which a fluid will flow through a porous medium. It is a function of the pore size and fluid properties of viscosity and density.

Hydraulic Head: An expression of potential energy of a fluid at a point expressed as a length. It includes the height of the point above a datum plane (normally mean sea level) plus the pressure of the column of water above the point expressed as the pressure-equivalent height of that water column.

Hydraulic-Rotary Drilling Method: A drilling method in which a bit on a long shaft, the drill stem, is rotated to drill a hole in the ground. Water, often mixed with clay or other substances, is pumped down the inside of the stem and forced out at the bit to lubricate the bit and to flush cuttings to the surface.

Hydrograph: A graph of flow rate of a stream vs. time. It also refers to a graph of the water level in a well vs. time.

Hygroscopic Coefficient: The maximum water content that can be held hygroscopically.

Hygroscopic Water: That water held in a thin film around grains. It is not available to plants.

Igneous Rock: A rock type that has solidified from the molten state (e.g., basalt, granite).

Induration: The process by which mineral grains become fused or cemented together to form a solid rock mass; as opposed to unconsolidated materials.

Infiltration Capacity: The maximum rate at which a soil will allow water to infiltrate it from the surface. It is dependent upon the initial moisture content of the soil, the vertical hydraulic gradient, and the rate of precipitation.

Interflow or Subsurface Stormflow: The flow of water between the surface permeable zone and a zone of low permeability below it.

Isotropic: The condition of a porous medium where the permeability is the same in all directions.

Juvenile Water: Water created by chemical reactions in volcanic and other geothermal activities.

Karst: A term describing an area of carbonate rocks which contains solution tunnels and caves. This is named after the "Karst" region of Yugoslavia.

Lacustrine Sediments: Generally fine-grained silts and clays deposited from still waters in lakes or ponds.

Liquid Limit: The water content of a soil at which the soil liquifies.

Liquefaction: The process by which a soil becomes so saturated with water that it can flow like a slurry.

Loess: "Rock flour," or fine silt deposited originally in wide outwash deposits, but later deposited downwind by the prevailing winds.

Losing Stream: A stream in which the water surface is above the water table, thus causing water to flow from the stream to the groundwater system below.

Metamorphic Rock: A rock type that was formed from either sedimentary rocks (e.g., limestone) or igneous rocks (e.g., granite) when they were subjected to heat and pressure to produce a totally different rock from the parent, but with similar chemical composition (e.g., marble or gneiss, respectively).

Mineral: A naturally occurring, non-organic substance, generally of crystalline form, that has a definite chemical composition or a narrow range of compositions.

Permeability: The property of a porous medium to transmit water. It is a function of pore diameter.

Phreatic Water (or soil water) That water above the capillary fringe that is under tension.

Plastic Limit: The water content of a soil at which the soil no longer behaves as a solid, but as a deformable plastic.

Pleistocene Epoch: A geological span of time beginning approximately 2,000,000 years ago during which four major glacial advances (Nebraskan, Kansan, Illinoian, and Wisconsinian) advanced over North America. The latest, the Wisconsinian, is contemporaneous with the Wurm advance of Europe.

Pore Velocity or Average Linear Velocity: The actual average velocity of flow through a porous medium. It is calculated as the specific discharge divided by the effective porosity.

Porosity: The percent ratio of void volume to total volume of a rock or soil.

Precipitates: Minerals such as calcite (CaCO_3) that are deposited in water from direct precipitation from the water.

Primary Porosity: The porosity characteristic of a rock or soil when first formed.

Pyroclastic: A rock type formed by the settling of sediment which in turn is the ash and cinders of igneous material from volcanic eruptions.

Reynold's Number: The ratio of accelerative forces to viscous forces which determines if a flow is laminar or turbulent.

Rock: A naturally-occurring stony entity made up of one or more minerals.

Safe Yield: The rate of withdrawal of groundwater from an aquifer such that no harm will be caused. The term, "harm" is relative to the economics of the area and time.

Saturation Ratio: The ratio of contained water in pores to the volume of the pores.

Secondary Porosity: The porosity that is added to a rock or soil after formation; it can include faults, fissures, fractures, etc.

Sedimentary Rock: A rock formed from the weathered products (detritus) of igneous, metamorphic or other sedimentary rocks (e.g., sandstone, siltstone, shale).

Seepage Face: The zone of wet soil just above the surface of a stream or lake which marks the atmospheric discharge of water from the capillary fringe.

Semi-Confining Aquifer: An aquifer overlain by a semi-permeable aquitard which will allow limited flow of water to pass through.

Specific Discharge: The volumetric flow rate per unit area of porous media perpendicular to the flow direction. It is sometimes called "Darcian Velocity."

Specific Retention: The ratio of the volume of water held by the soil to the total matrix volume.

Specific Storage: The volume of water that will be obtained from a unit volume of aquifer upon release of a unit value of head.

Specific Yield: The ratio of the volume of water drained from a soil to the total matrix volume.

Spring: A natural discharge point for groundwater to the surface.

Storage Coefficient: The specific storage time the saturated thickness of the aquifer.

Total Dissolved Solids (TDS): The mass of all dissolved solid material in a water sample divided by the volume of the sample.

Unconfined Aquifer: An aquifer that has no overlying confining impermeable layer.

Void Ratio: The volume of pores divided by the volume of solids in a sample of soil or rock.

Well-Head Protection Areas: Surface areas surrounding wells where groundwater recharge takes place or below which groundwater travels from recharge areas to the wells.

Wetlands: Areas that are continuously or temporarily saturated and support aquatic ecology.

Wilting Point: The moisture content of a soil at which capillary forces become greater than osmotic suction of plant roots, causing the plants to wilt.

Further Information

There are many journals and books about hydrology in general, including geology and engineering sources. However, the list below pertains mostly to hydrogeology.

Several very good college-level texts on the broad subject of hydrogeology exist, such as those listed in the *References* by Fetter, Freeze and Cherry, Todd, and Domenico and Schwartz. These books cover a wide variety of subjects and do not specialize in any one subdiscipline exclusively.

Water Supply Papers and Professional Papers by the U.S. Geological Survey are continuously produced on more specialized subjects in hydrogeology and are available from the USGS National Center in Reston, Virginia.

Similar publications are produced by the Canadian Geological Survey in Ottawa, and the Surveys of each of the Provinces.

Geotimes, published monthly by the American Geological Institute covers a wide range of geological and geo-environmental topics and news items.

Soil survey reports are excellent sources of information about agricultural and engineering properties of specific soils. They have been published for the majorities of counties in the United States and are generally available in university libraries and from state offices of the U.S. Department of Agriculture's Soil Conservation Service.

Various publications of the American Society of Civil Engineers and the American Society for Testing and Materials are also excellent sources.

Other excellent journals include:

Water Resources Research, American Geophysical Union, Washington, DC.

Groundwater, National Association of Groundwater Scientists and Engineers, Dublin, Ohio.

Hydrogeology Journal, co-sponsored by the Geological Society of America in Boulder, Colorado and the International Association of Hydrogeologists in Hanover, Germany.

Hydrological Science and Technology, American Institute of Hydrology, Minneapolis, Minnesota.

Bulletin of the Geological Society of America and *Geology*, both sponsored by the GSA, often contain papers on hydrogeology.

Special publications by the Geological Society of America and the American Geophysical Union are produced from time to time, specifically on hydrogeological subjects.

State geological surveys also produce results of studies of hydrogeology in each state.

3.1 Introduction

In Chapter 2, porosity n was defined as the volume V_p of the pores of a rock or soil sample divided by the total volume V_t of both pores and solid material so that $n = V_p/V_t$. But porosity at a geometric point cannot be defined since a porous medium is a conglomerate of solid grains and voids. It is then necessary to introduce the concept of representative elementary volume (REV). The REV is sufficiently large to define a *space-averaged* porosity, but it is small enough that the variation from one REV to the next may be approximated by a continuous function on the scale of the measuring instruments. Thus one could take, for example, an REV of 1 cm³ for a fine sand, but it could be quite larger for a fractured rock. An alternate approach is to consider the porous medium as a realization of a random process. The porosity at a geometrical point is then an *ensemble average* of an infinite number of realizations (de Marsily, 1986; Charbeneau, 2000). Either of these constructs allows us to use the infinitesimal calculus and thus to apply the concepts of fluid mechanics.

Essentially all natural groundwater flows are three dimensional (3D). That is, the average velocity of a percolating water particle is represented by a vector that has three components. A simple example is the 3D radial flow toward a well (see Chapter 10 and Chapter 11). However, there are many situations in which the velocities are nearly coplanar or there is radial symmetry. In these cases the flow can be analyzed as two dimensional (2D) with sufficient accuracy for many engineering problems. An example is the infiltration of water into a series of long, parallel horizontal tile drains. Away from the pipe extremities, the shape of the water table is independent of the location along the pipe drain. In some cases the flow problem can be further reduced to one dimension. For example, the flow in karst conduit can be regarded as approximately one dimensional (1D). The existence of symmetry or special assumptions permits the simplification of many problems. It is important, however, to recognize the size of the errors that such simplifications can entail.

Groundwater flow variables, such as velocity and pressure, can vary in time or can be independent of time. For example, when a well is pumped, the water table drawdown increases with time. This is an unsteady or transient flow problem. If the flow variables do not change with time, the flow is steady.

This chapter is concerned with elementary 1D and 2D steady groundwater flow and transport problems. Advanced 3D flows, transient flows, transport processes, and modeling are treated in subsequent chapters. The geological setting is discussed in Chapter 2. Chapter 2 and Chapter 3 can be regarded as an introduction to groundwater hydrogeology and engineering. The following chapters deal with a number of advanced or specialized subjects in more detail.

The notions of saturated zone, confined aquifer, unconfined aquifer, water table, aquitard, aquiclude, perched aquifer, unsaturated zone or vadose zone and the physical properties of aquifers are discussed in Chapter 2. This chapter starts directly with the discussion of the hydraulics of groundwater or the motion of water below ground. The second part of this chapter deals with the transport of contaminants by groundwater.

3.2 Pressure, Suction, Piezometric Head, and Hydraulic Gradient

The water pressures are not only expressed as *gage pressures* but they are also expressed as *absolute pressures*. These pressures are related by the equation (Figure 3.1)

$$\text{Absolute pressure} = \text{Local atmospheric pressure} + \text{Gage pressure} \quad (3.1)$$

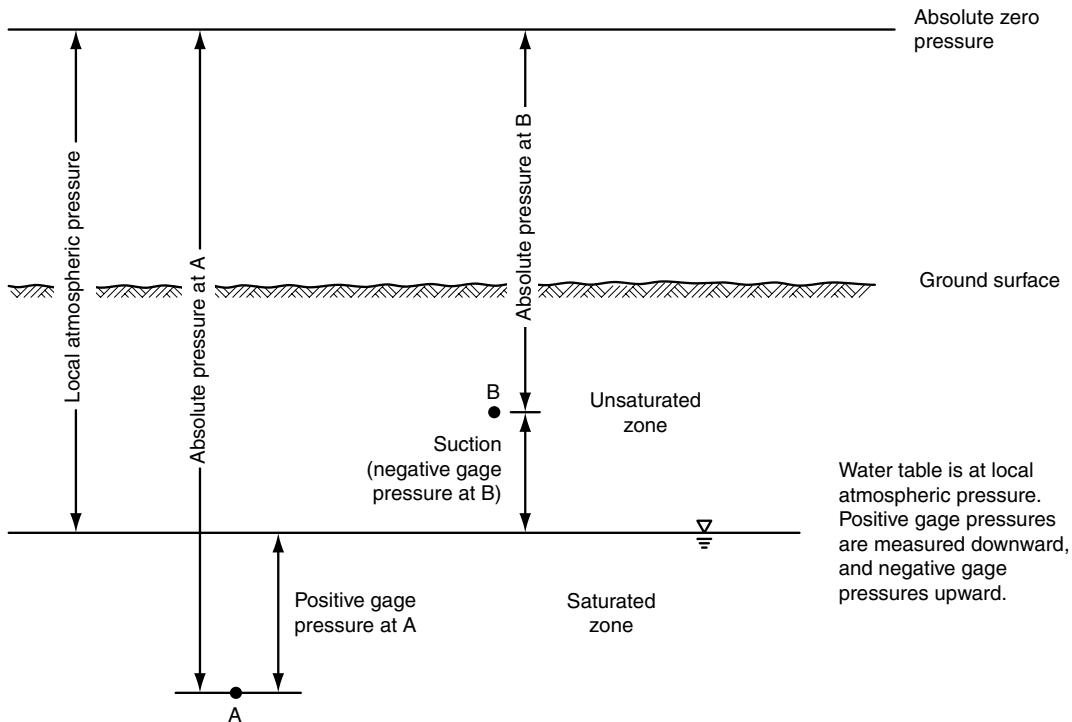

FIGURE 3.1 Absolute and gage pressures.

Gage pressures are used in the following discussion. The water table is at the local atmospheric pressure and serves as a datum for gage pressures. Point A in Figure 3.1 is in the saturated zone and the gage pressure is positive and is called the *pore pressure*. Point B is in the unsaturated zone and the gage pressure is negative. This negative pressure is referred to as a *suction* or *tension*. The suction is expressed as a positive number. Thus a positive suction corresponds to a negative gage pressure. The dimensions of pressure are F/L^2 , that is Newton per square meter or pascal (Pa), kiloNewton per square meter or kilopascal (kPa) in SI units and pound per square inch and pound per square feet in U.S. units. The law of hydrostatics states that pressure p can be expressed in terms of height of liquid h_p measured from the water table (assuming that groundwater is at rest or moving horizontally). This height is called the *pressure head*:

$$h_p = p/\gamma_w = p/\rho g \quad (3.2)$$

where $\gamma_w = \rho g$ is the specific weight, ρ is the density of water, and g is the gravitational acceleration. For point A the quantity h_p is positive whereas it is negative for point B. The pressure head is generally expressed in meters of water but it can also be expressed in centimeters of mercury. Some conversion factors for pressure and pressure heads are listed in Table 3.1 and some approximate equivalents of atmospheric pressure are listed in Table 3.2.

If the medium is saturated, pore pressure, p , can be measured by the pressure head, $h_p = p/\gamma_w$, in a *piezometer*, a nonflowing well. The difference between the altitude of the well, H (Figure 3.2), and the depth to the water inside the well is the *total head*, h_t , at the well.

In fluid mechanics the total head is defined as the sum of the *elevation head*, z , the *pressure head*, p/γ_w , and the *velocity head*, $v^2/2g$, where v is the flow velocity. For groundwater flow the velocity head can generally be ignored because the water moves very slowly. Therefore, the total head at an observation well is taken to be equal to the *piezometric head*, or the sum of the elevation head and the pressure head. The

symbol ψ is sometimes used to designate the pressure head.

$$h_t = z + p/\gamma_w = z + \psi \quad (3.3)$$

The piezometric head is also referred to as the *piezometric potential*. The change of piezometric head per unit distance in a given direction is the *hydraulic gradient*. If the direction is not specified it is assumed to be in the direction of the maximum gradient. The hydraulic gradient is a dimensionless quantity (L/L) when consistent units are used (see also Chapter 2, Sections 2.4.7 and 2.4.11).

Example 3.1

With the data of Figure 3.2, find the average hydraulic gradient.

Solution. The average hydraulic gradient is $h_L/L = [(100 - 10) - (95 - 15)]/2000 = (90 - 80)/2000 = 0.005$.

If the piezometric head is known at three observation wells A, B, and C that are not in a straight line, then both the direction of the groundwater flow and the hydraulic gradient can be calculated approximately. For this purpose, with reference to Figure 3.3, (1) select observation well C with the intermediate head. (2) By linear interpolation, find the location of the point P having the intermediate head on the line connecting the observation wells A and B with the maximum and minimum heads. (3) Connect point P with the intermediate well, this line is a segment of a piezometric contour line. (4) Draw a line perpendicular to this contour that passes either through the maximum head or through the minimum head observation well. This line is in the direction of groundwater movement. (5) The ratio of the head differential between the ends of the perpendicular line and the length of this line is the hydraulic gradient.

Example 3.2

Using the data of Figure 3.3, find the flow direction and the hydraulic gradient.

Solution. (1) Select well C with an intermediate head of 25.17 m. (2) Find the distance x from well A to point P: $x = (25.30 - 25.17) * 230.5 / (25.30 - 25.00) = 99.88$ m. (3) Draw the line BD perpendicular to

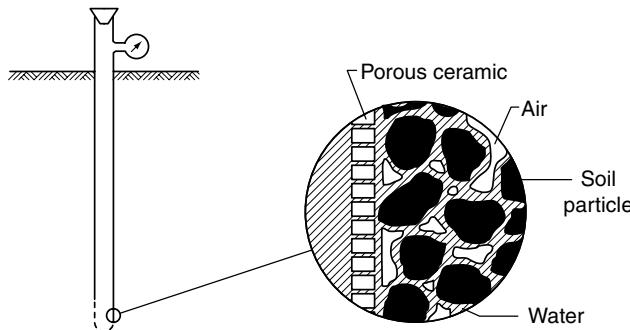

FIGURE 3.4 Tensiometer. (From Bouwer, H. 1978. *Groundwater Hydrology*. McGraw-Hill, New York. With permission.)

CP, this is the direction of groundwater movement. Measure the distance $BD = 114.29$ m. (4) Divide the head differential by the length BD to obtain the hydraulic gradient $(25.17 - 25.00)/114.29 = 0.0015$.

If the medium is unsaturated, the negative pressure or *suction* or *tension* is measured by a *tensiometer*. This instrument is composed of a vertical tube closed at the top and a porous ceramic cup at the bottom (Figure 3.4). The tensiometer is initially filled and the ceramic cup is saturated with water. When the instrument is placed in the soil, the water in the tensiometer is generally at atmospheric pressure. The soil water, which is at negative pressure, produces a suction that drains water from the tensiometer causing a pressure drop. When equilibrium is reached, the pressure inside the tensiometer is equal to that in the soil and can be measured with a vacuum gage. The practical suction range of a tensiometer is 0 to 0.8 bar or approximately 0 to 8 m of water. Relationships between the soil moisture content θ and the pressure head ψ are presented in Chapter 2 and in Chapter 6 and Chapter 7.

The *total pressure* at a point in a porous medium is the weight per unit area of the overburden above this point. This total pressure is the sum of the pore pressure and the *intergranular stress*, that is, the stress due to forces transmitted from grain to grain of the rock matrix.

3.3 The Motion of Groundwater

The motion of water requires energy. This energy can be expressed as a *head* above a *datum*. The elevation of this datum is arbitrary. This is because the difference in energy or the difference in head is the concern. It is therefore important that the energies be measured with respect to the *same* datum. In groundwater engineering the mean sea level (MSL) is usually taken as the datum. The *hydraulic head* is defined as the energy per unit weight measured relative to the datum.

Water can possess several forms of energy. Perhaps the most obvious is the energy that water possesses by virtue of its elevation above the datum. This is the *potential energy*. A mass m of water at an elevation z above the datum has a potential energy mgz , where g is the acceleration due to gravity. This is the work necessary to move the mass m from the datum to the elevation z . If ρ is the density of the water, a unit volume of water has a mass ρ and a weight ρg and a potential energy ρgz . The potential energy per unit weight, that is the *elevation head*, is thus $\rho gz/\rho g = z$. Note that the head has the unit of length.

The energy that water possesses by virtue of its motion is the *kinetic energy*. A mass m of water that moves with a velocity v has a kinetic energy $\frac{1}{2}mv^2$. Thus the kinetic energy per unit volume is $\frac{1}{2}\rho v^2$ and the kinetic energy per unit weight or *velocity head* is $\frac{1}{2}\rho v^2/\rho g = v^2/2g$. The velocity head has the dimension of length. When groundwater is flowing through the pores of the rock or soil formation, the velocity is very small, perhaps of the order of centimeters per year, and the velocity head is usually negligible with respect to the other forms of energy. One exception is near wells where the velocity increases significantly.

Another exception is in certain karst conduits where groundwater can flow fast enough that the velocity head is important.

The energy that water possesses by virtue of its pressure is the *pressure energy*. The pressure intensity of the fluid, p , acting on an area dA produces a force $p dA$. If the area is displaced by a distance ds , in the flow direction, then the force produces an amount of work $p dA ds$ known as *flow work*. The volume $dA ds$ has a weight $\rho g dA ds$ and the flow work per unit weight is $p dA ds / \rho g dA ds = p / \rho g$ known as the *pressure head*. The sum of the elevation head and the pressure head is known as the *piezometric head* $h = z + p / \rho g$.

3.4 Flow Through Porous Media — Darcy's Law

The French engineer Henry Darcy performed experiments on the filtration of water through sand columns. His finding that the rate of flow through a sand column is proportional to the loss of head appeared in an appendix to his treatise on the public fountains of the city of Dijon (Darcy, 1856). For further historic details, see Chapter 1. Figure 3.5 shows the original set up utilized by Darcy and Figure 3.6 shows some of his experimental results as plotted by Hubbert (1956) from Darcy's data. Darcy's law states that the volumetric flow rate, Q [$L^3 T^{-1}$], across a gross area A of a formation with a hydraulic conductivity K [LT^{-1}] (definition and values are given in Chapter 2), under a hydraulic gradient $i = -\partial h / \partial s$ in the

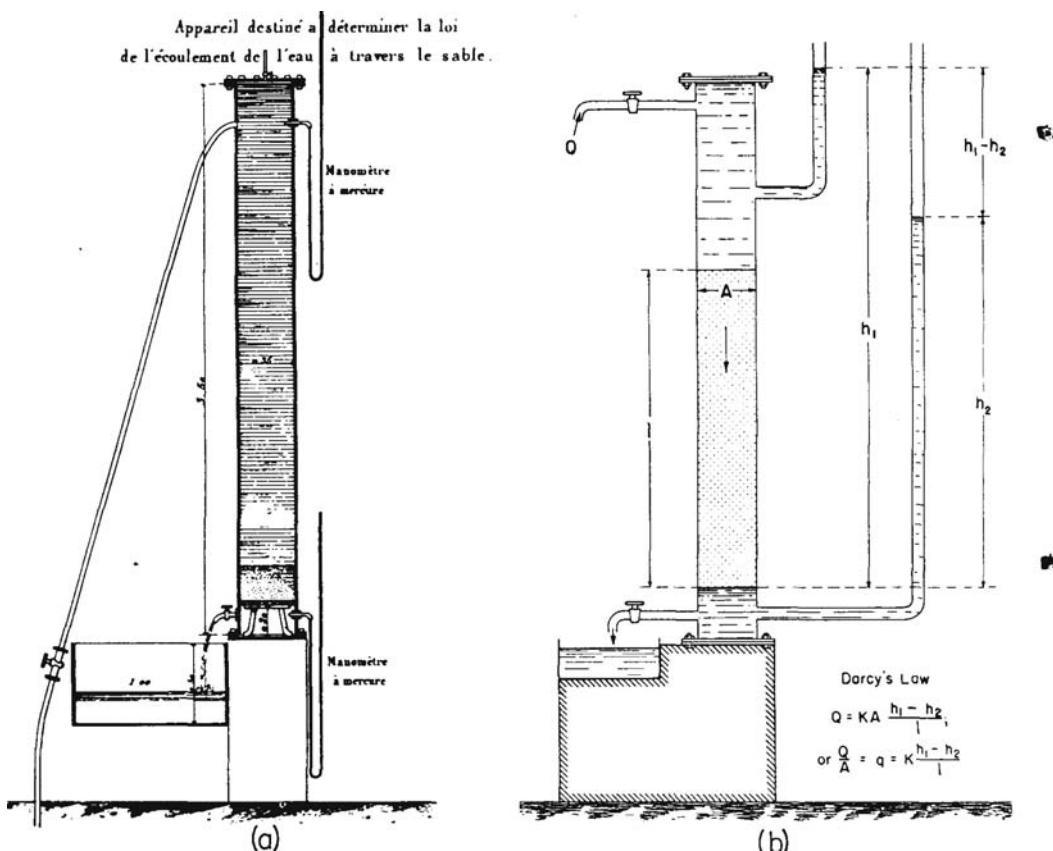

FIGURE 3.5 (a) Darcy's original apparatus with mercury manometer and (b) equivalent apparatus with water manometers. (From Hubbert, M.K. 1953. Entrapment of Petroleum under hydrodynamic conditions, *Bulletin of American Association of Petroleum Geologists*, 37, 1954–2026. With permission.)

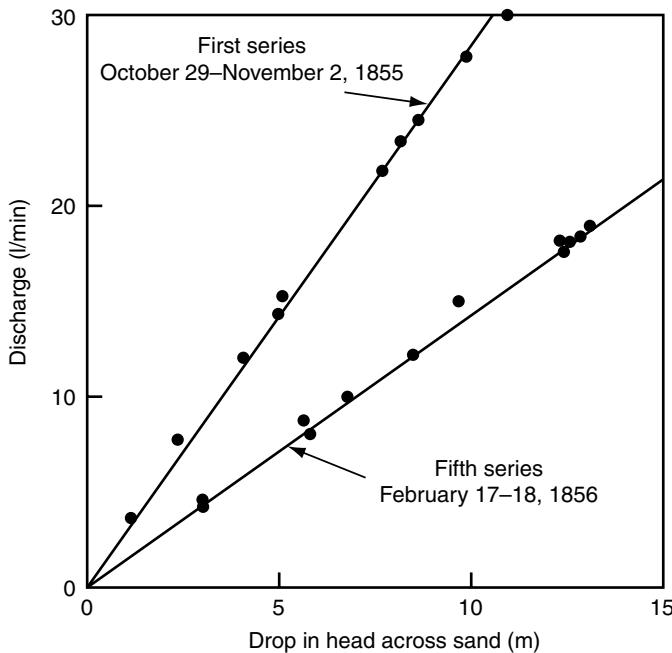

FIGURE 3.6 Darcy's data plotted by Hubbert. (From Hubbert, M.K. 1956. Darcy's law and the field equations of the flow of underground fluids. *Transactions of the American Institute of Mining, Metallurgical, and Petroleum Engineers*, 207, 229–239. With permission.)

s direction is given by

$$Q = qA = -KA\partial h/\partial s = KAi = \frac{k\rho g}{\mu} Ai \quad (3.4)$$

where q is a conceptual velocity called the *specific discharge* or flow rate per unit area [LT^{-1}] also known as the *Darcy velocity*, μ is the dynamic viscosity, and k is the *intrinsic permeability*. The hydraulic head, h , is the sum of the elevation head z and the pressure head p/γ_w . The minus sign in Equation 3.4 indicates that the flow takes place from high to low head, namely in the direction of decreasing head. The *pore velocity* is given by $v = q/n_e$, where n_e is the *effective porosity*, namely the porosity available for the fluid flow, and v is the average flow velocity in the pores, usually called the *seepage velocity*. It is the average velocity for the transport of solutes that are nonreacting. In the boundary determination of contributing areas for *well head protection zones* (see also Sect. 2.7.3) it is often necessary to find the time it takes for the water to move from a point to a bore hole. This can be done using the pore velocity. Pollutants that travel primarily by advection would move at the same velocity as the water, but those that are subject to the effects of diffusion and adsorption move more slowly. These effects are discussed in Section 3.13 and in more detail in Chapters 18 and 19, which are concerned with transport processes of nonreactive and reactive contaminants, respectively.

The one-dimensional form of Darcy's law is

$$q = K \frac{(p_1/\gamma_w + z_1) - (p_2/\gamma_w + z_2)}{L} \quad (3.5)$$

where subscripts 1 and 2 refer to the points at which the pressure heads and the elevation heads are considered, respectively, and L is the distance between these points.

Example 3.3

Find the hydraulic conductivity of the sands used in Darcy's first series experiments (Figure 3.6), assuming that the height of the sand column is 3 m and the diameter of the stand pipe is 0.35 m.

Solution. Take the flow rate $Q = 30 \text{ l/min} = 0.03 \text{ m}^3/\text{min}$. The specific discharge is $q = Q/A = 0.03/(\pi * 0.35^2/4) = 0.312 \text{ m/min}$. From Equation 3.5 $K = qL/\Delta h$. From the graph $\Delta h = 10.5 \text{ m}$. Thus $K = 0.312 * 3.0/10.5 = 0.089 \text{ m/min}$ or 0.0015 m/sec . This corresponds to a coarse sand.

Example 3.4

Find the time it takes for a molecule of water to move from a factory to a bore hole located 4 km away in a homogeneous silty sand unconfined aquifer with a hydraulic conductivity of $K = 5 \times 10^{-5} \text{ m/sec}$ or 4.32 m/d , an effective porosity of 0.4 and observing that the water table drops 12 m from the factory to the bore hole.

Solution. As a simple approximation $v = q/n_e = Ki/n_e$ and the pore velocity is calculated as

$$v = \frac{4.32 * (12/4000)}{0.4} = 0.0324 \text{ m/d}$$

It would take $4000/(0.0324 * 365) \approx 338 \text{ yr}$. If instead, the aquifer was a fractured limestone with a porosity of 0.01 and the hydraulic conductivity the same, the pore velocity would be approximately 1.3 m/d and the time to travel the 4 km would be 8.5 yr . With a porosity of 0.001 the travel time would reduce to 0.85 yr or about 10 months. Pumping at the bore hole will increase the hydraulic gradient and increase the pore velocity and thus decrease the travel time.

3.4.1 Similarity of Darcy's Law and Other Laws of Physics

Darcy's law is similar to Fourier's law of heat transfer, Ohm's law of electricity, and Fick's law of solute diffusion. *Fourier's law* governs the conduction of heat from high temperatures to low temperatures. It states that the heat flux is proportional to the temperature gradient and the constant of proportionality is the thermal conductivity. A number of flow through porous media problems have been solved using the heat conduction analogy. The Theis equation for transient flow toward wells (see Chapter 10 on "Well Hydraulics and Aquifer Tests") was obtained using an analogous problem in heat flow. *Ohm's law* can be stated as $I = V/R$, where I is the electric current, R is the resistance, and V is the voltage or potential difference across the resistor. For a cylindrical wire of length L , cross-sectional area A , and conductivity c , the resistance is $R = L/(cA)$ so that the expression for the current becomes

$$I = cA \frac{V}{L} \quad (3.6)$$

The similarity between Equation 3.4 and Equation 3.6 is now obvious. The flow rate is analogous to the current and the drop of head to the voltage drop. This analogy forms the basis for the resistance network models of aquifers (Karplus, 1958). *Fick's law* states that diffusion of a solute takes place along the concentration gradient from zones of high concentration to zones of low concentration, and the coefficient of proportionality is the diffusion coefficient. Fick's law is used in Section 3.13 and in Chapter 18 and Chapter 19, which are concerned with pollutant transport.

3.4.2 Limitations of Darcy's Law

Darcy's law implies that the flow is laminar, as is generally the case in porous media. The limit of validity can be stated in terms of the Reynolds number, N_R ,

$$N_R = qD/v \quad (3.7)$$

TABLE 3.3 Density and Viscosity of Water as a Function of Temperature

Temperature (°C)	Density ρ kg/cm ³	Viscosity $\mu \times 10^6$ Nsec/m ²	Kinematic Viscosity $v \times 10^6$ m ² /sec

Source: Daugherty, L., Franzini, J.B., and Finnemore, E.J. 1985. *Fluid Mechanics with Engineering Applications*, 8th ed., McGraw-Hill Inc., New York. With permission.

where q is the velocity, v is the kinematic viscosity of the fluid, defined as its dynamic viscosity μ divided by its density ρ , and D is a representative length. For flow in porous media, q is taken equal to the specific discharge, and the representative length, D , is often taken equal to the pore size or the effective grain diameter, d_{10} (the grain size such that 10% of the material is larger by weight). The Reynolds number measures the importance of the inertia forces relative to the viscous forces. It depends on the viscosity that varies with temperature as shown in Table 3.3. As a result N_R also varies with temperature. Likewise the hydraulic conductivity $K = k\rho g/\mu$, where k is the intrinsic permeability of the porous medium (See Chapter 2), also varies with temperature through μ . Schneebeli (1955), using spheres of uniform diameter, found that deviations from Darcy's law start at $N_R \cong 5$ as inertia forces become effective and that turbulent flow started around $N_R \cong 60$. For flows in which the dimension D is large, such as in rocks with large fractures (see Chapter 20) or in karstic limestones (see Chapter 21), the flow can be turbulent and Darcy's law does not apply.

Darcy's law, as given above, applies to *isotropic* media, that is, where the hydraulic conductivity is independent of direction. It also applies to flows where the direction of the hydraulic conductivity corresponds to the direction of the hydraulic gradient. In *anisotropic*, media the hydraulic conductivity depends upon the direction of measurement. Then a hydraulic conductivity *tensor* is used and Darcy's law is expressed as a *tensorial equation* (see Chapter 4 on "Two- and Three-Dimensional Flow of Groundwater").

3.4.3 Laboratory Measurement of Hydraulic Conductivity

Samples of the aquifer material must be obtained and returned to the laboratory in undisturbed condition. This is generally possible for consolidated materials but usually impossible for unconsolidated material and rarely possible for fissured aquifers. The samples must be representative of the aquifer. Where the aquifer has horizontally bedded strata, the samples can be collected from bore holes that intersect the several strata. They can also be obtained from cliffs or quarry faces. Where the strata are inclined the samples likewise can be obtained from bore holes as well as from the outcrop. Bore hole samples are preferred because the outcrop material may be weathered and consequently unrepresentative of the aquifer. Consolidated aquifer samples typically are cylinders or cubes with diameter and length of 25 to 50 mm. Cubes have the advantage that they permit the determination of the permeability in three directions.

Permeameters are used for the laboratory determination of hydraulic conductivity making use of Darcy's law. It is best to use groundwater from the formation in the permeameter test because this water will be

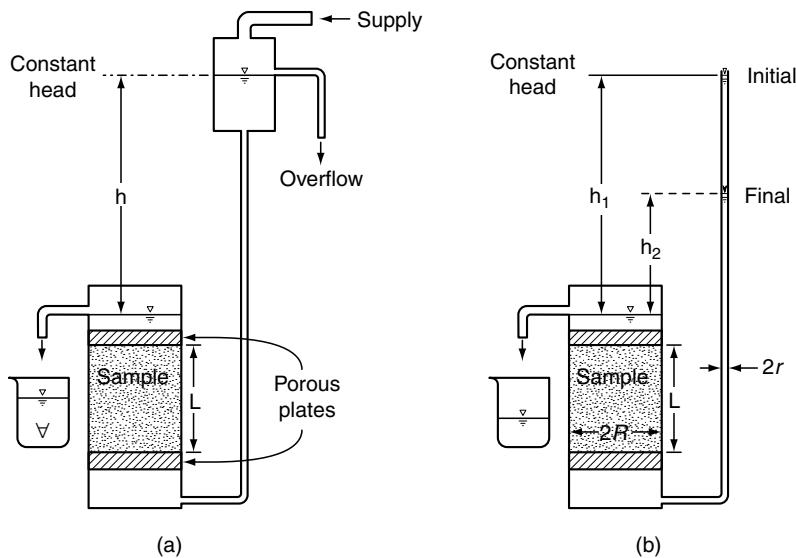

FIGURE 3.7 Permeameters. (a) Constant head and (b) falling head.

in chemical equilibrium with the aquifer material. In particular, clays can swell or shrink with changes in the water chemistry. There are two types of permeameter: the *constant head* permeameter (Figure 3.7a) used for noncohesive soils such as sands and gravels and the *falling head* permeameter (Figure 3.7b) used for materials with lower hydraulic conductivity. For the constant head permeameter, the hydraulic conductivity obtained from Darcy's law is

$$K = \frac{\forall L}{Ath} \quad (3.8)$$

where \forall is the volume of water collected in time t , A and L are the cross-section area and length of the sample, respectively, and h is the constant head. For the falling head permeameter, the hydraulic conductivity is obtained by equating the flow rate through the sample to the flow rate obtained from the observed head drop as

$$K = \frac{r^2 L}{R^2 t} \ln \frac{h_1}{h_2} \quad (3.9)$$

where R and r are the radii of the sample and of the tube, respectively, L is the length of the sample, h_1 and h_2 are the heads at the beginning and at a later time t .

3.4.4 Field Measurement of the Hydraulic Conductivity

A dependable method of field determination of hydraulic conductivity is by pumping tests. The hydraulic conductivity is obtained from observations of the water levels near pumping wells. It yields an integrated value of K (on a scale of 10 to 10^3 m) rather than the almost punctual information (on a scale of 10^{-2} to 10^{-1} m) obtained by laboratory tests. It also has the advantages that the aquifer is not disturbed and formation water is used. The pumping tests are described in detail in Chapter 10 on “Hydraulics of Wells and Aquifer Tests”.

Tracer tests using a dye such as fluorescein or a salt such as calcium chloride can also be used. If there is a drop of water table h in a distance L between the injection test hole and the observation bore hole and t is the observed travel time between the two bore holes, the hydraulic conductivity is obtained by

equating the pore velocity obtained by Darcy's law and that obtained by dividing the distance by the time. This results in

$$K = \frac{nL^2}{ht} \quad (3.10)$$

where n is the porosity of the material. In practice this test is difficult to accomplish because the flow direction must be known exactly, the distance between the bore holes should be small enough that the travel time does not become too long, and it is assumed that the aquifer is not stratified.

Other tests such as the *slug test*, the *auger-hole test*, and the *piezometer test* are based on the observation of the rate of recovery of the water level in a bore hole after the water level has been abruptly raised or lowered by addition or removal of water with a bailer or bucket or by insertion or withdrawal of a solid piece of pipe or slug into the well. These tests tend to give a more localized value of the hydraulic conductivity than the well tests but are less expensive to conduct. For more detail about these tests, the reader is referred to Bouwer (1978), Schwartz and Zhang (2003), or Butler (1997). Chapter 14 and Chapter 15 on aquifer characterization give a summary of several methods employed for the determination of aquifer properties.

3.5 One-Dimensional Hydraulics

The two basic laws of hydraulics are the continuity equation and the energy equation. They are discussed here for the case of *steady incompressible* flow. The *continuity equation* is a statement of the conservation of mass. For an incompressible fluid such as water, the equation becomes a conservation of volumes:

$$Q = A_1 V_1 = A_2 V_2 \quad (3.11)$$

where Q is the flow rate ($L^3 T^{-1}$), A_1 and A_2 are the cross-sectional areas, and V_1 and V_2 are the mean velocities at Sections 1 and 2, respectively. This assumes that there is no inflow or outflow between Sections 1 and 2. Figure 3.8 illustrates the continuity in a karst conduit.

The *conservation of energy* for steady flow is

$$z_1 + \frac{p_1}{\gamma} + \frac{V_1^2}{2g} = z_2 + \frac{p_2}{\gamma} + \frac{V_2^2}{2g} + h_L \quad (3.12)$$

where z is the elevation head or the elevation above a datum or reference plane, p/γ is the pressure head (where γ is the specific weight of the liquid), $V^2/2g$ is the velocity head, and h_L is the head loss. Each term has the dimension of length (L), and represents a form of energy per unit weight. As discussed earlier, the elevation head is the potential energy per unit weight, the pressure head is the flow work per unit weight,

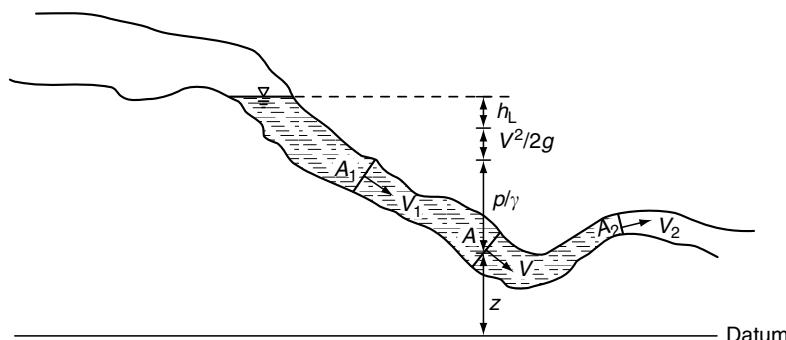

FIGURE 3.8 Continuity velocity head, pressure head, elevation head, and head loss in a karst system.

the velocity head is the kinetic energy per unit weight, and the head loss is the energy loss due to friction or other causes per unit weight. The equation can also be written as energy per unit mass

$$g z_1 + \frac{p_1}{\rho} + \frac{1}{2} V_1^2 = g z_2 + \frac{p_2}{\rho} + \frac{1}{2} V_2^2 + g h_L \quad (3.13)$$

where ρ is the fluid density. If the head loss is negligible and is made equal to zero, then the equation is known as the *Bernoulli equation*. It states that in an unbranched conduit the sum of the potential, pressure, and kinetic energies remains constant if the losses are neglected. In flow through porous media the velocity is very small and the velocity head is generally neglected but the friction losses due to viscosity, however, are important. Figure 3.8 illustrates the terms of Equation 3.12 in a karst system.

In a karst terrain, flow usually occurs in larger conduits that hydraulically act as pipes or fissures. If the Reynolds number is sufficiently small, the flow is laminar, otherwise it is turbulent. For circular pipes the *Reynolds number* is defined as

$$N_R = \frac{\rho V D}{\mu} = \frac{V D}{\nu} \quad (3.14)$$

where D is the diameter, $V = Q/A$ is the average flow velocity, that is, the flow rate Q divided by the cross-sectional area A , ρ is the density of the fluid, μ is the absolute viscosity, and ν is the kinematic viscosity. With a consistent set of units, the Reynolds number is a dimensionless quantity. The flow is laminar if the Reynolds number is less than 2000 and it is generally turbulent if the Reynolds number is larger than 4000. For values between 2000 and 4000 the flow is in a transitional regime.

For noncircular conduits such as fractures, the Reynolds number is defined as

$$N_R = \frac{\rho V (4R_h)}{\mu} \quad (3.15)$$

where $R_h = A/P$ is the *hydraulic radius* which is the ratio of the cross-sectional area, A , to the wetted perimeter, P . For a circular cross-section, $D = 4R_h$.

Friction head losses in conduits are calculated using the *Darcy–Weisbach formula* that is generally written as

$$h_L = f \frac{L}{D} \frac{V^2}{2g} \quad (3.16)$$

in which f is a dimensionless quantity called the *friction coefficient*. For laminar flow in circular conduits (also known as *Poiseuille flow*), $f = 64/N_R$ and the flow rate is thus expressed as

$$Q = \frac{\rho g D^2}{32\mu} A \frac{h_L}{L} \quad (3.17)$$

This equation is seen to be of the same form as Darcy's law (Equation 3.4) with $K = \rho g D^2 / (32\mu)$ or $k = D^2 / 32$ and $i = h_L / L$.

The Darcy–Weisbach formula (Equation 3.16) also holds for turbulent flows. Methods of calculation of the friction coefficient f for turbulent flows are described in fluid mechanics textbooks such as Finnemore and Franzini (2002).

Free surface *open channel flow* can occur in large karst cavities. Free surface streams in karst aquifers are discussed in Chapter 21.

3.6 One-Dimensional Flow through Porous Media — Leaky Aquifers

Simple 1D flows in porous media can be analyzed using Darcy's law as expressed in Equation 3.5. As an example, consider the case of a *leaky aquifer*. Many aquifers are either not fully confined or unconfined. One aquifer may be overlain by another and the stratum separating them is not fully impervious: its hydraulic conductivity is much less than that of either top or bottom aquifer but it is not zero. The rate of leakage q (volume per unit area per unit time) can be calculated using Darcy's law as

$$q = K' \frac{(h' - h)}{b} \quad (3.18)$$

where K' and b are the vertical hydraulic conductivity and the thickness of the aquitard; h' and h are either the heads at the top of the aquitard (bottom of upper aquifer) and at the top of the lower aquifer, just below the aquitard (Figure 3.9). Observe that the level in the right piezometer is slightly lower than the water table due to the downward motion of the flow. This can be verified by writing Darcy's law between point A at the water table and point B at the bottom of the unconfined aquifer: $q = K(H - h')/(y + z)$, from which $H - h' = q(y + z)/K$.

Example 3.5

As an example of a 1D flow problem, consider the case of the confined aquifer of Figure 3.9 that is recharged from an unconfined aquifer through an aquitard. The recharge rate is 0.3 m/yr or $8.22 \times 10^{-4} \text{ m/d}$. The water table is at $H = 30 \text{ m}$ above the datum. The aquitard is 2 m thick and its vertical hydraulic conductivity is $K' = 10^{-3} \text{ m/d}$. The unconfined aquifer is 20 m thick and has a hydraulic conductivity $K = 10^{-1} \text{ m/d}$. Find the piezometric head h' at the bottom of the unconfined aquifer and the difference in elevation between the water table and the piezometric surface of the confined aquifer.

Solution. Let y be the height of the piezometric surface over the top of the aquitard and z the difference in elevation between the water table and the piezometric surface (Figure 3.9). Applying Darcy's law (Equation 3.5) between points A and B yields $8.22 \times 10^{-4} = 10^{-1}(H - h')/(y + z)$. Thus $h' = H - 8.22 \times 10^{-3}(y + z) = 30 - 8.22 \times 10^{-3}(20) = 29.84 \text{ m}$. Writing Darcy's equation between the top

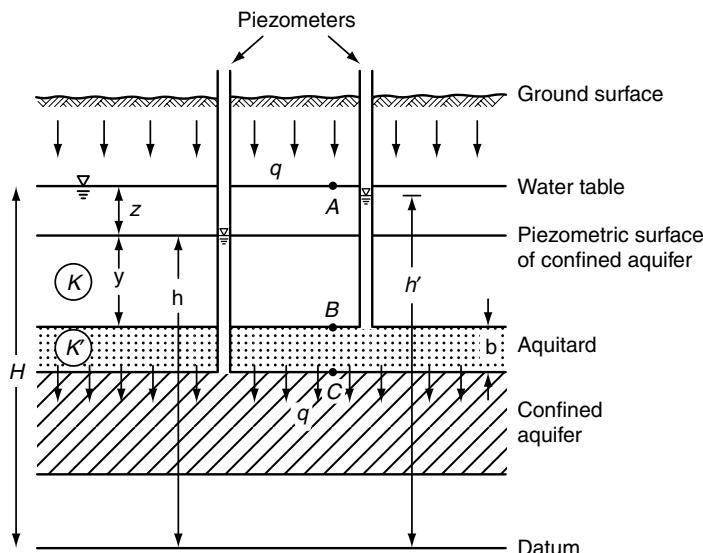

FIGURE 3.9 Leaky aquifer.

and the bottom of the aquitard yields $8.22 \times 10^{-4} = 10^{-3}(h' - h)/b$, thus $h = h' - 8.22 \times 10^{-1}b = 29.84 - 8.22 \times 10^{-1} \times 2 = 28.20$. Hence, $z = H - h = 30 - 28.20 = 1.80$ m.

When a well discharges from a leaky confined aquifer, the piezometric surface is lowered throughout a wide circular area. This lowering, called *drawdown*, is largest near the well and decreases outward. This variable drawdown changes the head differential between the confined and unconfined aquifers and alters the rate of leakage through the aquitard. From Darcy's law it follows that, at any point, the downward flow is proportional to the difference of elevation between the water table of the unconfined aquifer and the piezometric surface of the confined aquifer. Steady and unsteady flows toward wells in leaky aquifers are discussed in Chapter 10.

3.7 Dupuit–Forchheimer Assumptions

For some of the 2D flow problems, one component of the flow can be neglected with respect to the other. In particular, in some unconfined flows with a free surface, the vertical component of the flow can be neglected. This approximation pioneered by Dupuit (1863) and utilized later by Forchheimer (1930) is known as the Dupuit–Forchheimer assumption. It gives reasonable results when the depth of the unconfined flow is shallow and the slope of the free surface is small. These assumptions are summarized as follows:

1. The flow is horizontal at any vertical cross-section.
2. The velocity is constant over the depth.
3. The velocity is calculated using the slope of the free surface as the hydraulic gradient.
4. The slope of the water table is relatively small.

3.7.1 Steady Flow over a Horizontal Aquiclude

A simple application of the Dupuit–Forchheimer approximations is the analysis of steady flow through an unconfined aquifer overlying an impervious horizontal aquiclude (Figure 3.10). The discharge per unit width is $q_x = qh$, where q is the Darcy velocity or specific discharge and h is the depth of flow. From

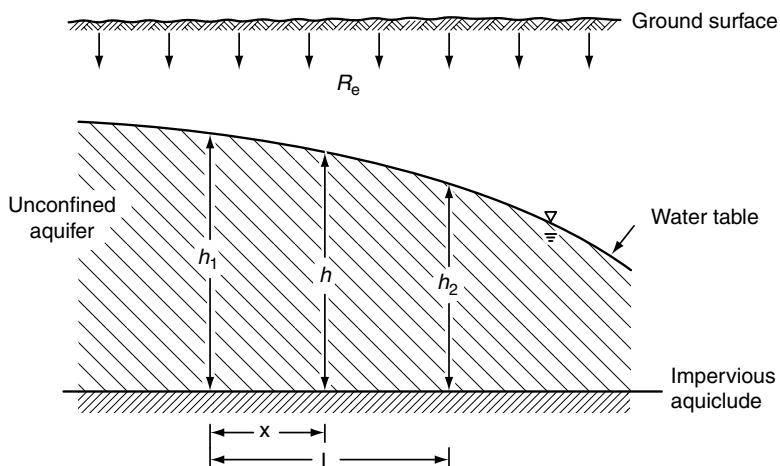

FIGURE 3.10 Steady flow through an unconfined aquifer overlying an impervious horizontal aquiclude.

Darcy's law,

$$q_x = -Kh \frac{dh}{dx} \quad (3.19)$$

Equation 3.19 is integrated from $x = 0$ (where $h = h_1$) to $x = L$ (where $h = h_2$) to obtain the *Dupuit equation*:

$$q_x = K \frac{h_1^2 - h_2^2}{2L} \quad (3.20)$$

If there is a uniform recharge with a rate R_e , then $q_x = R_e x$ with $x = 0$ at the groundwater divide and

$$R_e x = -Kh \frac{dh}{dx} \quad (3.21)$$

from which

$$K(h_1^2 - h_2^2) = R_e L^2 \quad (3.22)$$

Example 3.6

For an unconfined aquifer with a hydraulic conductivity $K = 1.75$ m/d, an effective porosity of 0.3, and water depths of 10 m and 8 m at two observation wells 200 m apart, calculate the discharge per unit width, the specific discharge, and the pore velocity.

Solution. From Equation 3.20, the discharge per unit width is $q_x = 1.75(10^2 - 8^2)/(2 * 200) = 0.1575$ m²/d. The Darcy velocity or specific discharge at the observation well with a 10 m depth is $q = q_x/h_1 = 0.1575/10 = 0.01575$ m/d. The pore velocity is $v = 0.01575/0.3 = 0.0525$ m/d. Thus, the pore water velocity changes with distance.

3.7.2 Seepage from Open Channels

The Dupuit–Forchheimer assumptions can be used to analyze the seepage from an open channel embedded in a homogeneous soil underlain by a material of much lower hydraulic conductivity, assumed impervious in the analysis (Figure 3.11). The average slope of the water table is $D_w/(L - 0.5W_s)$. The specific discharge

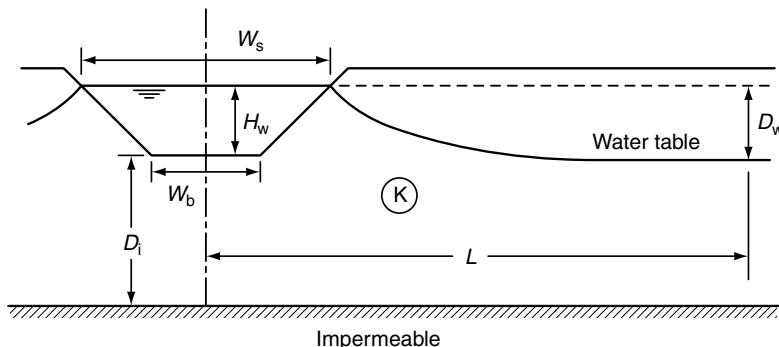

FIGURE 3.11 Seepage from a channel in a soil underlain by impervious material. (From Bouwer, H. 1978. *Groundwater Hydrology*, McGraw-Hill, New York. With permission.)

is given by Darcy's law (Equation 3.5) as $q = KD_w/(L - 0.5W_s)$. The average flow depth is $D_i + H_w - 0.5D_w$. The total seepage per unit length of channel (on both sides) is thus

$$Q = 2KD_w \frac{D_i + H_w - 0.5D_w}{L - 0.5W_s} \quad (3.23)$$

Bouwer (1969) states that this type of analysis gives reasonable results for $D_i < 3W_s$. General solutions of the canal seepage problem have been given by Bouwer (1969, 1978), Harr (1962), Polubarnova-Kochina (1962), and Yussuff *et al.* (1994). The case of partially lined channels has been examined by Subramanya *et al.* (1973). Integrated groundwater-surface water models have been developed and applied to the Imperial County in southern California by Saquib *et al.* (1995) and Taghavi *et al.* (1995).

Example 3.7

Estimate the seepage from a canal with a depth $H_w = 1$ m, dug in a soil with a hydraulic conductivity $K = 2$ m/d so that the distance from the bottom of the channel to the impervious stratum is $D_i = 10$ m, given a drop in the water table $D_w = 0.5$ m is observed at a distance $L - 0.5W_s = 400$ m from the shore. Is this seepage a significant portion of the flow?

Solution. Replacement in Equation 3.23 yields $Q = 0.05375 \text{ m}^3/\text{d}$ per meter of channel length or $53.75 \text{ m}^3/\text{d}$ per kilometer. Assume the channel had a bottom width $W_b = 4$ m, side slopes of 45° and a longitudinal slope of $S_o = 0.0004$, and a Manning roughness coefficient $n = 0.022$ (straight channel excavated in clean earth, after weathering) (Chow, 1959). The discharge capacity can be calculated by Manning's equation $Q = (1/n)AR_h^{2/3}S^{1/2}$ (see Equation 21.12, Chapter 21 on "Karst Hydrology"). The cross-sectional area is $A = 5 \text{ m}^2$, and the wet perimeter is $P = 6.828 \text{ m}$. The hydraulic radius is $R_h = 5/6.828 = 0.732 \text{ m}$. The flow rate is $Q = 5 * 0.732^{2/3} * 0.0004^{1/2}/0.022 = 3.692 \text{ m}^3/\text{sec}$ or $318,988 \text{ m}^3/\text{d}$. In a distance of 40 km, the seepage loss would amount to $40 * 53.75 * 100 / 318,988 = 0.674\%$ or less than 1%. This does not appear to be significant.

3.7.3 Recharge Basins

A third application of the Dupuit-Forchheimer assumptions is the analysis of the recharge of an unconfined aquifer from a recharge basin. A long rectangular basin of width W is considered with the assumption that the flow is horizontal and steady (Figure 3.12). Thus the depth of the aquifer, H , should not be large compared with the width, W , of the recharge basin, that is, $H \leq W$, otherwise a more detailed analysis, such as a digital model, should be used. Letting R_e be the infiltration rate from the recharge area, x the horizontal distance from the centerline of the recharge area, h the height of the groundwater mound above the static water table, and approximating the average transmissivity $T = K(H + h_c/2)$ by KH (Figure 3.12), the Dupuit-Forchheimer assumptions yield

$$R_e x = -T \frac{dh}{dx} \quad (3.24)$$

Integration of Equation 3.24 yields $h_c - h_e = R_e W^2 / (8T)$, where h_c and h_e are the height of the groundwater mound at the center and at the edge of the recharge basin, respectively. If h_c and h_e are measured in the field, then the aquifer transmissivity can be calculated.

Further discussion can be found in Bouwer (1970, 1978). An analytical solution has been given for rectangular recharging areas by Mariño (1975). Bouwer *et al.* (1999), and Bouwer (2002) developed additional equations to estimate heights of perched groundwater mounds above restricting layers in the vadose zone for narrow rectangular and circular recharge areas and gave design procedures for the design of recharge projects.

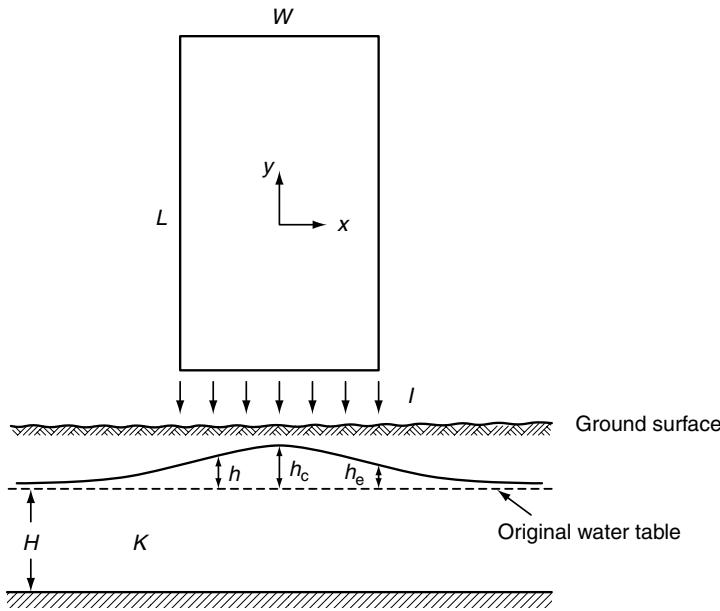

FIGURE 3.12 Seepage from a recharge basin.

Example 3.8

A long recharge basin has a width $W = 70$ m and recharge rate $R_e = 0.6$ m/d. The observed heights of the mound are $h_c = 1.2$ m and $h_e = 0.7$ m. Find the aquifer transmissivity.

Solution. From the integration of Equation 3.24, $T = 0.6(70)^2/[8(1.2 - 0.7)] = 735$ m²/d. Note that if $H > 70$ m, the transmissivity obtained is an “effective” transmissivity, as the lower layers of the aquifer are not fully contributing to the flow.

3.7.4 Steady Flow toward a Well in Confined and Unconfined Aquifers

Consider a well that fully penetrates an isotropic confined aquifer of hydraulic conductivity K . The initial piezometric level is assumed to be horizontal so that originally there is no motion of the groundwater. As water is being pumped, it flows from the aquifer toward the well lowering the piezometric surface and creating a drawdown (Figure 3.13).

For a constant pumping rate, a steady state is eventually achieved. Consider two imaginary cylinders around the well with radii r_1 and r_2 . The flows through each of these cylinders of height b are horizontal. Furthermore the flows must be equal to the discharge at the well for steady state conditions. Thus, from Darcy's law

$$Q = 2\pi r_1 b K i_1 = 2\pi r_2 b K i_2 \quad (3.25)$$

where i_1 and i_2 are the values of the hydraulic gradient at radii r_1 and r_2 , respectively. Since $2\pi b K$ is constant, and since $r_1 < r_2$, then $i_1 > i_2$. Thus the hydraulic gradient becomes steeper as the water approaches the well creating the *cone of depression*. As the same flow occurs through the two cylinders, the gross velocity, or specific discharge, increases as the well is approached. Writing Equation 3.25 as $Q = 2\pi r b K d h / dr$ and integrating yields the *Thiem equation* for confined aquifers:

$$Q = \frac{2\pi K b (h_2 - h_1)}{\ln(r_2/r_1)} = \frac{2\pi T (h_2 - h_1)}{\ln(r_2/r_1)} \quad (3.26a)$$

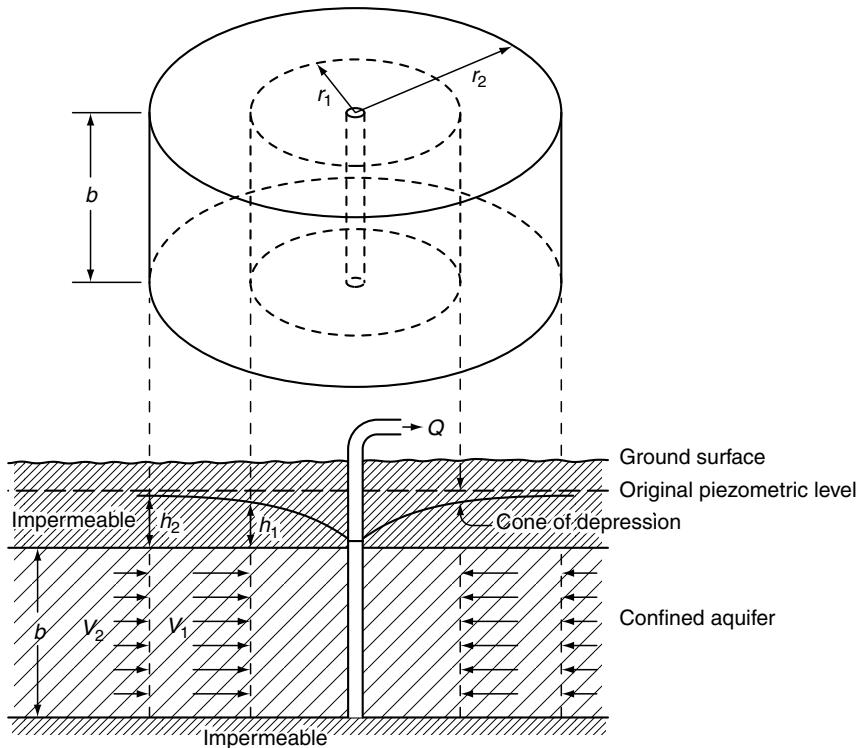

FIGURE 3.13 Flow toward a fully penetrating well in a confined aquifer.

where $T = Kb$ is the *transmissivity* of the aquifer. This solution is applicable between $r_w \leq r_1, r_2 < R$, where R is the *radius of influence*. This radius delineates the region inside of which the effect of pumping is felt and outside of which the drawdown is taken to be zero.

In the case of an *unconfined aquifer*, the saturated depth b is not constant and decreases toward the well. Perhaps the most important application of the Dupuit assumption is the computation of steady flow toward a well in an unconfined aquifer as done by Forchheimer. Assuming essentially horizontal flow, the discharge may be expressed as

$$Q = \frac{\pi K(h_2^2 - h_1^2)}{\ln(r_2/r_1)} \quad (3.26b)$$

where h_2 and h_1 are interpreted as the saturated thicknesses at locations r_1 and r_2 for $r_w \leq r_1, r_2 < R$. Equation 3.26b is known as the *Dupuit–Forchheimer formula*. Close to the well the vertical component of the flow comes into effect and the Dupuit–Forchheimer assumptions are not fully satisfied. Equation 3.26a can still be used with reasonable results for unconfined aquifers if T is interpreted as the average transmissivity $K(h_1 + h_2)/2$ and the drawdowns are small compared with the saturated thickness of the aquifer. Equation 3.26a and Equation 3.26b can also be used with one observation well and considering the pumping well as the other observation point. Both can be solved for the hydraulic conductivity K given the discharge and the heads h_1 and h_2 at radii r_1 and r_2 .

Example 3.9

A well with a radius of 50 cm completely penetrates an unconfined aquifer. It has been pumped for a long time at the rate of $15,000 \text{ m}^3/\text{d}$. The drawdown in the well is 10 m. Find the hydraulic conductivity of the

formation given that the well essentially does not affect the water table at a distance of 600 m = R , where the depth of the water table is 50 m. Well losses are neglected.

Solution. Using Equation 3.26b with $T = K(h_1 + h_2)/2$ and $h_1 = 50 - 10 = 40$ m, and solving for K gives

$$K = \frac{Q \ln(r_2/r_1)}{\pi(h_2^2 - h_1^2)} = \frac{15,000 \ln(600/0.50)}{\pi(50^2 - 40^2)} = 37.6 \text{ m/d}$$

Solving the well equation for the aquifer properties is called the *inverse problem*. The method employed in Example 3.9 using the Dupuit–Forchheimer equation only gives a rough approximation, as in practice steady state rarely exists and the transient flow formulas must be used instead. The transient flow methods (discussed in Chapter 10 on “Hydraulics of Wells and Aquifer Tests”) also yield the storage coefficient S in addition to the hydraulic conductivity K .

3.8 Velocity Potential, Force Potential, and Flow Nets

The piezometric head $h = z + p/\gamma$ is interpreted as an energy or potential per unit weight. The quantity

$$\Phi = Kh + C = K \left(z + \frac{p}{\gamma} \right) + C \quad (3.27)$$

where C is an arbitrary constant, is defined as the *velocity potential*, Φ . By virtue of Darcy’s law, the negative of its derivative in the flow direction, for constant K , is the Darcy velocity, q . As a more general term, the negative of the *gradient* of the velocity potential is a velocity. This is the definition of the velocity potential in classical hydrodynamics. (*Note:* In Chapter 5 a minus sign is introduced in the right-hand side of Equation 3.27, then the velocity is the derivative of the velocity potential.)

Hubbert (1953, 1987) introduced the concept of the *force potential* Ψ (with $C = 0$ in Equation 3.27)

$$\Psi = gh = \frac{g}{K} \Phi \quad (3.28)$$

(*Note:* In Chapter 5 the symbol Ψ is used for the “stream function,” Equation 5.16.) The force potential at a point is the work that is required to move a unit mass of fluid from a reference elevation and pressure to the elevation and pressure at the given point. In vector form, for K constant,

$$\mathbf{q} = -\nabla \Phi \quad (3.29a)$$

or

$$\mathbf{q} = -\frac{K}{g} \nabla \Psi \quad (3.29b)$$

The gradient of the force potential is the force per unit of mass acting upon the water at a given point. Formula 3.29b is a generalized Darcy’s law in three dimensions (Hubbert, 1953, 1987).

From Equation 3.29b \mathbf{q} is seen to have the same direction as $-\nabla \Psi$ as long as K is constant. Thus, the *streamlines*, which are lines everywhere tangent to the velocity vector, are perpendicular to lines of $\Psi = \text{constant}$ or *equipotential lines*. The streamlines and the equipotential lines are orthogonal. A network of streamlines and equipotential lines form the *flow net*, which is a useful tool in the analysis of 2D flows. When the hydraulic conductivity is not constant, then Equation 3.29a must be used. With some practice, good flow nets can be drawn by hand. The equipotential lines are drawn so that the drop of head Δh or potential drop $\Delta \Phi$ between adjacent lines is the same. The streamlines are drawn so that the same fraction

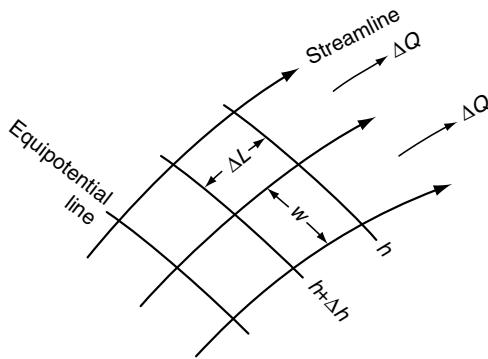

FIGURE 3.14 Streamlines and equipotential lines in a flow net.

of the total flow ΔQ takes place between adjacent streamlines. They are normal to the equipotential lines (Figure 3.14) forming “square” shapes. The flow between two streamlines, ΔQ , is obtained from Darcy’s equation as

$$\Delta Q = Kbw \frac{\Delta h}{\Delta L} \quad (3.30)$$

where b is the average depth of flow, Δh and ΔL are the difference in head and the distance between adjacent equipotential lines, respectively, and w is the width between adjacent streamlines for the square considered. The total flow through a group of n flow paths is $Q = n\Delta Q$. Figure 3.15 shows a flow net for a recharge area in an unconfined aquifer.

The mathematics, construction, and application of flow nets are discussed in Chapter 5 on Groundwater and Seepage.

3.9 Laplace’s Equation

Laplace’s equation is fundamental to the analysis of many groundwater flow problems. It arises from the combination of Darcy’s law and the equation of continuity or conservation of mass for a homogeneous isotropic aquifer. Consider a steady flow of an incompressible fluid through an elementary cube (Figure 3.16) of a porous medium of porosity n . Let u, v, w be the velocity components in the x, y, z directions, respectively. The inflow through the vertical face near the origin is $nu dy dz$. The outflow through the vertical face away from the origin is

$$\left[nu + \frac{\partial}{\partial x}(nu) dx \right] dy dz$$

and the net change of volume in the x -direction (inflow rate–outflow rate) is

$$-\frac{\partial}{\partial x}(nu) dx dy dz.$$

The sum of the net changes of volume in the x, y, z directions must be equal to zero. Thus

$$-\left[\frac{\partial}{\partial x}(nu) + \frac{\partial}{\partial y}(nv) + \frac{\partial}{\partial z}(nw) \right] = 0$$

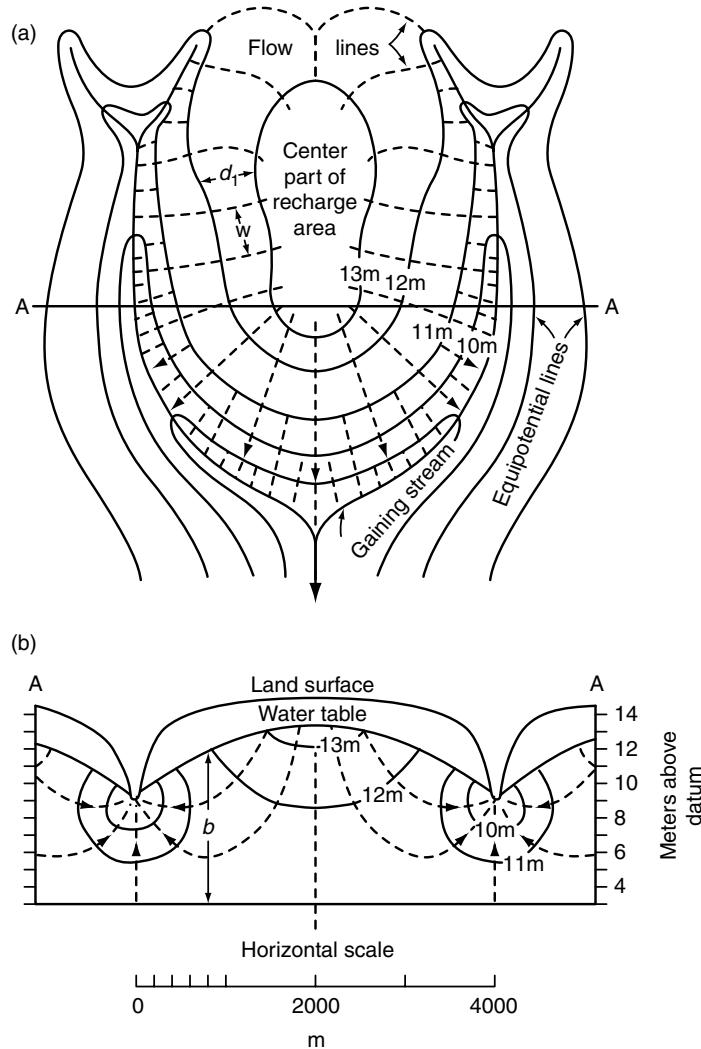

FIGURE 3.15 Flow net of a recharge area and gaining stream. (a) Plan view and (b) cross-section. (From Heath, R.C. 1995. *Basic Ground-Water Hydrology*. U.S. Geological Survey, Water-Supply Paper 2200, 7th printing, Denver, CO.)

For an incompressible isotropic homogeneous porous medium, the equation of continuity for steady incompressible flow is thus

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (3.31)$$

Using Darcy's law for an isotropic homogeneous medium

$$u = -K \frac{\partial h}{\partial x}, \quad v = -K \frac{\partial h}{\partial y}, \quad w = -K \frac{\partial h}{\partial z}$$

Laplace's equation is obtained in terms of the head h :

$$\nabla^2 h = \frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} + \frac{\partial^2 h}{\partial z^2} = 0 \quad (3.32)$$

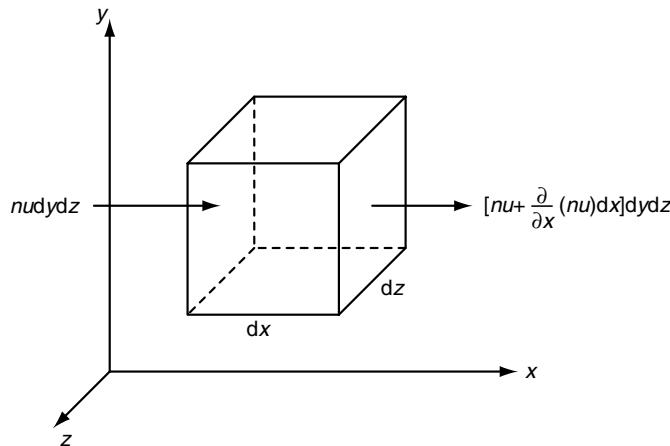

FIGURE 3.16 Elementary cube of porous media.

If in Equation 3.31 the velocity components are expressed in terms of the velocity potential (see Equation 3.29a)

$$u = -\frac{\partial \Phi}{\partial x}, \quad v = -\frac{\partial \Phi}{\partial y}, \quad w = -\frac{\partial \Phi}{\partial z}$$

then Laplace's equation is expressed in terms of the velocity potential Φ

$$\nabla^2 \Phi = \frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} + \frac{\partial^2 \Phi}{\partial z^2} = 0 \quad (3.33)$$

Equation 3.33 is fundamental to the analysis of flow nets as developed in Chapter 5.

If the porous medium of a confined aquifer is assumed to be compressible with a compressibility α (the reciprocal of the modulus of elasticity,) and the water with a compressibility β , then a *specific storage coefficient* S_s is introduced as (see Equation 4.57)

$$S_s = \rho g(\alpha + n\beta) \quad (3.34)$$

S_s has the dimension L^{-1} . The compressibility α has a range of values from 10^{-6} to 10^{-8} Pa^{-1} for clays and a range of 10^{-9} to 10^{-11} Pa^{-1} for sound rock with intermediate values for sand, gravel, and jointed rock, and the compressibility of water, β , is $4.4 \times 10^{-10} \text{ Pa}^{-1}$ (Freeze and Cherry, 1979). The term $\rho g \alpha$ represents the water yield from storage due to the compression of the porous medium and $\beta \rho g n$ is the water yield resulting from the expansion of water storage. Integrating S_s over the thickness of the confined aquifer one obtains the *storativity* or *storage coefficient* S . Thus, $S \approx S_s b$, where b is the thickness of the aquifer. The storativity S is dimensionless and for confined aquifers it is of the order of 5×10^{-2} to 10^{-5} (de Marsily, 1986). For a horizontal confined aquifer, the storage coefficient is interpreted as the volume of water that the aquifer releases per unit surface area of aquifer per unit drop of the piezometric surface.

For an unconfined aquifer, S is the *drainage porosity* or *specific yield*, which is the volume of water released per unit drop of the water table per unit horizontal area. The storage coefficient can be determined in the field from pumping tests as described in Chapter 10.

Since, for the elementary cube of Figure 3.16, the difference between the inflow and the outflow is now equal to the rate of change of storage, the flow is now unsteady, thus requiring the time derivative in the

right-hand side of Equation 3.32. For 2D flow in a horizontal confined aquifer, Equation 3.32 becomes

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} = \frac{S}{T} \frac{\partial h}{\partial t} \quad (3.35)$$

where $S (\approx S_s b)$ is the aquifer storativity, $T = Kb$ is the *transmissivity* of the aquifer, and b is the depth for a confined aquifer and is approximated as the average depth for an unconfined aquifer. If there is a leakage or inflow rate q in the aquifer per unit area, then Equation 3.35 becomes

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} + \frac{q}{T} = \frac{S}{T} \frac{\partial h}{\partial t} \quad (3.36)$$

The leakage rate can be calculated by Darcy's law (see Equation 3.18).

The *Dupuit–Forchheimer* assumption that was applied to 1D unconfined flow (see Equation 3.19 and Equation 3.20) can be generalized to the 2D case. In this case the inflows and outflows into a small parallelepiped of unconfined aquifer can be calculated by Darcy's law and their sum must be equal to zero for a steady incompressible flow. This yields

$$\frac{\partial^2(h^2)}{\partial x^2} + \frac{\partial^2(h^2)}{\partial y^2} = 0 \quad (3.37)$$

It is seen that for the Dupuit–Forchheimer assumptions, the square of the head must satisfy Laplace's equation (Harr, 1962). If there is recharge at the rate R_e , then Equation 3.37 is replaced by (Fetter, 2004)

$$-K \left(\frac{\partial^2(h^2)}{\partial x^2} + \frac{\partial^2(h^2)}{\partial y^2} \right) = 2R_e \quad (3.38)$$

Example 3.10

A river and a canal run parallel to each other $L = 500$ m apart (Figure 3.17). They fully penetrate an unconfined aquifer with a hydraulic conductivity of 0.3 m/d. The elevation of the water surface in the river is 1.25 m lower than in the canal where the depth is 5 m. Assuming no recharge, find the water table elevation midway between the river and the canal and find the discharge into the river.

Solution. The 1D form of Equation 3.37 is $d^2(h^2)/dx^2 = 0$, which integrates as $h^2 = c_1 x + c_2$. Applying the boundary conditions at $x = 0$, $h = h_1$ and $x = L$, $h = h_2$, one obtains $h^2 = h_1^2 - (h_1^2 - h_2^2)x/L$. Thus, with $h_1 = 5$ m, $h_2 = 3.75$ m, and $L = 500$ m, $h = [5^2 - (5^2 - 3.75^2) * 0.5]^{1/2} = 4.42$ m. The seepage into the river is given by $q = -Kh(dh/dx) = K(h_1^2 - h_2^2)/2L = 0.3(5^2 - 3.75^2)/1000 = 0.0033$ m³/(m d) or 3.3 m³/(km d).

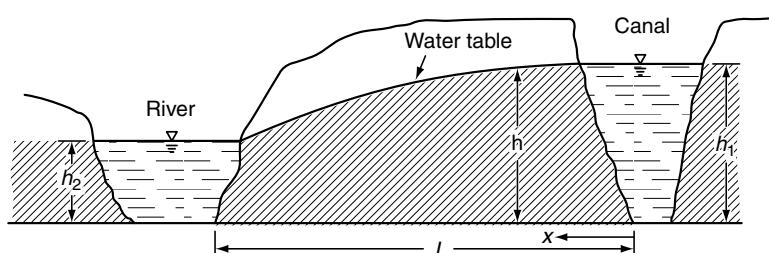

FIGURE 3.17 Example 3.10.

3.10 Land Subsidence

Pumping large volumes of water from confined aquifers at rates substantially larger than the natural recharge causes a contraction of the aquifer that can result into a downward movement of the land surface. In unconfined aquifers, groundwater pumping causes a downward movement of the water table that likewise can lead to a downward movement of the land surface. This downward movement of the land surface is called *subsidence* or *consolidation*. This movement can be a few centimeters to several meters. If the subsidence is not uniform, the differential settlement can produce severe damage to structures. Important subsidence has occurred in the San Joaquin Valley in California, in Mexico City, in Venice, around Shanghai, and in southern Taiwan.

Galloway et al. (1999) give a detailed description of subsidence in the United States where 17,000 square miles in 45 states have been affected. Man-induced subsidence is caused by three basic mechanisms (1) compaction of aquifer systems due to groundwater mining, (2) dewatering of organic soils, and (3) mass wasting through dissolution and collapse of rocks that are relatively soluble in water such as limestone, dolomite, and evaporites. Examples of these mechanisms are (1) the subsidence near Mendota in the San Joaquin Valley in California that in places, exceed 28 ft, (2) the extensive land subsidence caused by drainage and oxidation of peat soils in the Everglades in Florida, and (3) the dissolution and erosion of carbonate rocks (limestone and dolomite) in Missouri and solution of evaporites (salt and gypsum) in the Permian basin of Texas, New Mexico, Oklahoma, and Kansas.

Large subsidence that results from excessive pumping tends to occur in aquitards containing interbedded layers of silt and clay. As the drainage of the aquitard squeezes fluid from its interior, the internal stress increases. This causes the compressibility to increase by a factor of 20 to 100 resulting in compaction that is mostly not recoverable. Decrease of the groundwater pumpage can reduce and sometimes reverse the subsidence as is currently the case in the Harris-Galveston area in south central Texas (Hibbs, 1997). UNESCO has published a guidebook to studies of land subsidence due to groundwater withdrawals (Poland, 1984). The next section describes the calculation of subsidence by this mechanism.

Dewatering of organic soils accelerates the aerobic decomposition of the plant litter as compared to the anaerobic decomposition that occurs under undrained conditions. The natural rate of accumulation of organic soil is of the order of a few inches per century, whereas the rate of loss of drained organic soil can be 100 times greater.

Limestone dissolution and groundwater flow result in a geomorphology known as karst. It includes sinkholes, springs, caves, subsurface drainage networks. The frequency of occurrence of sinkholes can be accelerated by groundwater and land resources development as is the case in West Central Florida. Groundwater flow in karst aquifers is discussed in Chapter 21.

3.10.1 Calculation of Subsidence

Consider a unit area of a horizontal plane at a depth Z below the ground surface. The total downward pressure P_t due to the weight of the overburden on the plane is resisted partly by the upward hydrostatic pressure P_h and partly by the *intergranular pressure* P_i exerted between the grains of the material: $P_t = P_h + P_i$ or $P_i = P_t - P_h$.

A lowering of the water table results in a decrease of the hydrostatic pressure and a corresponding increase of the intergranular pressure. If P_{i1} and P_{i2} denote the intergranular pressures before and after a drop in the water table or piezometric surface, the vertical subsidence can be calculated as

$$S_u = Z \frac{P_{i2} - P_{i1}}{E} \quad (3.39)$$

where Z is the thickness of the soil layer and E is the modulus of elasticity of the soil. Typical ranges of values of E are given in Table 3.4. The reciprocal of the modulus of elasticity is the *compressibility*, generally designated by the symbol α and given in inverse Pascal or square meter per Newton. In general, the modulus of elasticity increases nonlinearly with the intergranular pressure. If there are layers of

TABLE 3.4 Modulus of Elasticity of Soils and Rocks

Material	Modulus of Elasticity N/cm ²
Peat	10–50
Clay, plastic	50–390
Clay, stiff	390–790
Clay, medium hard	790–1470
Sand, loose	980–1960
Sand, dense	4910–7850
Gravel, sandy gravel, dense	9806–19,620
Rock, fissured, jointed	14,710–294,200
Rock, sound	294,200–∞

Source: Jumikis, A.R. 1984. *Soil Mechanics*. Robert E. Krieger Co., Malabar, FL. Reproduced with permission.

different soil types, the subsidences are calculated separately for each layer and added to obtain the total subsidence. As the modulus of elasticity of clayey materials is much less than that of sand or gravel, most of the settlement occurs in the clayey layers.

The previous equation can also be used to calculate the rebound when the intergranular pressure decreases. Caution must be exercised because the modulus of elasticity is not the same for decompression as for compression. This is particularly the case for clays. For Boston blue clay, the rebound modulus of elasticity is only about 50% of that for compression (Bouwer, 1978, p. 323). If subsidence has occurred for a long time, complete rebound is unlikely.

Example 3.11

Consider a 60 m thick sand layer. The water table is located at a depth of 10 m below the ground surface. Calculate the total and the intergranular pressures at 10 m depth and at the bottom of the sand layer, given that the porosity of the sand is $n = 0.35$, its volumetric water content above the water table is $\theta = 0.08$, the specific weight of the solids is $\gamma_s = 25.5 \text{ kN/m}^3$, and the specific weight of the water is $\gamma = 9.81 \text{ kN/m}^3$.

Solution. At the water table the intergranular pressure, which is also the total pressure, is $P_t = 10[(1 - 0.35)25.5 + 0.08 * 9.81] = 173.6 \text{ kPa}$. The total pressure at the bottom of the sand layer is $P_t = 173.6 + 50[(1 - 0.35)25.5 + 0.35 * 9.81] = 1174.0 \text{ kPa}$. The hydrostatic pressure at the bottom of the sand layer is $P_h = 9.81 * 50 = 490.5 \text{ kPa}$. The intergranular pressure is thus $1174.0 - 490.5 = 683.5 \text{ kPa}$.

Example 3.12

If in Example 3.11 the water table drops 40 m, what is the change in intergranular pressure at the bottom of the sand layer? See Figure 3.18.

Solution. The depth to the water table would then be 50 m. The total pressure at the bottom of the sand layer is $P_t = 50[(1 - 0.35)25.5 + 0.08 * 9.81] + 10[(1 - 0.35)25.5 + 0.35 * 9.81] = 1068.1 \text{ kPa}$. The hydrostatic pressure is $P_h = 9.81 * 10 = 98.1 \text{ kPa}$. The intergranular pressure is $1068.1 - 98.1 = 970.0 \text{ kPa}$. The increase in intergranular pressure due to the 40 m drop in the water table is $970.0 - 683.5 = 286.5 \text{ kPa}$.

Example 3.13

Calculate the subsidence for the situation depicted in the previous problem if the modulus of elasticity of the sand is $10,000 \text{ N/cm}^2$ or 10^5 kN/m^2 .

Solution. The drop in the water table produces a linear increase in the intergranular pressure varying from 0.0 at the 10 m depth to 286.5 kPa at the 50 m depth. The average increment in intergranular pressure

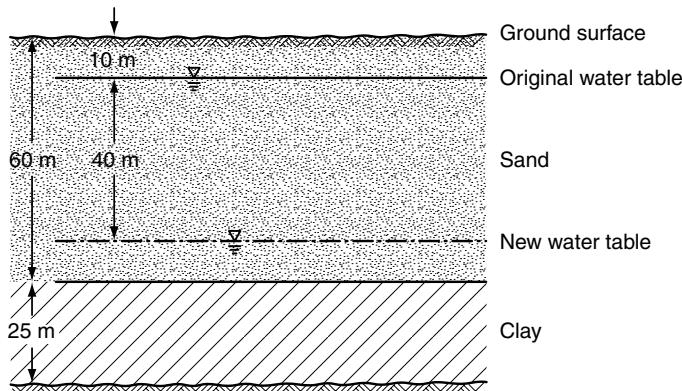

FIGURE 3.18 Subsidence problems.

is $(0 + 286.5)/2 = 143.25$ kPa and the settlement in the layer from 10 to 50 m is $S_{u1} = 40 * 143.25/10^5 = 0.0573$ m. The subsidence in the layer from 50 to 60 m is $S_{u2} = 10 * 286.5/10^5 = 0.0287$ m. The total subsidence is thus $0.0573 + 0.0287 = 0.086$ m.

Example 3.14

If the sand layer of the previous problem is underlain by a 25 m thick layer of clay with a modulus of elasticity of 10^3 N/cm 2 or 10^4 kN/m 2 , what is the total subsidence?

Solution. The increment of intergranular pressure of 286.5 kPa carries through the clay layer. The subsidence is thus $Z_3 = 25 * 286.5/10^4 = 0.716$ m. The total subsidence of the sand and clay layers is thus $0.086 + 0.716 = 0.802$ m. It is seen that 89% of the subsidence occurs in the clay layer because its modulus of elasticity is 10 times smaller.

3.10.2 Seepage Force

When water flows horizontally through an aquifer, the flow undergoes a reduction of pressure head because of friction. Thus the pressure on the upstream side of a small element is larger than on the downstream side. The water then exerts a net force on the aquifer element. The net force in the flow direction is the *seepage force*. This force can cause lateral displacements. If the drop of the water table in a length L is Δh , the horizontal movement is $S_h = \gamma_w \Delta h L / E_h$, where E_h is the modulus of elasticity in the horizontal direction. Letting i be the slope of the water table and $\Delta h = iL$, the horizontal movement, S_h , is calculated as

$$S_h = \gamma_w i \frac{L^2}{E_h} \quad (3.40)$$

If there is an upward vertical flow, the head loss due to friction, as the water flows into the pores, results in an increase in the hydrostatic pressure. This in turn results in a decrease of the intergranular pressure. A point can be reached when the upward seepage force is large enough to carry the weight of the sand grains so that the sand or silt behaves like a liquid. It has no strength to support any weight on it. This condition is known as *quicksand*. It is reached when the intergranular pressure vanishes and sand loses its bearing capacity. It can be shown that the upward hydraulic gradient necessary to produce quicksand is very close to one (Harr, 1962; Bauwer, 1978).

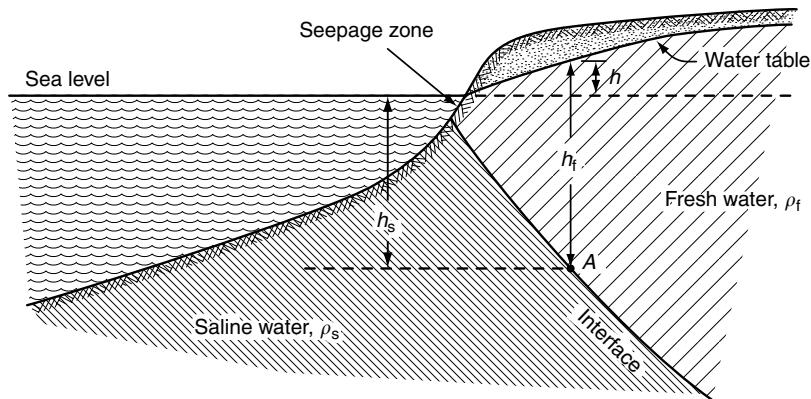

FIGURE 3.19 Coastal aquifer under natural conditions.

3.11 Salt Water Interfaces

The fresh and saline groundwaters have densities ρ_f and ρ_s . In coastal aquifers under natural conditions, the lighter fresh water lies over the heavier saline water and the flow is usually from the aquifer to the sea. Mixing of fresh water and salt water occurs only by molecular diffusion. Turbulent diffusion, the most effective mixing mechanism, is absent in aquifers. As a result, the mixing zone between salt water and fresh water is small compared with the thickness of the aquifer and an abrupt well-defined interface is usually assumed. At a point on the interface between the fresh and saline waters, the pressure of the fresh water, $\rho_f g h_f$, usually exceeds the pressure of the saline water, $\rho_s g h_s$, causing the flow from land to sea (Figure 3.19). But when pumping takes place in excess of replenishment, the drawdown of the water table creates a piezometric head in the fresh water that becomes less than in the adjacent salt water wedge. Then the saline water moves inland causing a *salt water intrusion*. The salt water may reach the well that becomes contaminated. Salt water intrusions have occurred in many coastal aquifers, for example, in the coastal aquifers of Florida, California, the Netherlands, Israel, and the South coast of England, mostly because of excessive pumping.

Assuming static conditions, the seepage zone is reduced to a point. The pressure at point A on the interface must be the same on the salt water side and on the fresh water side. Thus, the depth h_s of the interface below sea level is (Figure 3.19)

$$h_s = \frac{\rho_f}{\rho_s - \rho_f} h \quad (3.41)$$

where h is the height of the water table above sea level. With $\rho_s/\rho_f = 1.025$, the fraction in Equation 3.41 is equal to 40. For a confined aquifer, h is the fresh water piezometric head. The wedge of fresh water is known as the *Ghyben–Hertzberg lens* after the Dutch and German scientists who first obtained Equation 3.41.

When fresh water is pumped from an aquifer overlying a body of salt water, the drawdown of the fresh water table around the well causes a pressure reduction on the interface. This in turn causes the interface to rise below the well. This is called *upconing*. If the salt water cone reaches the well, it will discharge a mixture of salt and fresh water. For a water table well, assuming hydrostatic conditions, a rough approximation of the height δ of the cone is (Figure 3.20)

$$\delta = \frac{\rho_f}{\rho_s - \rho_f} s_w \quad (3.42)$$

where s_w is the drawdown at the well. More exact relationships are given in Chapter 12 on *Sea Water Intrusion into Coastal Aquifers* and, among others, in Bear and Dagan (1964), Dagan and Bear (1968), and Bear (1979).

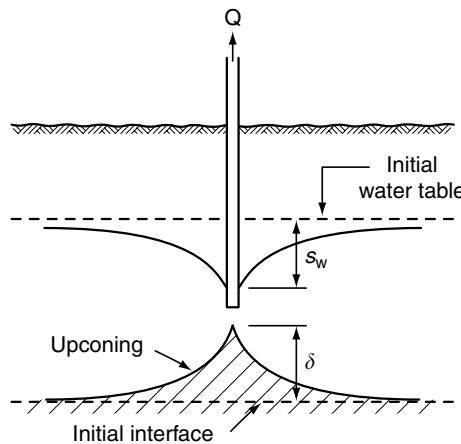

FIGURE 3.20 Upconing.

3.12 Groundwater Quality

The quality of groundwater is determined by the dissolved elements and gases and by the presence of suspended solids, bacteria, and viruses. The quality of the groundwater depends upon its natural and physical state and on the changes due to human activity. In its natural state, the dissolved elements and their concentrations depend on the chemical composition of the aquifer and on the travel time of the water through the rock formation. If the rock minerals are relatively soluble, slow water velocity and the ensuing long travel time result in a chemical equilibrium between the water and the rock medium. Because of the large range of flow velocities and of chemical compositions of the aquifers, there is a very wide range of compositions of the groundwater. Figure 3.21 shows the comparison of the range of concentrations of several constituents in groundwater to the concentrations of a 2.7 g sugar cube dissolved in a 2.7 l bottle, in a gasoline truck and in an oil tanker.

If the groundwater is no longer fit for a specific use, such as drinking, the water is said to be *contaminated*. If the water becomes heavily contaminated it is said to be *polluted*. Chapter 17 discusses in detail the types of groundwater contaminants, and a table of drinking water standards can be found in Table 32.2 in Chapter 32 on the legal framework for groundwater in the United States. Groundwater monitoring for water quality is discussed in Chapter 35.

Figure 3.22 illustrates the principal groundwater contaminant sources. These sources can be classified as *point*, *line*, or *nonpoint* (areal) sources. The geometry of the source affects the geometry of the contaminant plume. Contaminants can reach the groundwater in several manners. The contaminant may be *miscible*, that is, it can be dissolved in water, *immiscible*, that is, the water and the contaminant are in separate phases: lighter or heavier than water and the contaminant can be *adsorbed* on fine particles that are transported in suspension by the water. The miscible liquid and the water form a single phase. The movement of this single phase flow is governed by Darcy's law, discussed earlier in this chapter. Solutes are further classified as *conservative* and *nonconservative*. Conservative solutes remain stable in the groundwater: they do not react with the rock medium. Chloride solutions fall in this category. *Tracers* are conservative constituents that do not affect the viscosity and density of the water, such as fluoresceine in low concentration, for example. Conservative and nonconservative transport processes are discussed in detail in Chapter 18 and Chapter 19, respectively. Multiphase flow occurs primarily in the unsaturated zone, for example in the case of spills of hydrocarbons resulting in hydrocarbon and water phases. Multiphase flow is discussed in detail in Chapter 22 entitled "Contaminant Transport in the Unsaturated Zone—Theory and Modeling."

3.13 Transport Mechanisms of Dissolved Contaminants

The principal fate and transport mechanisms are advection, diffusion, dispersion, sorption, and decay. These processes are discussed in their simplest 1D form in this section and in more detail in Chapter 18 and Chapter 19. Other processes such as hydrolysis, volatilization, and biotransformation are not discussed in this section. Biotransformation is discussed in Chapter 31. The combined effects of advection, dispersion, and biodegradation on the transport of contaminants were visualized in the Cape Cod experiments described in LeBlanc et al. (1991) (see also Section 18.10.2) as well as in the Experiments in the Columbus Air Force Base in Mississippi that are discussed in Chapter 26.

3.13.1 Advection

Advection is the transport of solute by the bulk groundwater flow. The average pore velocity, v , is obtained by dividing the Darcy flux q (see Example 3.4) by the effective porosity n_e

$$v = \frac{q}{n_e} \quad (3.43)$$

The 1D mass flux due to advection, F , is the product of the quantity of water flowing and the concentration of dissolved solids

$$F = v n_e C \quad (3.44)$$

The change of mass of contaminant over time in a control volume

$$n_e \frac{\partial C}{\partial t} dx dy dz$$

is equal to the balance between the mass inflow and outflow of contaminant

$$F dz dy - \left(F + \frac{\partial F}{\partial x} dx \right) dz dy = - \frac{\partial F}{\partial x} dx dy dz = - n_e \frac{\partial}{\partial x} (vC) dx dy dz$$

Thus, for a conservative solute in a homogeneous aquifer, the 1D advective transport equation is

$$\frac{\partial C}{\partial t} = -v \frac{\partial C}{\partial x} \quad (3.45)$$

where x is distance in the flow direction [L], t is time [T], C is the concentration [$M L^{-3}$], and v is the advective transport velocity [$L T^{-1}$]. It is observed that a precise estimation of the flow velocity is needed for an accurate estimation of the transport. In sand/gravel aquifers with significant groundwater, the plume movement is dominated by advection. However, it must be recalled that Equation 3.45 is not valid in karstic aquifers for which Darcy's law is not applicable.

3.13.2 Diffusion

Diffusion is the flux of solute from a zone of higher concentration to one of lower concentration due to the Brownian motion of ionic and molecular species. Under steady-state condition, the diffusion flux F is described by Fick's first law

$$F = -D \frac{\partial C}{\partial x} \quad (3.46)$$

where D is the *diffusion coefficient* [$\text{L}^2 \text{T}^{-1}$]. For diffusion in water, D for different cations and anions ranges approximately from 6×10^{-10} to $9 \times 10^{-9} \text{ m}^2/\text{s}$ (Fetter, 1999). For diffusion in porous media, Freeze and Cherry (1979) suggest taking an *effective diffusion coefficient* $D^* = \omega D$ to account for the tortuosity of the flow paths with ω ranging from 0.5 to 0.01 for laboratory studies of nonadsorbed ions in porous geological materials. A value of $\omega = 0.7$ was obtained by Perkins and Johnson (1963) for uniform sand columns. The change of concentration over time inside a control volume subject to diffusion flux is given by Fick's second law

$$\frac{\partial C}{\partial t} = D^* \frac{\partial^2 C}{\partial x^2} \quad (3.47)$$

Consider the case of two adjacent saturated strata. The first one is initially with zero concentration throughout its length $C(x, 0) = 0$ and the second stratum maintains constant concentration at the interface $C(0, t) = C_0$. Because of the concentration step at the interface, diffusion takes place from the interface into the first stratum. Far away in the first stratum, where the effect of diffusion has not yet reached, the concentration is still zero, namely $C(\infty, t) = 0$. Crank (1956) gives the following solution of Equation 3.47 subject to the above boundary and initial conditions for the evolution of the concentration as a function of time and distance from the interface:

$$C(x, t) = C_0 \operatorname{erfc} \left(\frac{x}{2\sqrt{D^* t}} \right) \quad (3.48)$$

where erfc is the complementary error function

$$\operatorname{erfc}(u) = 1 - \operatorname{erf}(u) \quad (3.49)$$

and erf is the error function

$$\operatorname{erf}(u) = \frac{2}{\pi} \int_0^u e^{-v^2} dv \quad (3.50)$$

Tables of the error function and of the complementary error function can be found, for example, in Appendix 3.1.

Example 3.15

Consider a substance diffusing at the boundary of a clay layer with an effective diffusion coefficient of $10^{-9} \text{ m}^2/\text{sec}$. Find the time it will take to obtain a concentration of 15% of the initial concentration at a distance of 20 m.

Solution. Equation 3.48 yields $\operatorname{erfc}[x/(2\sqrt{D^* t})] = 0.15$. Interpolating from a table of complementary error functions, one finds $x/(2\sqrt{D^* t}) = 1.02$. Thus

$$t = \frac{400}{4 * 10^{-9} (1.02)^2} = 9.61 \times 10^{10} \text{ sec} \approx 3047 \text{ yr}$$

This shows that diffusion is a very slow mechanism but over geological time it can become important.

The importance of diffusion increases as flow velocities decrease. Thus diffusion may be the governing transport mechanism in unfractured clays with low hydraulic conductivities. Diffusion can generally be neglected in gravel aquifers with high flow velocities. It can also be significant in fractured porous aquifers. Flow and transport processes in fractured rocks are discussed in Chapter 20.

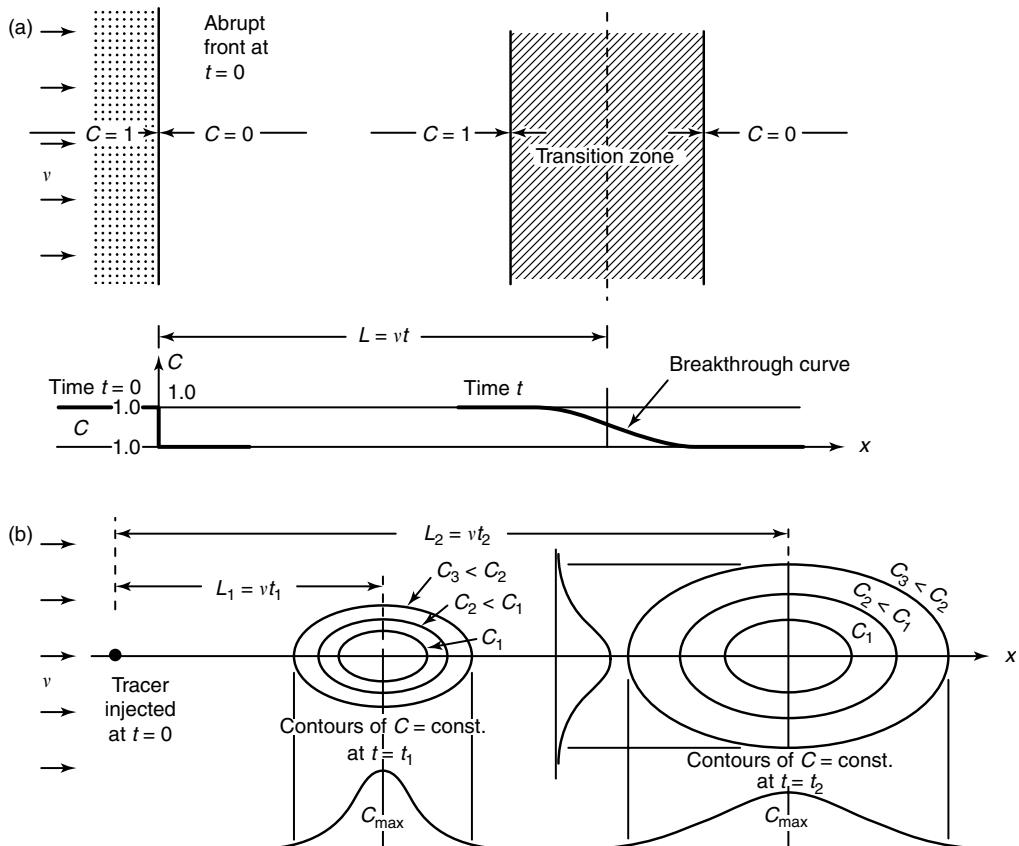

FIGURE 3.23 (a) Longitudinal and (b) transverse spreading due to mechanical dispersion. (From Bear, J. and Verruijt, A. 1987. *Modeling Groundwater Flow and Pollution*, Springer, Germany. With permission.)

3.13.3 Dispersion

Dispersion is the spreading of the plume that occurs along and across the main flow direction due to aquifer heterogeneities at both the small scale (pore scale) and at the macroscale (regional scale). Dispersion tends to increase the plume uniformity as it travels downstream. Factors that contribute to dispersion include faster flow at the center of the pores than at the edges, some pathways being longer than others, flow velocity larger in smaller pores than in larger ones. This is known as *mechanical dispersion*. The spreading due to both mechanical dispersion and molecular diffusion is known as *hydrodynamic dispersion*.

As a conceptual example, consider an aquifer with an abrupt concentration front at $t = 0$. At that time there is a *tracer*, such as sodium chloride, with a concentration $C = 1$ to the left of the front and there is no tracer to the right of the front, that is $C = 0$, as shown in Figure 3.23a. At a later time t , the *center* of the front has moved through a distance $L = vt$, where v is the pore flow velocity. But, due to dispersion, the tracer has spread around the center as shown in the lower part of Figure 3.23a. The plot of the S-shaped curve of the concentration at time t , $C(t)$, is called the *breakthrough curve*. In a second experiment, a quantity of tracer is injected at point $x = 0$ at time $t = 0$. At a later time t_1 , the center of the plume has moved a distance $L_1 = vt_1$ but, due to dispersion, the tracer has spread around the center with elliptical concentration contours as shown in Figure 3.23b. At time $t_2 > t_1$ the spreading has extended further as shown in the figure.

If one considers a *representative elementary volume* REV (see Chapter 4; Section 4.1.3), dispersion can be described by Fick's law (Equation 3.46). The *dispersion coefficient* D_L replaces the diffusion coefficient D^* and becomes a phenomenological coefficient that combines the effects of diffusion and dispersion. As mechanical dispersion is more pronounced in the longitudinal direction than in the transverse direction,

a longitudinal dispersion coefficient D_L and a transverse dispersion coefficient D_T are introduced. The longitudinal and the transverse dispersion–diffusion coefficients are defined as

$$D_L = \alpha_L v + D^* \quad (3.51a)$$

and

$$D_T = \alpha_T v + D^* \quad (3.51b)$$

where α_L is the longitudinal dispersivity [L], α_T is the transverse dispersivity [L], and v is the pore velocity [$L T^{-1}$].

The use of the Fickian theory to describe dispersion requires that the dispersion coefficients be travel-distance dependent or time dependent. A rough approximation based on averaging published data is (Gelhar, 1986, Gelhar et al., 1992)

$$\alpha_L \approx 0.1L \quad (3.52)$$

where L is the length of the flow path. Another estimate for flow lengths between 100 and 3500 m was given by Neuman (1990) as

$$\alpha_L \approx 0.0175L^{1.46} \quad (3.53a)$$

where α_L and L are in meters. Xu and Eckstein (1995) gave an estimate of α_L that does not have travel length limitation as

$$\alpha_L \approx 0.83(\log L)^{2.414} \quad (3.53b)$$

where α_L and L are in meters. This regression equation is based on weights of 1:2:3 to points of low, medium, and high reliability, respectively. When the scale is greater than 1 km, then the increase in longitudinal dispersivity becomes so small that it can be ignored without significant error.

The transverse dispersivity α_T is typically 1/10 to 1/100 of the longitudinal dispersivity α_L .

The combined advection–dispersion equation in 1D is thus

$$\frac{\partial C}{\partial t} = -v \frac{\partial C}{\partial x} + D_L \frac{\partial^2 C}{\partial x^2} \quad (3.54)$$

The solution of Equation 3.54 subject to the fixed step conditions:

$$\text{Initial condition} \quad C(x, 0) = 0 \quad x \geq 0$$

$$\text{Boundary condition} \quad C(0, t) = C_0 \quad t \geq 0$$

$$\text{Boundary condition} \quad C(\infty, t) = 0 \quad t \geq 0$$

has been given by Ogata and Banks (1961) as

$$C(x, t) = \frac{C_0}{2} \left[\operatorname{erfc} \left(\frac{x - vt}{2\sqrt{D_L t}} \right) + \exp \left(\frac{vx}{D_L} \right) \operatorname{erfc} \left(\frac{x + vt}{2\sqrt{D_L t}} \right) \right] \quad (3.55)$$

where x is the distance from the injection point. The argument of the exponential is the *Peclet number* ($P_e = vx/D_L$). The Peclet number is a measure of the ratio of the rate of transport by advection to the rate of transport by diffusion. For large Peclet numbers ($P_e > 100$), the advection dominates and the second term in the right-hand side becomes negligible. Figure 3.24 shows the behavior of the solution (3.55).

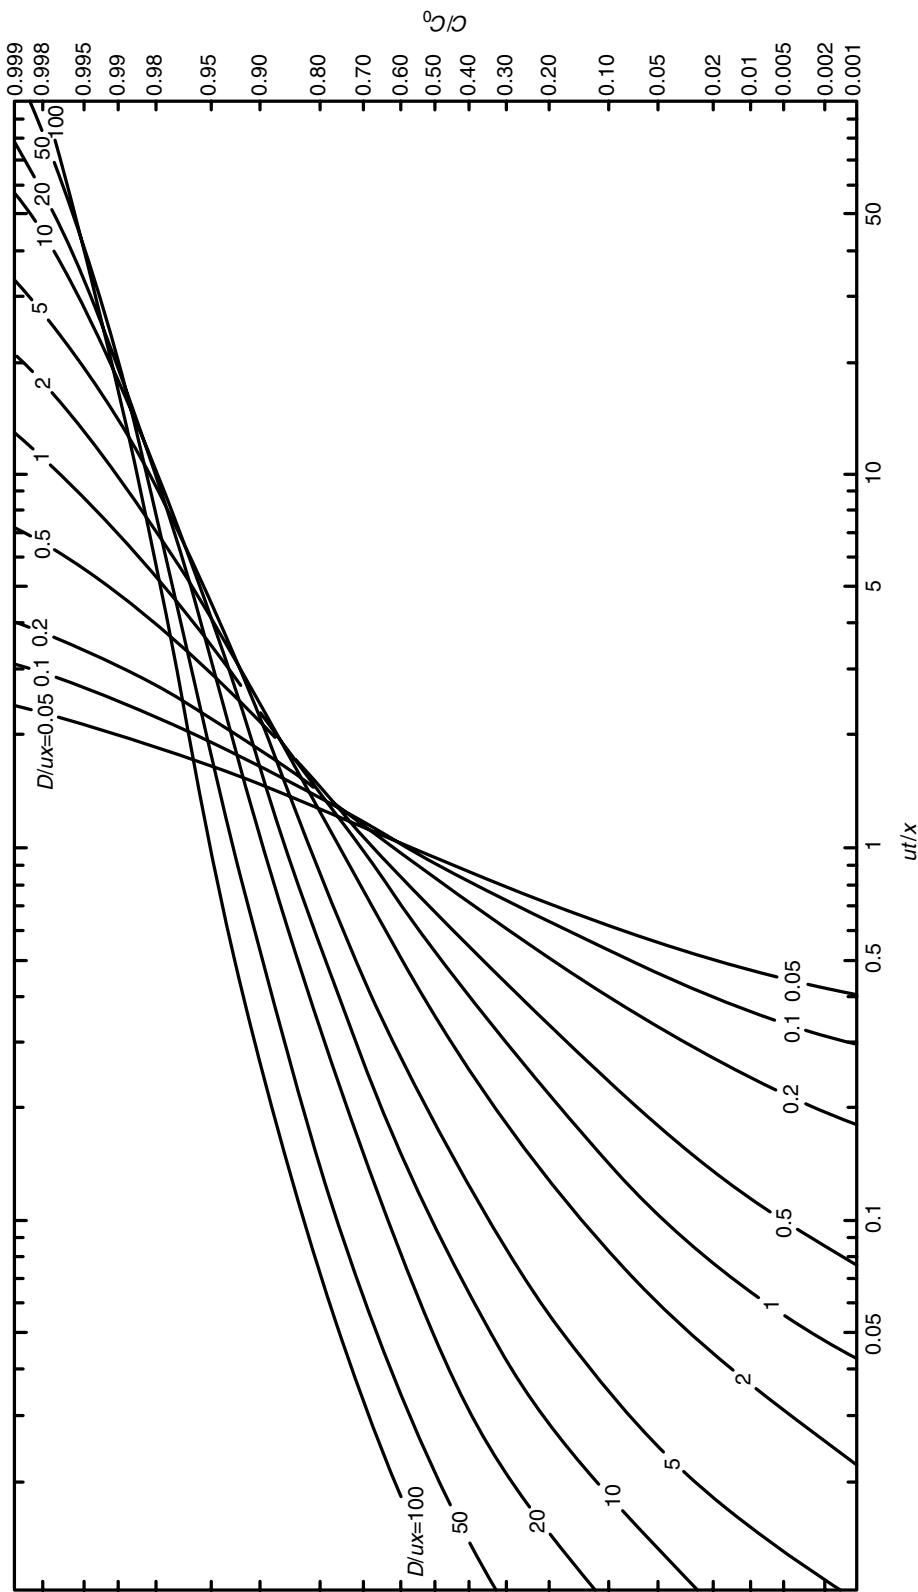

FIGURE 3.24 Solution of the 1D advection-dispersion equation. (From Ogata, A. and Banks, R.B. 1961. *A Solution of the Differential Equation of Longitudinal Dispersion in Porous Media*, U.S. Geological Survey, Professional Paper 411A, U.S. Government Printing Office, Washington, DC.)

If instead of a fixed step function a line source with continuous injection into the aquifer is considered as, for example, the leakage from a canal, Sauty (1978) found that in the solution (3.55) the + sign in the right hand side is replaced by a – sign. For large Peclet numbers the fixed step solution and the line source solution are essentially identical as the second term in the right hand side of Equation 3.55 is negligible. Further discussion and other boundary conditions are considered in Fetter (1999).

Example 3.16

An aquifer has a hydraulic conductivity of 2×10^{-5} m/sec, a hydraulic gradient of 0.003 m/m, an effective porosity $n_e = 0.2$, and an effective diffusion coefficient $D^* = 0.5 \times 10^{-9}$ m²/sec. A chloride solution with a concentration of 500 mg/l penetrates in the aquifer along a line source. Find the chloride concentration at a distance of 20 m from the point of entry, after a period of two years.

Solution. From Darcy's law, the pore flow velocity is

$$v = \frac{K}{n_e} dh/dx = \frac{2 \times 10^{-5} * 0.003}{0.2} = 3 \times 10^{-7} \text{ m/sec}$$

Using Neuman's approximation (3.53), the longitudinal dispersivity is

$$\alpha_L = 0.0175 * 20^{1.46} = 1.388 \text{ m}$$

The coefficient of longitudinal dispersion–diffusion, from Equation 3.51a is

$$D_L = 1.388 * 3.0 \times 10^{-7} + 0.5 \times 10^{-9} = 4.170 \times 10^{-7} \text{ m}^2/\text{sec}$$

The Peclet number is $P_e = vL/D_L = 3 \times 10^{-7} * 20 / 4.170 \times 10^{-7} = 14.387$. As $P_e < 100$ both terms in the right-hand side of Equation 3.55 need to be considered. Thus after 2 yr = $2 * 365 * 24 * 60 * 60 = 6.3072 \times 10^7$ sec and at a distance of 20 m the concentration is obtained from Equation 3.55 as

$$\begin{aligned} C &= \frac{500}{2} \left[\operatorname{erfc} \left(\frac{20 - 3 \times 10^{-7} * 6.3072 \times 10^7}{2\sqrt{4.170 \times 10^{-7} * 6.3072 \times 10^7}} \right) \right. \\ &\quad \left. + \exp 14.384 * \operatorname{erfc} \left(\frac{20 + 3 \times 10^{-7} * 6.3072 \times 10^7}{2\sqrt{4.170 \times 10^{-7} * 6.3072 \times 10^7}} \right) \right] \\ &= 250(\operatorname{erfc} 0.105 + 14.384 * \operatorname{erfc} 3.795) \approx 250 * 0.0.881984 = 220.5 \text{ mg/l} \end{aligned}$$

as the last $\operatorname{erfc}(\cdot)$ is negligible as seen in Appendix 3.1.

3.13.4 Sorption

Sorption refers to the exchange of molecules and ions between the solid phase and the liquid phase. It includes adsorption and desorption. *Adsorption* is the attachment of molecules and ions from the solute to the rock material. Adsorption produces a decrease of the concentration of the solute or, equivalently, causes a *retardation* of the contaminant transport compared with water movement. *Desorption* is the release of molecules and ions from the solid phase to the solute.

The relationship between the solute concentration in the adsorbed phase and in the water phase is called a *sorption isotherm*. The simplest expression is the *linear isotherm*

$$C_a = K_d C \quad (3.56)$$

where C_a is the sorbed concentration as mass of contaminant per mass of dry rock matrix [dimensionless], C is the dissolved concentration in mass of contaminant per volume of water [M L⁻³], and K_d is the

distribution coefficient [$\text{L}^3 \text{M}^{-1}$]. This expression implies that there is *equilibrium* between the adsorbed concentration and the dissolved concentration. This can be assumed when the adsorption process is fast compared with advection of contaminant.

The adsorption causes retardation in the migration of contaminants compared with advection. The contaminant transport gets more retarded as the fraction adsorbed increases. This effect can be described by a *retardation factor*, R_a , which for a linear isotherm, is

$$R_a = 1 + \frac{(1 - n)\rho_s}{n} K_d \quad (3.57)$$

where n is the porosity and ρ_s is the density of the solids. The retardation coefficient may take values from 1 to 10,000. The velocity of the solute front v_c (where the concentration is half that of the original concentration) is given by

$$v_c = \frac{v}{R_a} \quad (3.58)$$

The 1D advection–dispersion equation then becomes

$$\frac{\partial C}{\partial t} = -\frac{v}{R} \frac{\partial C}{\partial x} + \frac{D_L}{R_a} \frac{\partial^2 C}{\partial x^2} \quad (3.59)$$

where the term on the left side represents the time rate of change in storage of contaminant in the control volume, the first term on the right-hand side represents the retarded advective inflow–outflow, and the last term represents the retarded diffusion and dispersion. Solutions of the advection/dispersion/adsorption equation have been given by van Genuchten (1981).

The linear isotherm also applies to the case of organic compounds dissolved in groundwater. If the aquifer or soil contains at least 1% of organic carbon, then

$$K_d = K_{oc} f_{oc} \quad (3.60)$$

where K_{oc} is the organic carbon partition coefficient for the organic solute and f_{oc} is the fraction of organic carbon by weight in the soil. Methods for estimating K_{oc} from solubility data and from the octanol–water partition coefficient can be found, for example, in Fetter (1999) and in Spitz and Moreno (1996) (see Table 17.9 in Chapter 17 on “Groundwater Contaminants”; see also Section 3.15).

In this section it was assumed that the adsorption was fast compared with the advection of the contaminant. If instead the reaction is slow compared to the travel time and if chemical equilibrium cannot be attained, then it is necessary to describe the kinetics of the reaction. The reader is referred to Chapter 19 and to de Marsily (1986) or Fetter (1999).

3.13.5 Radioactive Decay and Degradation

The simplest model for decay of contaminants without transport is first order model:

$$\frac{\partial C}{\partial t} = -\lambda C \quad (3.61)$$

where λ is the first order decay rate constant [T^{-1}]. This relation also applies to *radioactive decay* and *degradation processes*. Equation 3.61 integrates as

$$C = C_0 e^{-\lambda t} \quad (3.62)$$

where C_0 is the concentration at time $t = 0$ and

$$\lambda = \frac{\ln 2}{T_{1/2}} \quad (3.63)$$

where $T_{1/2}$ is the *half-life* [T] of the radioactive isotope or of the degraded contaminant. Some values of radioactive and organic half-lives can be found in Spitz and Moreno (1996). The degradation causes a mass λC to disappear per unit volume per unit of time. The transport equation including decay is obtained by appending the quantity $-\lambda C$ to the right-hand side of Equation 3.59.

3.14 Monitoring, Site Remediation, and Landfills

Monitoring wells are necessary to measure the elevations of the water table or of the piezometric level, to collect samples of water for chemical analyses, to collect samples of nonaqueous phase liquids, to provide access for geophysical instruments, etc. The techniques used in groundwater monitoring and soil sampling are discussed in detail in Chapter 35 and the geophysical exploration techniques requiring wells and of other types are presented in Chapter 14 and Chapter 15.

Site remediation must consider at least source control and treatment of contaminated water or soil or both. Source control is necessary to prevent continuing discharge of contaminants to the subsurface or the groundwater. Treatment may be necessary to remove or substantially decrease the concentration of contaminants. Techniques for the proper design of landfills have been developed to eliminate or minimize the leakage to the vadose zone or the groundwater. These activities are regulated by legislation such as the Resource Conservation and Recovery Act (RCRA) and the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA).

These topics of regulations, landfills, and site remediation are the subject of Chapters 32, 33, and 36, respectively.

3.15 Parameter Values

In the previous sections, a number of equations have been presented that describe the flow of groundwater and the transport of contaminants. The application of these equations and of the models that are based upon them requires the use of a number of parameters. In general, the hydrogeological parameters and the pollutant characteristics exhibit great variability and hence uncertainty exists in the model predictions. In many applications data may not be readily available. It may then be useful to have access to a database that brings together most of the previous experience, at least until field experiments can be conducted.

Spitz and Moreno (1996) present an extensive compilation of hydrogeological and pollutant transport parameters and list the literature sources of these data: porosity, pp. 342–344; specific yield, p. 345; horizontal hydraulic conductivity, pp. 346–350; vertical hydraulic conductivity, pp. 351–352; specific storage, p. 353; unsaturated hydraulic conductivity relationships, pp. 353–354; moisture content relationships, p. 354; molecular diffusion coefficients, pp. 368–369; mechanical dispersion coefficients, pp. 370–371; field-scale dispersivities, pp. 372–379; K_d values for metals, pp. 380–389; K_d values for organics, pp. 390–392; organic carbon content of sediments, f_{oc} , pp. 392; empirical K_{oc} relationships, pp. 393–394; radioactive half-lives, p. 395; half-lives for organics, pp. 396–409.

Glossary

Adsorption: Adhesion of solute molecules and ions to the rock or soil material.

Advection: Mass transport of solute by the gross movement of groundwater.

Conservative solute: Solute that remains stable and does not react with rock or soil material.

Contaminant: Substance that causes contamination.

Contamination: Degradation of groundwater quality that renders it unfit for domestic consumption.

Darcy's law: An equation that relates the gross flow velocity (i.e., the discharge divided by the gross cross-section of an aquifer segment) to the product of the hydraulic conductivity and the gradient of the total head.

Datum: An arbitrary reference elevation from which the hydraulic heads are measured.

Desorption: Removal of molecules or ions from the rock or the soil.

Diffusion: The flux of solute from areas of higher concentration to areas of lower concentration due to random molecular motion.

Dispersion: The spread of solute due to heterogeneities of the pore sizes and shapes (mechanical dispersion) and heterogeneities in the aquifer (macrodispersion).

Dispersion coefficient: A coefficient in Fick's law that relates mass flux to concentration gradient.

Dispersivity: A constant of dispersion that, when multiplied by the pore flow velocity, yields the dispersion coefficient.

Dupuit–Forchheimer assumption: The assumption of primarily horizontal flow, neglecting unimportant vertical flow.

Effective porosity: The part of the porosity that is available for the fluid flow.

Elevation head: Difference in elevation between a point in a flow field and an arbitrary reference datum, the latter often being taken as the mean sea level.

Equipotential line: Line of equal potential, used in the flow net.

Fick's law: Equation that describes the diffusion or dispersion of solutes.

Force potential: The product of the acceleration of gravity and the total head; it represents the total energy per unit of mass.

Flow net: A network of streamlines and equipotential lines that intersect at right angles.

Half-life: The time required for the concentration of a solute to be reduced to half its initial value by radioactive decay or biodegradation.

Head: See elevation head, pressure head, velocity head, and total head.

Hydraulic gradient: The rate of change of the piezometric head with displacement in a given direction.

Karst: Geological formation characterized by features associated with dissolution and collapse of carbonate rocks such as underground drainage, caves, sinkholes, and deep gullies. Named after the Karst plateau, a barren limestone plateau in West Slovenia.

Leakage: Seepage of water through a semipermeable layer called aquitard.

Leaky aquifer: An aquifer into which there is seepage from an overlying formation.

Linear isotherm: A chemical equilibrium relationship in which the concentration of the adsorbed solute in the solid phase is assumed to be proportional to the concentration in the water phase.

Longitudinal dispersion coefficient: Dispersion coefficient in the flow direction.

Monitoring well: A nonpumping well used to measure water levels or to obtain water samples for chemical analysis.

Organic: Pertaining to carbon compound usually in rings or chains and with other elements, not necessarily derived from a living organism.

Peclet number: A dimensionless quantity that expresses the relative importance of convection and dispersion of solutes.

Piezometric head: The sum of the elevation head and the pressure head.

Pollutant: Substance that causes pollution.

Pollution: Excessive contamination of the environment, in this chapter specifically contamination of groundwater that renders it unfit for human consumption as a result of human or natural activities.

Pressure head: The ratio of the fluid pressure intensity to the fluid specific weight; it has the dimension of length.

Retardation factor: Ratio of transport velocity of nonreacting solute to transport velocity of solute reacting with the solid phase.

Reynolds number: A dimensionless quantity that expresses the relative importance of inertia forces and viscous forces in a flow system. A small Reynolds number is associated with laminar flow; a large Reynolds number is associated with turbulent flow.

Salt-water interface: A surface forming a common boundary between adjacent salt water and fresh water.

Sorption: Includes adsorption and desorption.

Specific discharge: The flow rate through a cross-section of an aquifer divided by the area of that cross-section.

Streamline: A line that is everywhere tangent to the flow velocity vector, also called the flow line. It is used in the construction of flow nets.

Suction: A negative pressure head found in the unsaturated zone.

Total head: The sum of the elevation head, pressure head, and velocity head. In flow through porous media, the velocity head is small and often neglected in the calculation of the total head.

Tracer: A conservative solute that is used to track the path of groundwater movement.

Transverse dispersion coefficient: Dispersion coefficient in the direction perpendicular to the flow direction.

Velocity head: The kinetic energy of the flow per unit weight of fluid; it has the dimension of length.

Velocity potential: The product of the hydraulic conductivity and the total head. By virtue of Darcy's law, the negative of the gradient of the velocity potential is a flow velocity (specific discharge or Darcy velocity).

Water balance: An accounting of the inflows and outflows in a fluid control volume.

Further Information

This chapter deals with elementary groundwater flow and transport problems. More advanced aspects are deferred to subsequent chapters. The following books give an introductory treatment of groundwater problems:

Heath R.C. [1995] provides an excellent, practical, and well-illustrated introduction to groundwater flow, well hydraulics, well tests, and groundwater pollution.

Hudak P.F. [2005] gives introductory principles and applications of hydrogeology for students with little or no background in hydrogeology. The principal topics covered are aquifers, monitoring wells, groundwater flow, wells and aquifer tests, groundwater quality and solute transport, and management of groundwater pollution.

Lowman S.W. [1972] gives a good introductory treatment of hydrologic properties of water-bearing materials, flowing wells, aquifer tests by well methods and by areal methods.

National Research Council [1984] provides a well-documented, nonmathematical introduction to groundwater contamination, including case studies.

Palmer C.M. [1996] gives a nonmathematical introduction to contaminant hydrogeology. A practical approach to completing investigations and the basics of collecting data are presented.

Price M. [1996] gives an excellent physical, nonmathematical, and exceptionally well-written description of the phenomena associated with groundwater occurrence, movement, pumping, and pollution.

There are a number of excellent textbooks on the subject of this chapter. Here we select a few:

Bedient et al. [1994] give a good introduction on groundwater hydraulics and then concentrate on groundwater quality, pollution of groundwater, contaminant transport, and groundwater management and remediation.

Deming D. [2002] discusses introductory hydrogeological theory and covers other topics such as environmental hydrogeology, heat transport, earthquakes, and petroleum migration. It is easy to read and is well illustrated.

Fetter C.W. [1999] focuses on the transport of contaminants in the saturated and unsaturated zones and gives practical information on monitoring and site remediation.

Fetter C.W. [2004] provides a general treatment of groundwater occurrence, movement, contamination, development and management, and models. It is a very popular textbook, now in its fourth edition.

Fitts C.R. [2002] has written a good undergraduate textbook. The mathematical modeling is treated in more detail than in the other chapters.

Freeze R.A. and Cherry J.A. [1979] have written a classical text that covers the fundamentals of groundwater geology, the flow and chemical evolution of groundwater, and groundwater contamination. It is still one of the favorite textbooks and a standard reference.

Schwartz F.W. and Zhang H. [2003] provide an excellent up-to-date textbook that integrates the concepts of hydrology with geology. Its organization is similar to that of Freeze R.A. and Cherry J.A. [1979] but includes many results developed in the interim time. It includes a section on groundwater modeling centered on MODFLOW and an excellent chapter on groundwater management. Transport processes are very well presented. There are some similarities to Domenico P.A. and Schwartz F.W. [1990] discussed below.

Todd D.K. [1980] wrote a good practical text on groundwater hydrology. This has recently been updated and extended as Todd D.K. and Mays L.W. [2005]. It contains a good listing of journals, web sites, and organizations with interests in subsurface flows and contaminants issues.

At a more advanced level there are also excellent textbooks among which we have selected the following:

Bear J. [1979] gives an excellent mathematical treatment of the laws and equations that describe the flow of groundwater and the management of groundwater.

Bear J. and Verruijt A. [1987] are concerned with the movement and accumulation of groundwater and pollutants in aquifers, and the construction of conceptual and mathematical models. A number of computer programs written in BASIC are included.

de Marsily G. [1986] presents a very lucid and classical treatment of the mathematics of groundwater flow and contaminant transport.

Domenico P.A. and Schwartz F.W. [1990] give an advanced treatment of physical and chemical hydrogeology. This book has more breadth and depth than Schwartz F.W. and Zhang H. [2003] discussed above.

Zheng C. and Bennett G.D. [2002] provide an excellent graduate level text on modeling of contaminant transport that is useful for students and practitioners. The first part includes advective transport, diffusion, dispersion, chemical reactions, and numerical formulation. Part 2 is concerned with field applications and part 3 is on advanced topics that include variable density, unsaturated flow and transport, and groundwater management.

If one needs a handy bibliographical reference of publications in the groundwater field there is Van der Leeden F. [1991]. He lists approximately 5600 references on general bibliographies, journals, texts, handbooks, and dictionaries, and references by subjects such as history, environment, geophysical exploration, well logging, hydraulics of soils and aquifers, theory of groundwater flow, pumping, well maintenance, pumping equipment, tracers, water quality, contamination, salt water intrusion, models, laws and regulations, management, etc.

4.1 Fundamentals

4.1.1 Introduction

The objective of this chapter is to show the logical development of equations that explain and predict the movement of groundwater in two- and three-dimensions (2D and 3D) as observed in nature. Flow of groundwater is a special case of fluid flow in porous media, and is governed by the laws of physics, in particular the laws of fluid mechanics. Fluid mechanics deals with the motion of fluids and with the forces exerted on solid bodies in contact with fluids. The fundamental principles are *conservation of mass* and *conservation of momentum*. It will be shown that these fundamental principles are sufficient to explain groundwater flow.

The purpose of this chapter is to obtain flow equations that enable to calculate the state variables of groundwater in each point of the flow domain and if necessary also in time. Therefore, groundwater flow

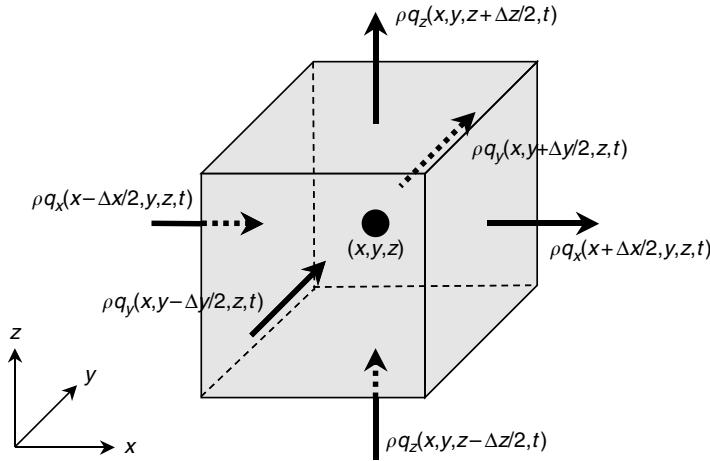

FIGURE 4.1 Mass conservation of the water phase in a reference elementary volume of saturated porous material.

equations are expressed in the form of partial differential equations, with the spatial coordinates, and time as independent variables. Hence, the variables that describe the state of groundwater are explicit functions of position and time, as for instance the groundwater potential

$$h = h(x, y, z, t) \quad (4.1)$$

where h represents the groundwater potential, the space position is denoted by Cartesian coordinates x, y, z , and time is represented by the symbol t ; x, y, z , and t are independent variables, while other variables, as h , are considered dependent, that is, with each set of values (x, y, z, t) variables can be associated, as $h(x, y, z, t)$.

Variables have dimensions. Whenever a new variable is introduced the dimensions will be indicated between brackets, []. The symbols used are: [L] for length, [T] for time, [M] for mass, and [F = ML/T²] for force. For practical applications the dimensions can be substituted by any consistent set of units. A logical choice would be the International Systems of Units (SI units), that is, meter (m), second (sec), kilogram (kg), and Newton (N), respectively; however, because groundwater flow is usually extremely slow often days are used instead of seconds for the time dimension.

4.1.2 Continuity Equation

The first fundamental law governing groundwater flow is the continuity equation, that expresses the principle of mass conservation. Consider in a fully saturated soil an *elementary control volume* centered around a point with Cartesian coordinates (x, y, z) as shown in Figure 4.1. It is customary and convenient to choose the z -axis vertical and pointing upward in the positive direction. The size of the elementary volume is Δx in the x -direction, Δy in the y -direction, and Δz in the z -direction. At a certain time instant, t , the mass of groundwater, M , present in the elementary control volume is given by

$$M = \rho n \Delta x \Delta y \Delta z \quad (4.2)$$

where ρ is the density of water with dimensions [M/L³], and n the porosity of the porous medium with dimensions [L³/L³]. The principle of mass conservation implies that the net result of inflow minus outflow is balanced by the change in storage versus time, or

$$\frac{\partial M}{\partial t} = \text{inflow} - \text{outflow} \quad (4.3)$$

Hence, it is necessary to calculate the groundwater flows through the sides of the elementary control volume in order to evaluate the net result of inflow minus outflow. The amount of groundwater flow is denoted by means of the flux, \mathbf{q} , which is the volumetric discharge or flow rate per cross-sectional area. The flux is a vector quantity with components along the x -, y - and z -directions: $\mathbf{q} = (q_x, q_y, q_z)$; the dimensions are [$L^3/T/L^2 = L/T$]. For instance, the mass inflow of groundwater along the left side, situated at $x - \Delta x/2$ of the control volume, is given by

$$\rho q_x(x - \Delta x/2, y, z, t) \Delta y \Delta z \quad (4.4)$$

As Δx is small, q_x at position $x - \Delta x/2$ can be approximated by a *Taylor series expansion*, where only zero and first order terms are maintained, such that this inflow can be calculated as

$$\left(\rho q_x - \frac{\Delta x}{2} \frac{\partial \rho q_x}{\partial x} \right) \Delta y \Delta z \quad (4.5)$$

In this expression ρq_x and its derivative with respect to x are evaluated at the center of the control volume. Similar expressions can be established for the other sides; for instance at the right side, at position $x + \Delta x/2$ of the control volume, the groundwater outflow is given by

$$\rho q_x(x + \Delta x/2, y, z, t) \Delta y \Delta z \approx \left(\rho q_x + \frac{\Delta x}{2} \frac{\partial \rho q_x}{\partial x} \right) \Delta y \Delta z \quad (4.6)$$

Hence, the total inflow minus outflow can be calculated as

$$\begin{aligned} & \left(\rho q_x - \frac{\Delta x}{2} \frac{\partial \rho q_x}{\partial x} \right) \Delta y \Delta z + \left(\rho q_y - \frac{\Delta y}{2} \frac{\partial \rho q_y}{\partial y} \right) \Delta x \Delta z + \left(\rho q_z - \frac{\Delta z}{2} \frac{\partial \rho q_z}{\partial z} \right) \Delta x \Delta y \\ & - \left(\rho q_x + \frac{\Delta x}{2} \frac{\partial \rho q_x}{\partial x} \right) \Delta y \Delta z - \left(\rho q_y + \frac{\Delta y}{2} \frac{\partial \rho q_y}{\partial y} \right) \Delta x \Delta z - \left(\rho q_z + \frac{\Delta z}{2} \frac{\partial \rho q_z}{\partial z} \right) \Delta x \Delta y \end{aligned} \quad (4.7)$$

Working out term by term and combining, yields following expression

$$-\left(\frac{\partial \rho q_x}{\partial x} + \frac{\partial \rho q_y}{\partial y} + \frac{\partial \rho q_z}{\partial z} \right) \Delta x \Delta y \Delta z \quad (4.8)$$

Using the *del operator* $\nabla = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$ [L^{-1}], this can be written as

$$-\nabla \cdot (\rho \mathbf{q}) \Delta x \Delta y \Delta z \quad (4.9)$$

where the dot represents the scalar product of two vectors.

The principle of mass balance states that the inflow minus outflow is equal to the change in storage; using Equation 4.2 the change in storage is given by

$$\frac{\partial M}{\partial t} = \frac{\partial}{\partial t} (\rho n \Delta x \Delta y \Delta z) \quad (4.10)$$

In this expression, the variables that can change with time are the density of the water, ρ , because water is compressible, and the porosity, n , and size of the control volume, $\Delta x \Delta y \Delta z$, because the porous medium can be compressible. However, for the latter it is assumed that under natural conditions only vertical

deformation needs to be considered, such that only n , and Δz depend upon time while $\Delta x \Delta y$ remains constant. Hence, the storage term can be worked out by using the rules of differentiation as

$$\begin{aligned}\frac{\partial M}{\partial t} &= \rho n \Delta x \Delta y \frac{\partial \Delta z}{\partial t} + \rho \frac{\partial n}{\partial t} \Delta x \Delta y \Delta z + \frac{\partial \rho}{\partial t} n \Delta x \Delta y \Delta z \\ &= \rho \left(\frac{n}{\Delta z} \frac{\partial \Delta z}{\partial t} + \frac{\partial n}{\partial t} + \frac{n}{\rho} \frac{\partial \rho}{\partial t} \right) \Delta x \Delta y \Delta z\end{aligned}\quad (4.11)$$

In addition, it is generally assumed that Δz changes only because of changes in porosity, while the solid phase may be considered as incompressible. Hence, the solid volume per unit surface area, $(1 - n)\Delta z$, remains constant in time, or

$$\frac{\partial}{\partial t}[(1 - n)\Delta z] = (1 - n) \frac{\partial \Delta z}{\partial t} - \Delta z \frac{\partial n}{\partial t} = 0 \quad (4.12)$$

from which we obtain the relationship between changes in n , and Δz

$$\frac{\partial n}{\partial t} = \frac{1 - n}{\Delta z} \frac{\partial \Delta z}{\partial t} \quad (4.13)$$

so that Equation 4.11 becomes

$$\frac{\partial M}{\partial t} = \rho \left(\frac{1}{\Delta z} \frac{\partial \Delta z}{\partial t} + \frac{n}{\rho} \frac{\partial \rho}{\partial t} \right) \Delta x \Delta y \Delta z \quad (4.14)$$

The compression of a porous formation can be expressed in function of the water pressure (Bear, 1972)

$$\frac{1}{\Delta z} \frac{\partial \Delta z}{\partial t} = \alpha \frac{\partial p}{\partial t} \quad (4.15)$$

where α is the elastic compressibility coefficient of the porous formation, with dimensions $[L^2/F]$, and p represents the groundwater pressure, $[F/L^2]$. The compressibility of the water can be expressed by a similar law

$$\frac{1}{\rho} \frac{\partial \rho}{\partial t} = \beta \frac{\partial p}{\partial y} \quad (4.16)$$

with β the compressibility coefficient of water, $[L^2/F]$. It is assumed that other effects on the density, such as solutes or temperature, are of minor importance and can be ignored. Substitution of these relations into Equation 4.14 gives

$$\frac{\partial M}{\partial t} = \rho \left[(\alpha + n\beta) \frac{\partial p}{\partial t} \right] \Delta x \Delta y \Delta z \quad (4.17)$$

In the derivation of Equation 4.17 we have followed the classical approach initiated by Jacob (1940) and finalized by Jacob (1950), where the elemental volume is allowed to deform. This was later criticized by, for example, De Wiest (1966) and Cooper (1966), arguing that a control volume should not deform. A more rigorous development using a fixed control volume and fixed coordinates is possible. In this case the movement of the solid phase has to be taken into account and also its conservation of mass. This has been achieved by Gambolati and Freeze (1973), Freeze and Cherry (1979), and Dagan (1989), resulting in an expression that is independent of the coordinate system and that corresponds to Equation 4.17 for the Cartesian coordinate system used here. Another more general approach considers 3D deformation as proposed by Biot (1955); a very good overview of this approach is given by Verruijt (1969).

The continuity equation is obtained by putting the change in storage, Equation 4.17, equal to the net inflow given by Equation 4.9, and dividing by $\Delta x \Delta y \Delta z$ to express the mass balance per unit volume of porous medium. This gives following result

$$\rho \left[(\alpha + n\beta) \frac{\partial p}{\partial t} \right] = -\nabla \cdot (\rho \mathbf{q}) \quad (4.18)$$

This relationship states the principle of mass conservation of groundwater in its most general form in a notation that is independent from the choice of a particular coordinate system. However, often density changes of water are of limited importance, and a simplified continuity equation can be obtained by dividing Equation 4.18 by ρ , and neglecting spatial density differences as

$$\left[(\alpha + n\beta) \frac{\partial p}{\partial t} \right] = -\frac{1}{\rho} \nabla \cdot (\rho \mathbf{q}) = -\nabla \cdot \mathbf{q} - \frac{1}{\rho} \mathbf{q} \cdot \nabla \rho \approx -\nabla \cdot \mathbf{q} \quad (4.19)$$

In this simplified form, the continuity equation expresses the groundwater balance on a volumetric basis. The left-hand side of the equation gives the change in volume of groundwater present in the porous medium; this change in storage can be due to compression of the medium and the water. The right-hand side of the equation gives the convergence or divergence of the volumetric flow rate of groundwater. When the flow rate is converging, the storage increases, and vice versa; when it diverges the storage decreases.

4.1.3 Macroscopic Approach

The obtained continuity equation is elementary, yet fundamental, but not without ambiguity. The problem arises from the fact whether Δx , Δy , and Δz can be made small enough to justify the truncation of the Taylor series to terms of order zero and one in the derivation of the inflows and outflows, as in Equation 4.6. Indeed, when the limit is taken of Δx , Δy , and Δz going to zero, the elementary control volume reduces to a point, such that the concept of a porous medium becomes illusive, because a point is either situated in the solid phase, the air phase, or the water phase, and variables as water content and groundwater flux lose their meaning.

Hence, it seems that groundwater flow problems cannot be formulated and solved correctly at the microscopic level. Of course, such a microscopic approach is not really of any interest in practice. But nevertheless, this ambiguity needs to be cleared up. This is achieved by abandoning the microscopic pore-scale level and by moving to a coarser macroscopic level. At this level microscopic features as solid grains and in between pore spaces are ignored, and the medium is conceived as a continuous space with average properties, such that porosity exists in any point of the medium, regardless of whether this point is situated in the solid phase or in the pore space. Also the variables describing the state and movement of water through the medium become macroscopic, therefore the average behavior is described, and not the fate of individual fluid particles moving in the pores of the porous medium.

The question remains how macroscopic variables need to be defined and interpreted. Different approaches are in use. The first and still most popular technique is the method of the representative elementary volume (REV), developed by Bear (1972), where macroscopic variables are defined as mean values over an REV, and attributed to the center of the REV. The exact size of the REV is not determined, but it is assumed that the size is much larger than the pore scale and much smaller than the scale of the porous medium. The results obtained with this approach yield macroscopic values for the groundwater flow, representing the average behavior of the fluid over the REV. The main advantage of the method is that macroscopic quantities have a clear physical meaning as they are measurable in the field by taking and analyzing soil samples of an adequate size. The main disadvantages are the loss of detailed information on the microscopic pore scale level, and the uncertainty due to the assumption that the values of the macroscopic variables are independent of the size of the REV. A detailed discussion can be found in Pinder (1983).

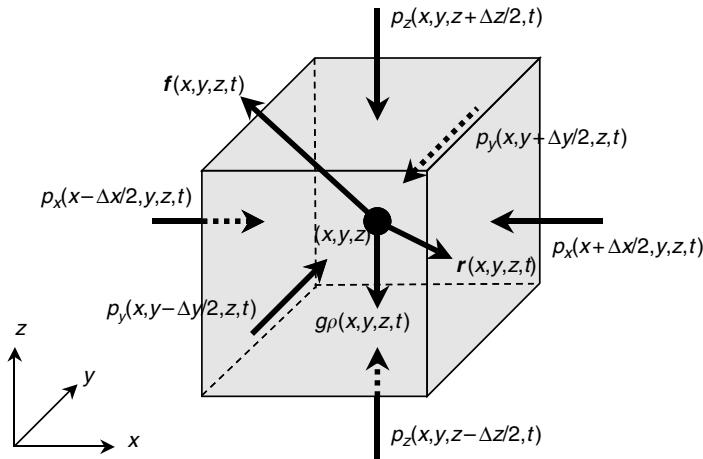

FIGURE 4.2 Forces acting in the water phase of a reference elementary volume of saturated porous material.

A second, more recent, technique is a statistical approach taking into account the uncertainty of the spatial distribution on a microscopic scale (Dagan, 1989). The microscopic arrangement of the porous medium is considered to be random, such that a set of media can be imagined with similar characteristics. The macroscopic variables are considered to be the averages of the variables of the media in the set. The main conceptual difficulty stems from the fact that statistical averaging should be carried out over an ensemble of realizations, whereas in practice usually only one particular porous formation is available from which the statistical information needs to be determined. This is feasible under the assumption of ergodicity, that is, the characteristics of one sample are assumed to be representative for the whole set. Hence, with the theory of random functions, macroscopic laws can be derived. As long as only relationships between averaged quantities are derived, with no special concern about their fluctuations, the results obtained are essentially the same as with the REV approach. However, the statistical technique is more powerful when dealing with fluctuations and deviations, as in case of particle or pollutant transport in groundwater.

4.1.4 Equation of Motion

The second fundamental law is the momentum equation, based on Newton's second law of motion, that is, forces induce motion or a change in motion. Consider the elementary control volume as used previously when deriving the continuity equation. An inventory of all forces acting on the water present in the control volume can be made in order to obtain a momentum equation. Under natural conditions, the forces to consider are pressure forces, gravity forces, and reaction forces of the solid matrix exerted on the fluid. As forces are vectors, it is necessary to consider different components along the different directions, as shown in Figure 4.2. For instance, along the left side of the control volume, pressure is acting on the water phase, which yields following contribution to the force balance in the x -direction

$$np(x - \Delta x/2, y, z, t)\Delta y\Delta z \quad (4.20)$$

where the porosity, n , appears in the expression because the water occupies only that fraction of the boundary. A similar force is acting on the right side, but in opposite direction as

$$-np(x + \Delta x/2, y, z, t)\Delta y\Delta z \quad (4.21)$$

Using truncated Taylor series expansions to relate the np -terms to the center of the control volume, the resulting pressure force component in the x -direction becomes

$$\left[\left(np - \frac{\Delta x}{2} \frac{\partial np}{\partial x} \right) - \left(np + \frac{\Delta x}{2} \frac{\partial np}{\partial x} \right) \right] \Delta y \Delta z = -\frac{\partial np}{\partial x} \Delta x \Delta y \Delta z \quad (4.22)$$

Similar expressions can be obtained for the pressure force components in the y -, and z -directions, acting on the other sides of the elementary control volume.

The gravity force only acts in the z -direction downwards, and is equal to the total weight of the water in the control volume

$$-\rho g n \Delta x \Delta y \Delta z \quad (4.23)$$

where g is the gravity constant, with dimension [L/T²].

The evaluation of the reaction force of the solid material on the water is more complicated. It consists of forces acting against the water pressure and friction forces due to the groundwater movement. These forces are extremely difficult to evaluate on a pore scale level, because the shape of the contact surface between the solid phase and the water phase is very complex from geometrical point of view. As, the exact contact surface is generally not known and would be very difficult to express in mathematical terms anyway, it is impossible to describe these forces on a microscopic scale, and one is forced to adapt a less precise macroscopic approach. Therefore, the reaction forces are defined as average body forces per water volume; the reaction force against the water pressure is denoted as $\mathbf{r} = (r_x, r_y, r_z)$, [F/L³], and the friction force against water movement, as $\mathbf{f} = (f_x, f_y, f_z)$, [F/L³]. Hence, the effect of these forces in the x -direction can be written as

$$(r_x + f_x) n \Delta x \Delta y \Delta z \quad (4.24)$$

with similar expressions in the y - and z -directions.

Now, the force balance in the three directions can be calculated as,

$$\left[-\frac{\partial np}{\partial x} + (r_x + f_x) n \right] \Delta x \Delta y \Delta z \quad (4.25)$$

$$\left[-\frac{\partial np}{\partial y} + (r_y + f_y) n \right] \Delta x \Delta y \Delta z \quad (4.26)$$

$$\left[-\frac{\partial np}{\partial z} + (r_z + f_z) n \right] \Delta x \Delta y \Delta z \quad (4.27)$$

Using the del operator, ∇ , these can be combined in one vector equation

$$[-\nabla(np) - \rho g n \nabla z + (\mathbf{r} + \mathbf{f}) n] \Delta x \Delta y \Delta z \quad (4.28)$$

This equation can be worked out further and simplified by dividing by the total volume of water present in the control volume, $n \Delta x \Delta y \Delta z$, yielding

$$-\nabla p - \frac{p}{n} \nabla n - \rho g \nabla z + \mathbf{r} + \mathbf{f} \quad (4.29)$$

Next, note that in case the fluid is at rest, the sum of all forces should be zero. Also, there would be no friction, $\mathbf{f} = 0$, and the pressure should be hydrostatic, $\nabla p = -\rho g \nabla z$, from which the overall reaction force, \mathbf{r} , of the grains opposing the water pressure can be evaluated (Dagan, 1989, p. 73) as

$$\mathbf{r} = \frac{p}{n} \nabla n \quad (4.30)$$

Substituting this result in the force balance simplifies Equation 4.29 to

$$-\nabla p - \rho g \nabla z + \mathbf{f} \quad (4.31)$$

In case of motion, the sum of forces is not zero, but equals the change in momentum of the fluid. Furthermore, the friction along the solid–water interface is non-zero and should be specified in function of the motion and friction properties. Several additional assumptions and considerations are necessary to arrive at a useful result.

From field observations it is known that groundwater flow under natural conditions is generally very slow, leading to a series of important simplifications. First, changes in momentum are also very small and can be neglected compared to other forces acting on the fluid. Hence, although the fluid is in motion, the forces acting on the fluid are approximately in equilibrium as seen in the force balance equation given below.

$$-\nabla p - \rho g \nabla z + \mathbf{f} \approx 0 \quad (4.32)$$

This type of flow is known in fluid dynamics as creeping motion. The active forces yielding motion, as pressure and gravity, are immediately balanced by resisting friction forces of equal strength. Of course, in porous media this is due to the large contact area between fluid and solid material which causes extensive friction, such that significant movement of the fluid is prevented.

Second, because water is a viscous fluid the friction force results from viscous momentum transfer between the stagnant pore walls and the moving fluid. In principle, the *Navier–Stokes equation* should enable to calculate the overall resistance force, but due to the complex geometry of the pore walls and pore sizes this is unfeasible in practice. However, in case of viscous creeping flow it is known that for an isotropic medium the overall resistance force has a component that is opposite in direction to the fluid flow, proportional to the viscosity of the fluid and the magnitude of the flow, and depending on the size of the obstacles in the flow field. Hence, it is justified to express the friction force as

$$\mathbf{f} = -\mu \underline{\underline{k}}^{-1} \cdot \mathbf{q} \quad (4.33)$$

where μ is the dynamic viscosity of the fluid, [FT/L²], \mathbf{q} is the flux as defined in the previous paragraph, here representing the amount and direction of the water movement, and $\underline{\underline{k}}$ is matrix with proportionality factors representing the geometry of the pore space; this matrix of coefficients has dimensions [L²] and is denoted as intrinsic permeability or sometimes permeability in short, for reasons that will become evident hereafter.

Substitution of Equation 4.33 into the force balance Equation 4.32, and rearranging, results in the following equation of motion

$$\mathbf{q} = -\mu^{-1} \underline{\underline{k}} \cdot (\nabla p + \rho g \nabla z) \quad (4.34)$$

The obtained expression, called Darcy's law, describes the flow of a fluid in a porous medium, also if the fluid has a variable density (and viscosity). Such conditions can be present in, for instance, coastal aquifers where salt and fresh water intermix, or in geothermal reservoirs where the density (and viscosity) of the fluid changes with temperature.

However, if density gradients are not significant, or when the density only changes due to compressibility of the fluid, the equation of motion can be simplified as

$$\mathbf{q} = -\rho g \mu^{-1} \underline{\underline{k}} \cdot \nabla(\phi + z) = -\underline{\underline{K}} \cdot \nabla h \quad (4.35)$$

where $\underline{\underline{K}} = \rho g \mu^{-1} \underline{\underline{k}}$ is the hydraulic conductivity matrix [L/T], $\phi = p/\rho g$ the pressure potential [L], and $h = \phi + z$ the groundwater potential [L]. Hence, Darcy's law, which originally was based on experimental evidence, is nothing else but an expression of equilibrium of forces reduced to a form suitable for describing flow of fluids in porous media. The derivation presented above sheds more light on the underlying principles and assumptions that result in Darcy's law, and enables to appreciate more its applicability in field conditions.

The basic assumption leading to Darcy's law is that movement of a fluid through a porous medium is very restricted, due to large friction forces that balance the driving forces for motion. Hence, Darcy's law is applicable in cases as water flow in soils or other types of granular porous media, or flow in fractured rocks, but not in cases as caves or other large sized openings, like cracks, fissures, and the like. These latter problems should be analyzed with viscous flow theories. Next, all ambiguity as discussed in case of the mass balance equation is also present here. Darcy's law is a macroscopic approach; on a microscopic level there are no such things as hydraulic conductivity or permeability. Hence, one might wonder about the errors involved in using a macroscopic approach as Darcy's law. However, this is not really an important issue, because the uncertainty in obtaining representative and accurate values for the hydraulic conductivity or permeability has a much larger effect on the overall accuracy. Indeed, field investigations show that natural porous media as aquifers and aquitards exhibit a large variability in conductive properties, which is difficult to quantify accurately by experimental or deterministic means.

4.1.5 Extensions of Darcy's Law

Darcy's law, like the momentum equation, is a vector relationship. When the flow is 3D, a Darcy's law can be written for each of the directions. For instance, in case of an isotropic porous medium, the conductivity matrix becomes a scalar, K , resulting in three Darcy equations

$$q_x = -K \frac{\partial h}{\partial x} \quad (4.36)$$

$$q_y = -K \frac{\partial h}{\partial y} \quad (4.37)$$

$$q_z = -K \frac{\partial h}{\partial z} \quad (4.38)$$

In case of other coordinate systems, the rules of vector-calculus should be applied in order to find the different expressions along the coordinate axes. For instance, in a cylindrical coordinate system (r, φ, z) , this becomes

$$q_r = -K \frac{\partial h}{\partial r} \quad (4.39)$$

$$q_\varphi = -\frac{K}{r} \frac{\partial h}{\partial \varphi} \quad (4.40)$$

$$q_z = -K \frac{\partial h}{\partial z} \quad (4.41)$$

In addition to heterogeneity, that is, porosity and conductivity variations from point to point, a dependence on direction is possible. This is the case for so-called anisotropic porous media, where due to some

direction-related properties, as preferential lining of fractures, stratifications, or layering, the conductivity changes depending upon direction. Such situations can be described by an extension of previous equations, where the conductivity becomes a symmetrical matrix, $\underline{\underline{K}}$, with following components

$$\underline{\underline{K}} = \begin{bmatrix} K_{xx} & K_{xy} & K_{xz} \\ K_{xy} & K_{yy} & K_{yz} \\ K_{xz} & K_{yz} & K_{zz} \end{bmatrix} \quad (4.42)$$

In Cartesian coordinates, Darcy's law becomes

$$q_x = -K_{xx} \frac{\partial h}{\partial x} - K_{xy} \frac{\partial h}{\partial y} - K_{xz} \frac{\partial h}{\partial z} \quad (4.43)$$

$$q_y = -K_{xy} \frac{\partial h}{\partial x} - K_{yy} \frac{\partial h}{\partial y} - K_{yz} \frac{\partial h}{\partial z} \quad (4.44)$$

$$q_z = -K_{xz} \frac{\partial h}{\partial x} - K_{yz} \frac{\partial h}{\partial y} - K_{zz} \frac{\partial h}{\partial z} \quad (4.45)$$

Notice that a potential gradient in one direction can yield flows in other directions. Especially in fractured porous media, anisotropy can be important. Anisotropy also plays a role in case of layered formations, usually of sedimentary origin. For horizontal layering only two conductivity components exist: a horizontal conductivity, K_h , and a vertical conductivity, K_v . In such case, Darcy's law becomes

$$q_x = -K_h \frac{\partial h}{\partial x} \quad (4.46)$$

$$q_y = -K_h \frac{\partial h}{\partial y} \quad (4.47)$$

$$q_z = -K_v \frac{\partial h}{\partial z} \quad (4.48)$$

These equations are useful in practice, also in view of the fact that effects of horizontal layering on the conductivity are rather the rule than the exception in ground layers. In case of folded or dipping layered formations also off-diagonal terms are important; all components of the conductivity tensor can be calculated from the dip angle and the conductivity values normal and parallel to the layering, following the rules of tensor calculus (Bear, 1972).

4.2 Groundwater Flow Equations

4.2.1 General

The groundwater flow equation is obtained by combining the continuity equation with Darcy's law. The most general form is obtained when the groundwater balance, Equation 4.19, is combined with the general Darcy Equation 4.34, yielding

$$(\alpha + n\beta) \frac{\partial p}{\partial t} = \nabla \cdot \left[\mu^{-1} \underline{\underline{k}} \cdot (\nabla p + \rho g \nabla z) \right] \quad (4.49)$$

Note that the porosity, n , on the left-hand side of the equation, depends upon the water pressure due to elastic deformation of the porous medium; actually the same holds for the permeability matrix, $\underline{\underline{k}}$.

However, these effects are generally ignored and the groundwater flow equation is expressed as a linear partial differential function of the water pressure as follows

$$S_p \frac{\partial p}{\partial t} = \nabla \cdot \left[\mu^{-1} \underline{\underline{K}} \cdot (\nabla p + \rho g \nabla z) \right] \quad (4.50)$$

where S_p is the storage coefficient of the porous medium related to water pressure changes, with dimensions $[L^2/F]$, and given by

$$S_p = \alpha + n\beta \quad (4.51)$$

This storage coefficient depends upon different soil and water properties. Hence, it is a rather complicated parameter, but fortunately it has a simple physical interpretation, that is, the storage coefficient gives the volume of water released by a unit volume of porous medium due to a unit decline of the water pressure.

It is instructive to write the obtained groundwater flow equation in Cartesian coordinates, taking into consideration different horizontal and vertical permeabilities

$$S_p \frac{\partial p}{\partial t} = \frac{\partial}{\partial x} \left(\frac{k_h}{\mu} \frac{\partial p}{\partial x} \right) + \frac{\partial}{\partial y} \left(\frac{k_h}{\mu} \frac{\partial p}{\partial y} \right) + \frac{\partial}{\partial z} \left[\frac{k_v}{\mu} \left(\frac{\partial p}{\partial z} + \rho g \right) \right] \quad (4.52)$$

This equation describes 3D movement of groundwater in its most general form. Notice that as a consequence the flow equation is expressed as a function of the water pressure, and not as a function of the groundwater potential. A state of the art of density-driven flow in porous media is for instance given by Holzbecher (1998).

4.2.2 Groundwater Flow Equation

In practice the general groundwater flow equation is not much used, because simplifications are usually introduced. When density-driven flow can be ignored, a groundwater flow equation can be obtained by combining the continuity equation with the simple form of Darcy's law, given by Equation 4.35, which yields

$$(\alpha + n\beta) \frac{\partial p}{\partial t} = \nabla \cdot (\underline{\underline{K}} \cdot \nabla h) \quad (4.53)$$

Making use of the fact that when the fluid density is constant, the water pressure differences in time can be related to the temporal variation of the groundwater potential

$$\frac{\partial p}{\partial t} = \rho g \frac{\partial h}{\partial t} \quad (4.54)$$

the resulting flow equation can be written as

$$\rho g (\alpha + n\beta) \frac{\partial h}{\partial t} = \nabla \cdot (\underline{\underline{K}} \cdot \nabla h) \quad (4.55)$$

This expression can be considered as a basic groundwater flow equation, because it enables to calculate the groundwater potential, h , in function of characteristics of the porous medium and the fluid. The equation is usually written in following form

$$S_s \frac{\partial h}{\partial t} = \nabla \cdot (\underline{\underline{K}} \cdot \nabla h) \quad (4.56)$$

where S_s is the specific storage coefficient, which depends upon compressibility of the porous medium and the fluid, then

$$S_s = \rho g(\alpha + n\beta) \quad (4.57)$$

The specific storage can be interpreted physically as the volume of water released by a unit volume of saturated porous medium due to a unit decline of the groundwater potential. The units are [L^{-1}]. Common values are usually very small because elastic deformation of ground layers or water is limited and certainly not noticeable in the field. Of course, plastic deformation of ground layers, consisting of materials like clay or peat, is excluded. Such deformations mainly occur under the influence of external loads or extensive groundwater pumping, and are noticeable in the field as *land subsidence*. Elastic deformations and storage in aquifers are described by Verruijt (1969). Theories on porous medium deformability under various soil conditions, with special attention to the subject of land subsidence, are discussed in part 2 of Bear and Corapcioglu (1984).

Written in Cartesian coordinates and using vertical and horizontal conductivities, the saturated groundwater flow equation becomes

$$S_s \frac{\partial h}{\partial t} = \frac{\partial}{\partial x} \left(K_h \frac{\partial h}{\partial x} \right) + \frac{\partial}{\partial y} \left(K_h \frac{\partial h}{\partial y} \right) + \frac{\partial}{\partial z} \left(K_v \frac{\partial h}{\partial z} \right) \quad (4.58)$$

This is the most used groundwater flow equation in practice. The equation is of the diffusive type, indicating that potential differences will be dissipated through the medium with a speed depending upon the value of K/S_s . Hence, because S_s is usually small, this process can be rather fast, unless K is also small as for instance in case of clay layers.

It is also interesting to write the flow equation in cylindrical coordinates (r, φ, z) as

$$S_s \frac{\partial h}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left(r K_h \frac{\partial h}{\partial r} \right) + \frac{1}{r^2} \frac{\partial}{\partial \varphi} \left(K_h \frac{\partial h}{\partial \varphi} \right) + \frac{\partial}{\partial z} \left(K_v \frac{\partial h}{\partial z} \right) \quad (4.59)$$

This equation is used for the prediction of groundwater flow toward wells, as for instance described by Hantush (1964), Walton (1970), Huisman (1972), and Kruseman and de Ridder (1991).

When groundwater flow is stationary, the variables become independent of time, and the flow equation is reduced to

$$\nabla \cdot (K \nabla h) = 0 \quad (4.60)$$

Written in Cartesian coordinates, and generalizing by using vertical and horizontal conductivities, we obtain

$$\frac{\partial}{\partial x} \left(K_h \frac{\partial h}{\partial x} \right) + \frac{\partial}{\partial y} \left(K_h \frac{\partial h}{\partial y} \right) + \frac{\partial}{\partial z} \left(K_v \frac{\partial h}{\partial z} \right) = 0 \quad (4.61)$$

This equation clearly shows that movement of groundwater is a *potential flow problem*. The driving forces for the movement are differences in groundwater potential and the resulting fluxes depend upon the conductive properties of the medium. In this way groundwater flow resembles other types of potential flow, like heat flow in heat conducting media under influence of temperature gradients, or electric flow in electric conductive materials under influence of electric potential differences. Many solutions have been obtained for groundwater flow problems based on the theory of potential functions, especially in 2D (Polubarnova-Kochina, 1962; Harr, 1962; Verruijt, 1970; Halek and Svec, 1979; Strack, 1989).

Another possibility is to assume that the groundwater flow occurs under unsaturated conditions, but we will not go into detail as these derivations can be found in Chapter 6.

4.2.3 Boundary Conditions

Groundwater flow equations are partial differential equations that relate the dependent variable, the groundwater potential, to the independent variables, the coordinates of the flow domain and the time. However, flow equations are only valid inside the flow domain, and not on the boundaries, because there the porous medium ends and other phenomena occur, which can influence the groundwater flow inside of the domain. These interactions at the boundaries are governed by other physical laws and have to be described separately by mathematical expressions, the so-called *boundary conditions*.

First, consider the time dimension. As transient groundwater flow equations contain first order partial derivatives vs. time, it can be shown mathematically that only conditions at the start, that is, at time zero, are needed. Hence, knowing the distribution of the dependent variable in the flow domain at the start is sufficient to describe the further evolution in time. For instance, in case the groundwater potential is the dependent variable, the so-called initial condition is

$$h(x, y, z, 0) = h_0(x, y, z) \quad (4.62)$$

where h_0 represents a known function of x , y , and z .

Boundary conditions for the physical domain are somewhat more complicated. Mathematically, it can be shown that because groundwater flow equations contain second order partial derivatives with respect to the space coordinates, conditions are required at every point of the boundary of the physical flow domain, even when the boundaries tend to infinity. Because the interaction between the inside groundwater flow and the outside world can be complex, and our ability to conceive such phenomena accurately is rather limited, boundary conditions are usually described in a simplified way.

Generally, three types of boundary conditions are considered. First type boundary conditions apply when the value of the dependent variable at the boundary is known. For instance, in case of groundwater potentials, such a boundary condition would be

$$h(x_b, y_b, z_b, t) = h_b(t) \quad (4.63)$$

where (x_b, y_b, z_b) represents a point on the boundary, and h_b is a known function of time. Such an expression is called a potential boundary condition, and is used when the groundwater is in contact with a water body, having a known potential h_b , as for instance a river, lake or reservoir, and so on. The key assumption is that whatever groundwater flow occurs at the inside of the flow domain and at the boundary, it will have no influence on the potential of the outside water body, such that this potential remains fixed as stated by the boundary condition.

Second type boundary conditions are so-called flux boundary conditions, where it is assumed that the amount of groundwater exchange through the boundary is known. The amount of water exchange is given by the groundwater flux component perpendicular to the boundary, such that the boundary condition can be expressed as

$$q_n(x_b, y_b, z_b, t) = q_b(t) \quad (4.64)$$

where q_n represents the flux component normal to the boundary, and $q_b(t)$ is a known function of time. A flux type condition can be expressed in function of the dependent variable, the groundwater potential, by using Darcy's law

$$q_n = -K \frac{\partial h}{\partial n} = q_b(t) \quad (4.65)$$

where $\partial h / \partial n$ represents the derivative of the potential perpendicular to the boundary. From mathematical point of view, the choice of the positive direction of the normal to the boundary determines whether q_n -values are positive or negative. However, in practice, often a simpler convention is used, by considering

fluxes entering the flow domain as positive, and outgoing fluxes as negative, regardless of the sense of the normal on the boundary.

A flux boundary condition implies that whatever the state and flow of the groundwater inside the flow domain and at the boundary, the normal flux is fixed by external conditions, and remains as stated by the boundary condition. Typical examples of such conditions are pumping wells, groundwater recharge, infiltration, and the like; in general any situation where the flux is supposedly fixed and known. An obvious example is an impervious boundary, as the flux component perpendicular to the boundary is strictly zero.

A third type boundary condition is a mixture of the two previous types. It applies when potential and normal flux components at the boundary are related to each other. Such condition applies in case of a flow domain in contact with a water body with a fixed potential, h_b , but where the exchange between the groundwater reservoir and the water body is restricted, due to the presence of some resistance. Mathematically, this condition is expressed as

$$q_n(x_b, y_b, z_b, t) = C_b[h_b(t) - h(x_b, y_b, z_b, t)] \quad (4.66)$$

where we have used the above mentioned sign convention for the normal boundary flux, and C_b represents the boundary conductance, with dimensions $[T^{-1}]$, between the groundwater reservoir and the outside water source or sink. This parameter can be explained physically as the conductive capacity of a permeable boundary layer, present between the groundwater flow domain and the water body, such that

$$C_b = K_b/D_b \quad (4.67)$$

where K_b is the hydraulic conductivity of the boundary layer, and D_b its thickness. For instance, this situation would apply when a river is in contact with the groundwater, but the interaction is restricted due to the presence of a mud layer in the river bed. Another example is a well with a clogged filter.

One of the most complicated boundary conditions is the water table. Actually, the water table is not a true boundary, because groundwater flow can cross the water table when transfer of water occurs between the unsaturated and saturated zones. However, because unsaturated flow is usually difficult to solve, it is often neglected and the water table is considered as an upper boundary of the groundwater flow domain. If such a simplification is used, it becomes necessary to specify the water table as a boundary condition. When the position of the water table is known, this is not so complicated, because the pressure at the water table is atmospheric such that the relative pressure is zero, and the following potential boundary condition applies

$$h(x_w, y_w, z_w, t) = z_w \quad (4.68)$$

where (x_w, y_w, z_w) represents a point on the water table. However, in most cases the position of the water table is not known exactly, and in addition to Equation 4.68 another boundary condition is needed to solve the groundwater flow problem, which now also includes the determination of the shape and position of the water table. Obviously, this additional condition should state something about the amount of flow crossing the water table. Several possibilities exist, the most simple one being the case where a steady water table acts as an impervious upper boundary, that is, no flow crosses this surface. This can mathematically be expressed as follows. An implicit equation describing the position of the water table is $h - z = 0$. The gradient of this expression is a vector perpendicular to the water table, and hence, the scalar product with the groundwater flux is zero if no water is crossing the water table, hence

$$\mathbf{q} \cdot \nabla(h - z) = 0 \quad (4.69)$$

When this is worked out further and Darcy's law is used to express the flux, the following boundary condition is obtained.

$$K_h \left(\frac{\partial h}{\partial x} \right)^2 + K_h \left(\frac{\partial h}{\partial y} \right)^2 + K_v \left(\frac{\partial h}{\partial z} \right)^2 - K_v \frac{\partial h}{\partial z} = 0 \quad (4.70)$$

This equation applies to every point (x_w, y_w, z_w) of the water table. Notice, that it is nonlinear, which is the price to pay for neglecting the unsaturated flow (there is no such thing as a free lunch). More complicated equations are needed when the water table is moving in time, or when certain flows are crossing the water table as for instance a groundwater recharge flux. It is not possible to go into more details here. For the interested reader these cases are discussed by Bear (1972). However, in practice, these types of boundary conditions are not used very much, because they are too complicated; therefore it becomes impossible to solve the groundwater flow problem accurately. Hence, approximate techniques are used. For instance, in case of numerical simulation models, the position of the water table is determined in an iterative way. For steady state problems, first a water table position is chosen above the expected position, then the groundwater flow equation is solved with a flux type boundary condition as Equation 4.65, and afterwards a new water table position is determined by identifying the surface where $h = z$, after which the procedure can be restarted. For transient conditions, the position of the water table is tracked in time, by equating the inputs and outputs of groundwater at the water table and calculating the resulting changes in water table position.

4.3 Hydraulic Approach to Groundwater Flow

4.3.1 Concept

In general, groundwater flow is 3D, but due to the geometry of ground layers, and differences in hydraulic conductivities, actual groundwater flows tend to be concentrated in certain directions, as illustrated in Figure 4.3. The reason for this is that ground layers usually extend horizontally over large distances, while the vertical dimensions are rather restricted. Also, due to the large variety in conductive properties, ground layers can be grouped into three classes: pervious formations or aquifers, semi-pervious formations or aquitards, and impervious formations. As water flows through a porous medium along the path of least resistance, groundwater moves predominantly longitudinally in the pervious formations, and transversely in the semi-pervious layers. Hence, due to the horizontal layering, groundwater flow is essentially horizontal in aquifers, and vertical in aquitards, as shown schematically in Figure 4.3b. Therefore, instead of considering the flow as 3D a simplified description of groundwater flow is possible, when horizontal flow components are considered to be dominant in aquifers and vertical components in aquitards, as shown in Figure 4.3c. This concept is termed the hydraulic approach to groundwater flow, because the movement is considered to be directed as water flow in pipes or channels (Polubarnova-Kochina, 1962; Bear, 1972, 1979). In case of a phreatic aquifer, this is also called the Dupuit–Forchheimer theory, after the two scientists who pioneered this approach in the second half of the 19th century.

4.3.2 Motion Equations

To have a clear understanding of the basic concepts of the hydraulic approach, it is convenient to start with the equation of motion, before discussing the continuity equation. Consider a confined aquifer, bounded by a bottom surface, $b(x, y)$, and an upper surface, $s(x, y)$, such that its thickness is given by $D = s - b$, as shown in Figure 4.4a. When the groundwater potential is measured by a piezometer, the actual depth of the piezometer is unimportant because vertical potential differences are very small. Hence, h is almost independent of z , and the total horizontal volumetric flow rate of the groundwater over the

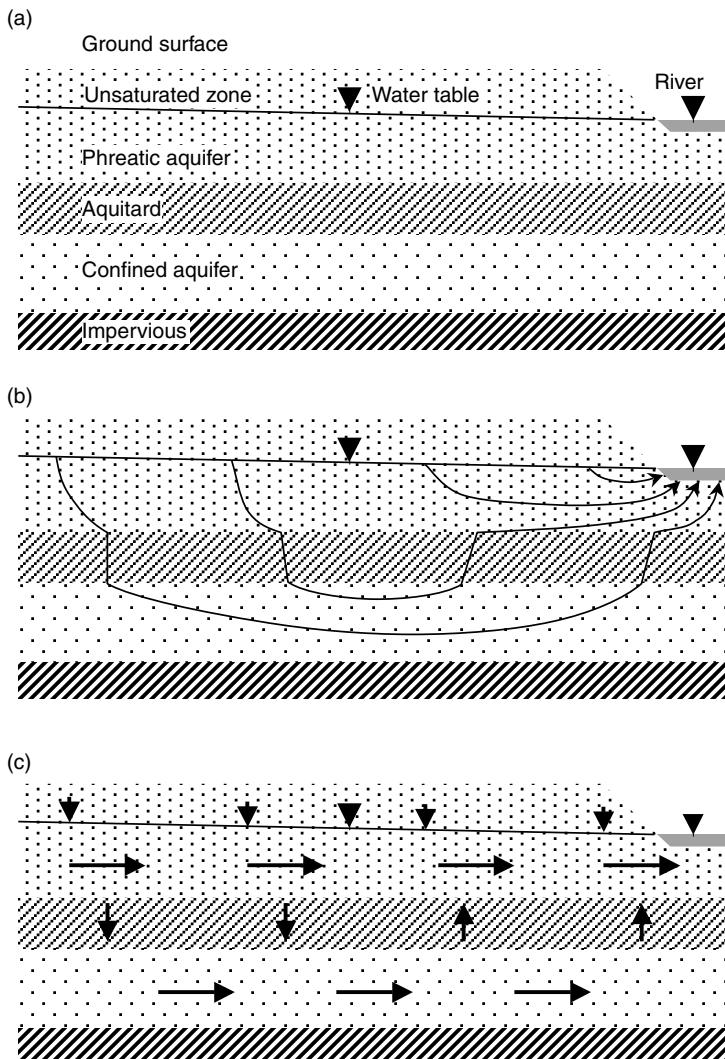

FIGURE 4.3 Occurrence and movement of groundwater: (a) types of hydrogeological layers, (b) actual groundwater flow paths, and (c) predominant groundwater flow directions.

entire thickness of the aquifer, in the x -direction, can be calculated as

$$Q_x = \int_b^s q_x dz = \int_b^s -K_h \frac{\partial h}{\partial x} dz \approx - \int_b^s K_h dz \frac{\partial h}{\partial x} = -T \frac{\partial h}{\partial x} \quad (4.71)$$

where Q_x is the x -component of the hydraulic groundwater flux, $\mathbf{Q} = (Q_x, Q_y)$, with dimensions volume per time per length [$L^3/TL = L^2/T$], and T is the transmissivity [L^2/T], defined as

$$T = \int_b^s K_h dz \quad (4.72)$$

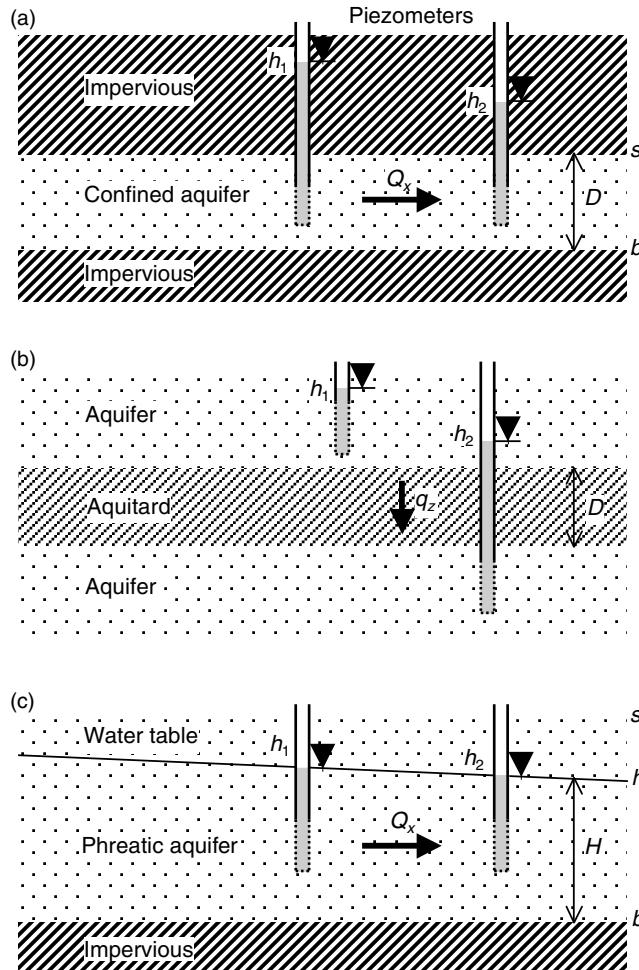

FIGURE 4.4 Hydraulic approach to groundwater flow: (a) horizontal flow in a confined aquifer, (b) vertical flow in an aquitard, and (c) horizontal flow in a phreatic aquifer.

In a similar way, the y -component of the hydraulic flux is given as

$$Q_y = -T \frac{\partial h}{\partial y} \quad (4.73)$$

The transmissivity is a parameter expressing the overall horizontal conductivity of a confined aquifer. Equation 4.72 and Equation 4.73 are extensions of Darcy's law, describing overall horizontal movement of groundwater in a confined aquifer.

In the case of an aquitard bounded by two aquifers, vertical flow can pass through the aquitard from one aquifer to the other, as depicted in Figure 4.4b. This vertical groundwater flux can be calculated by Darcy's law as

$$q_v = -K_v \frac{h_2 - h_1}{D} = C(h_1 - h_2) \quad (4.74)$$

where K_v is the vertical conductivity of the aquitard, D , its thickness, and the potential gradient is obtained from the difference in potential between the two aquifers bounding the aquitard. Parameter C ,

is the conductance, commonly called the leakage coefficient, and defined as

$$C = K_v/D \quad (4.75)$$

with dimensions $[T^{-1}]$; this coefficient expresses the leaking capacity of an aquitard, allowing vertical groundwater transfer between two aquifers bounding the aquitard. In case of a layered aquitard, the leakage coefficient is given by $C = [\int_b^s K_v^{-1} dz]^{-1}$. Hence, the leakage coefficient depends on the harmonic average of the conductivity over the aquitard thickness, while the transmissivity on the arithmetic average over the aquifer thickness.

The case of a phreatic aquifer is shown schematically in Figure 4.4c. The aquifer is bounded from below by its base, $b(x, y)$, and from above by the soil surface, $s(x, y)$. Actually, the true upper boundary of the phreatic aquifer is the water table. If a piezometer would be installed at a certain depth below the water table, the water level would reveal a potential, closer to the water table elevation, because vertical potential differences are insignificant as vertical groundwater flow is very small. Hence, h is nearly independent of z and almost coincides with the position of the water table, which is the upper surface of the saturated zone. Consequently, the total flow of groundwater passing horizontally through the aquifer in the x -direction, is given by

$$Q_x = \int_b^s q_x dz = \int_b^h q_x dz = \int_b^h -K_h \frac{\partial h}{\partial x} dz \approx - \int_b^h K_h dz \frac{\partial h}{\partial x} = -K_e(h - b) \frac{\partial h}{\partial x} \quad (4.76)$$

where horizontal flows in the unsaturated zone have been neglected, and K_e is an effective hydraulic conductivity given by

$$K_e = \frac{1}{h - b} \int_b^h K_h dz \quad (4.77)$$

In case of a homogeneous medium, K_e is equal to K_h . However, ground layers are generally heterogeneous, such that K_e needs to be determined by averaging; this is called upscaling or homogenization and requires careful consideration of the hydrogeological and stratigraphical characteristics of the subsurface and of the averaging procedure. Theoretical and mathematical aspects are discussed by, for example, Zijl and Nawalany (1993) and Rubin (2003).

An expression similar as Equation 4.76 can be obtained for the flow component in the y -direction

$$Q_y = -K_e(h - b) \frac{\partial h}{\partial y} \quad (4.78)$$

This is basically the approach of Dupuit, who postulated that groundwater flow in a phreatic aquifer is proportional to the slope of the groundwater table. Also, a transmissivity can be defined similar as for a confined aquifer, but this makes little sense, because the thickness of the phreatic aquifer changes with water table position, such that the transmissivity is not constant.

A simplification is possible when the base of the phreatic aquifer is horizontal. If the water table position is measured from this base, $H = h - b$, the hydraulic flow approximation can be written as

$$Q_x = -K_e H \frac{\partial H}{\partial x} = -K_e \frac{\partial}{\partial x} \left(\frac{H^2}{2} \right) \quad (4.79)$$

$$Q_y = -K_e H \frac{\partial H}{\partial y} = -K_e \frac{\partial}{\partial y} \left(\frac{H^2}{2} \right) \quad (4.80)$$

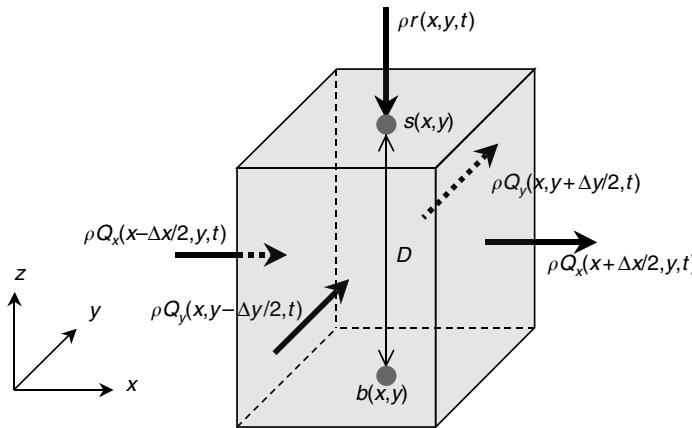

FIGURE 4.5 Mass conservation in a reference elementary volume in a confined aquifer.

Dupuit's equation is mostly known in this form. It replaces Darcy's law for describing overall horizontal groundwater flow in a phreatic aquifer.

4.3.3 Flow Equation for a Confined Aquifer

To obtain a flow equation, the equation of motion has to be combined with the continuity equation. The latter results from the principle of mass conservation applied to a control volume. Because, in the hydraulic approach the flow is integrated over the total depth of an aquifer, the control volume should be of a similar concept, that is, encompass the total vertical extent of the aquifer, as shown in Figure 4.5. Hence, the control box centered around a point (x, y) has sizes Δx and Δy in the horizontal plane, and extends from the bottom plane, $b(x, y)$, to the upper surface, $s(x, y)$, along the vertical, such that its vertical size is the aquifer thickness, D . The dimensions of the control volume reflect the hydraulic approach concept, that is, elementary sizes in the horizontal direction are of the same order as the thickness of the aquifer; hence, the aquifer is considered to be essentially a 2D object.

The groundwater mass inflow minus outflow in the control volume can be calculated as

$$[\rho Q_x(x - \Delta x/2, y, t) - \rho Q_x(x + \Delta x/2, y, t)]\Delta y + [\rho Q_y(x, y - \Delta y/2, t) - \rho Q_y(x, y + \Delta y/2, t)]\Delta x + \rho R(x, y, t)\Delta x\Delta y \quad (4.81)$$

where $R(x, y, t)$ [L/T] is a recharge or net exchange of groundwater passing through the base or through the upper surface of the aquifer. Actually, we consider here a semi-confined aquifer; in case of a truly confined aquifer R would be zero. The sign convention for R is that inputs are considered positive, irrespective of the direction along the z -axis.

Using Taylor series expansions, the total net inflow in the control box, becomes

$$\left(-\frac{\partial \rho Q_x}{\partial x} - \frac{\partial \rho Q_y}{\partial y} + \rho R \right) \Delta x \Delta y \quad (4.82)$$

This should be balanced by a change in storage. The amount of water mass, M , present in the control volume, is given by

$$M = \int_b^s \rho n dz \Delta x \Delta y = \rho n D \Delta x \Delta y \quad (4.83)$$

where in the last term we have considered average porosity and density values over the thickness of the aquifer. The change in storage can be calculated as

$$\frac{\partial M}{\partial t} = \left(\frac{\partial \rho}{\partial t} nD + n \frac{\partial n}{\partial t} D + \rho n \frac{\partial D}{\partial t} \right) \Delta x \Delta y \quad (4.84)$$

where compression of the water and aquifer is considered, and vertical deformation of the aquifer. Using the relationships for expressing the compressibility of water and porous medium and assuming that the solid grains are incompressible, this can be worked out as

$$\frac{\partial M}{\partial t} = \rho D(\alpha + n\beta) \frac{\partial p}{\partial t} \Delta x \Delta y = \rho^2 g D(\alpha + n\beta) \frac{\partial h}{\partial t} \Delta x \Delta y \quad (4.85)$$

Making use of the definition of specific storage coefficient, Equation 4.57, this can also be written as

$$\frac{\partial M}{\partial t} = \rho S_s D \frac{\partial h}{\partial t} \Delta x \Delta y = \rho S \frac{\partial h}{\partial t} \Delta x \Delta y \quad (4.86)$$

where S is the aquifer storage coefficient or storativity, defined as

$$S = S_s D = \rho g (\alpha + n\beta) D \quad (4.87)$$

which is a measure of the overall aquifer storage properties. The storativity is dimensionless. It can be defined as the volume of groundwater released by a confined aquifer per unit horizontal aquifer surface and per unit decline of groundwater potential, all in accordance with the hydraulic approach, where variables are considered averaged or integrated over the vertical dimensions of the aquifer.

Combining Equation 4.80 and Equation 4.84, dividing by $\rho \Delta x \Delta y$, and neglecting density gradients, results in

$$S \frac{\partial h}{\partial t} = - \frac{\partial Q_x}{\partial x} - \frac{\partial Q_y}{\partial y} + R \quad (4.88)$$

Using the expression for horizontal hydraulic flow given by Equation 4.71 and Equation 4.73, results in the following hydraulic groundwater flow equation for a (semi-)confined aquifer

$$S \frac{\partial h}{\partial t} = \frac{\partial}{\partial x} \left(T \frac{\partial h}{\partial x} \right) + \frac{\partial}{\partial y} \left(T \frac{\partial h}{\partial y} \right) + R \quad (4.89)$$

Compared to saturated 3D groundwater flow, Equation 4.58, it can be noted that this equation contains no z -dimension, which is the main simplification resulting from the hydraulic approach. Also, as a consequence, the needed porous medium properties are transmissivity and storativity, which are aquifer properties integrated over the vertical dimension. Therefore, Equation 4.89 is very useful in practice, because it is simpler and needs less detailed knowledge about the medium properties. Care should be taken when applying this equation to practical situations, because boundary conditions are required in accordance with the hydraulic approach. This implies that boundary conditions should be independent of the elevation, that is, they should apply to the total aquifer thickness. For instance, pumping by a fully penetrating well can be considered with the hydraulic approach, but not a partially penetrating well because this induces vertical potential gradients in the aquifer.

4.3.4 Flow Equation for a Phreatic Aquifer

A flow equation for a phreatic aquifer based on the hydraulic approach can be obtained as for a confined aquifer, but some complications occur. The control volume is similar; it is centered around the point (x, y) ,

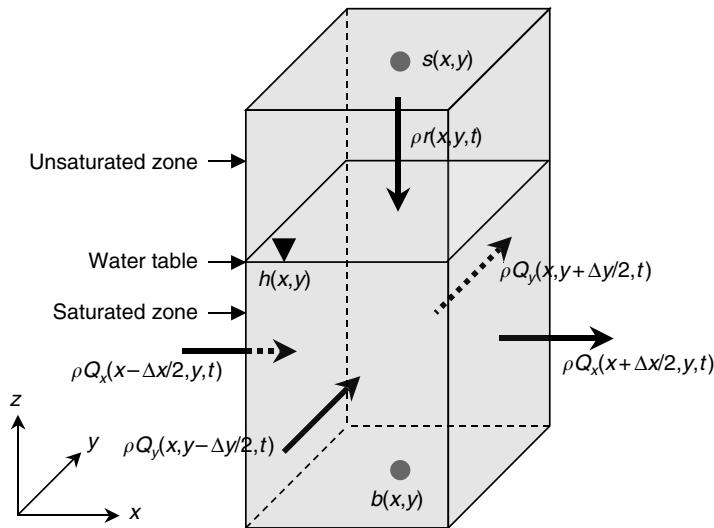

FIGURE 4.6 Mass conservation in a reference elementary volume in a phreatic aquifer.

with sizes Δx and Δy horizontally, and extends from the base to the soil surface, as shown in Figure 4.6. Notice that the control volume includes the unsaturated zone, because the groundwater flow and in particular the resulting changes in the water table elevation will also have effects on the water balance in the unsaturated zone, which have to be taken into account.

The inflow minus the outflow depends upon the hydraulic horizontal flow components in the saturated zone and possible vertical inputs or outputs through the upper or lower boundary. For the latter, we can think of water exchanges at the soil surface as infiltration and evapotranspiration. Actually, the true input from above in the phreatic aquifer occurs at the water table, and is also the result of processes occurring in the unsaturated zone. As groundwater flow is a slow process, it is reasonable to consider an average flux over long periods of time for the recharge, and if we consider no horizontal flow in the unsaturated zone (often a good approximation), the average flux at the upper boundary equals the average flux at passing through the water table. Hence, the water balance can be equated in a control box with sizes Δx and Δy in the horizontal plane, and extending from the bottom plane, $b(x, y)$, to the top surface, $s(x, y)$, similar as in Equation 4.81 and when developed further by Taylor series expansions the same expression as Equation 4.82 is obtained. Of course, in addition to recharge at the water table, transfer could also take place through the base of the phreatic aquifer if an aquitard is present connected to an underlying aquifer, in which case another R -term should be added to the equation.

Somewhat more complicated than in case of a confined aquifer is the calculation of the change in storage in a phreatic aquifer, because the position of the water table water table is not fixed in time, and part of the saturated zone can become unsaturated, or vice versa. The total mass of water present can be calculated by integration along the vertical

$$M = \Delta x \Delta y \int_b^s \rho \theta dz \quad (4.90)$$

where θ is the volumetric water content [L^3/L^3]; the water content is equal to the porosity in the saturated part below the water table, and is either smaller than or equal to the porosity in the unsaturated zone above the water table.

The change in storage is given by

$$\frac{\partial M}{\partial t} = \Delta x \Delta y \frac{\partial}{\partial t} \int_b^s \rho \theta dz \quad (4.91)$$

Now, it becomes clear why the control volume extends to the soil surface, as changes in storage can be significant when there are differences in water content especially in the unsaturated zone. In presence of such changes, storage effects due to compressibility of the water or porous medium become insignificant and can be neglected. It follows that the change in storage can be evaluated as

$$\frac{\partial M}{\partial t} \approx \rho \Delta x \Delta y \int_b^s \frac{\partial \theta}{\partial t} dz \quad (4.92)$$

The exact evaluation of the integral is not simple. The situation is shown schematically in Figure 4.7. If the water table drops by an amount Δh , the change in storage depends upon the moisture distribution above the water table, before, and after the drop in water table position. Actually, time will also have an influence because the water in the unsaturated zone needs time to percolate downwards to the water table. Hence, the exact change in storage is difficult to calculate, unless unsaturated flow is taken into consideration, which is exactly what one would like to avoid by applying the hydraulic approach. Hence, the storage needs to be approximated in a more simple way. This can be achieved as follows. Consider the situation depicted in Figure 4.7a, where the soil surface is high above the water table. Under normal average conditions, the distribution of the water content will vary with elevation above the water table. It will equal the porosity at the water table, and generally will decrease with height above the water table, gradually approaching a residual water content, which is characteristic for the unsaturated zone far above the water table. This residual water content is denoted by θ_r . Now, if the position of water table is changed by an amount Δh , and given sufficient time, the moisture distribution will eventually be similar as before, by

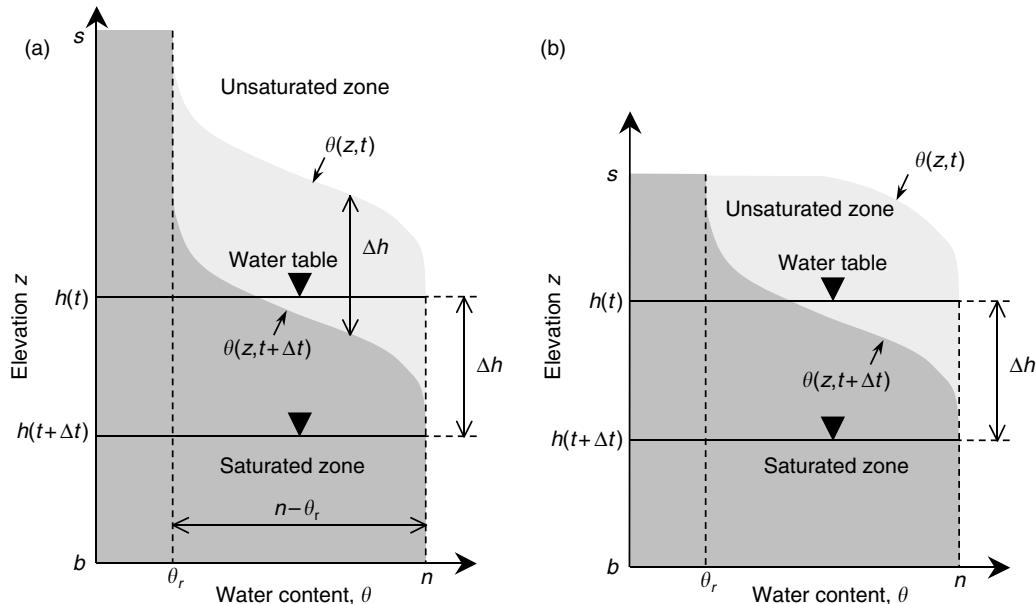

FIGURE 4.7 Storage and release of groundwater in a phreatic aquifer due to changes in water table position: (a) deep water table, and (b) shallow water table.

shifting over a distance Δh . Hence, the volumetric difference in storage can be calculated as

$$\int_b^a \frac{\partial \theta}{\partial t} dz = \int_b^a \lim_{\Delta t \rightarrow 0} \left[\frac{\theta(z, t + \Delta t) - \theta(z, t)}{\Delta t} \right] dz = \lim_{\Delta t \rightarrow 0} \left[(n - \theta_r) \frac{\Delta h}{\Delta t} \right] = (n - \theta_r) \frac{\partial h}{\partial t} = S_y \frac{\partial h}{\partial t} \quad (4.93)$$

where $S_y = n - \theta_r$ [−] is defined as the specific yield, that is, the amount of water released per volume of porous medium when changing from saturated state to unsaturated state high above the water table. In reality, things are not that simple. First, it could be possible that the soil surface is not situated far above the water table, as shown in Figure 4.7b, such that the mathematical derivation given above is not valid. Second, retardation effects will occur, because conductivities in the unsaturated zone are generally much smaller than in the saturated zone, and, consequently, water movement in the unsaturated zone lags behind saturated groundwater flow. Third, soil heterogeneity complicates the concept of residual water content and equilibrium moisture distributions in the unsaturated zone. Hence, in practice the change in storage will usually be smaller. Therefore, Equation 4.93 remains only useful when the concept of specific yield is extended to match any particular situation. This gross simplification is justified in view of the fact that with the hydraulic approach groundwater flow is described in a simplified way. However, the concept of specific yield has a clear physical interpretation, similar as storativity, that is, the volume of water released by a phreatic aquifer per unit horizontal aquifer surface and per unit decline of the water table. Of course, the position of the water table, the speed of water table decline, and the soil heterogeneity play an important role in this.

When we combine the obtained storage equation with the net inflow, Equation 4.82, divide by $\rho \Delta x \Delta y$, and use the hydraulic flow approximation, given by Equation 4.76 and Equation 4.78, the following hydraulic flow equation for a phreatic aquifer is obtained

$$S_y \frac{\partial h}{\partial t} = \frac{\partial}{\partial x} \left[K_e (h - b) \frac{\partial h}{\partial x} \right] + \frac{\partial}{\partial y} \left[K_e (h - b) \frac{\partial h}{\partial y} \right] + R \quad (4.94)$$

Also, in this equation, there are no terms with respect to the z -dimension, which is again the main advantage of the hydraulic approach. However, the equation is nonlinear, which complicates practical applications and finding exact analytical solutions. Nevertheless, the equation is extensively used, especially in numerical groundwater flow simulation models.

A simplification is possible for phreatic aquifers with a horizontal base, using the elevation of the water table above the base, $H = h - b$, as dependent variable; the flow equation becomes

$$S_y \frac{\partial H}{\partial t} = \frac{\partial}{\partial x} \left[K_e H \frac{\partial H}{\partial x} \right] + \frac{\partial}{\partial y} \left[K_e H \frac{\partial H}{\partial y} \right] + R \quad (4.95)$$

This is called the Boussinesq equation. The equation is still non-linear, but in case of steady state conditions, becomes linear in $H^2/2$

$$\frac{\partial}{\partial x} \left[K_e \frac{\partial}{\partial x} \left(\frac{H^2}{2} \right) \right] + \frac{\partial}{\partial y} \left[K_e \frac{\partial}{\partial y} \left(\frac{H^2}{2} \right) \right] + R = 0 \quad (4.96)$$

Several useful solutions have been derived with this equation (Polubarnova-Kochina, 1962; Bear, 1972, 1979). However, care should be taken with respect to boundary conditions, because these have to respect the hydraulic approach and consequently be independent of elevation. Consider for instance the very common boundary condition: a river in contact with a phreatic aquifer. The water level in the river can only be used as a potential boundary condition when the river is wide and deep such that the groundwater underneath the river is effectively having the same potential. If the surface water body is narrow and shallow, as in drains or ditches, there can be significant vertical flow components resulting in a potential

difference between the surface water and the groundwater underneath. In practice, such a situation can be treated with a third type boundary condition, where a boundary resistance is introduced that takes into account the effect of converging groundwater flow towards the drain or ditch.

4.3.5 Flow Equation for an Aquitard

To obtain a flow equation for an aquitard, it is sufficient to note that the flow is considered to be strictly vertical, such that the flow equation can be derived from the 3D saturated groundwater flow, Equation 4.56, by only considering the z -component of the flow

$$S_s \frac{\partial h}{\partial t} = \frac{\partial}{\partial z} \left(K_v \frac{\partial h}{\partial z} \right) \quad (4.97)$$

This equation describes flow through an aquitard, while the potentials of the aquifers bounding the aquitard can be used as boundary conditions. However, in practice this equation is not used much. Usually, an additional simplifying assumption is made, namely that the specific storage coefficient is negligibly small, such that

$$\frac{\partial}{\partial z} \left(K_v \frac{\partial h}{\partial z} \right) = 0 \quad (4.98)$$

This means that the flow is considered to be in quasi steady state, and the solution is given by Equation 4.74, that is, the flow adjusts immediately to changes in the aquifer potentials above and below the aquitard. This simplification makes vertical flows through aquitards easy to evaluate, such that these can be incorporated as inputs or outputs in above or underlying aquifers. However, the approach is not very accurate, because conductivities of aquitards are much smaller than for aquifers, as a result of which, in general, the flow through an aquitard lags behind the flow in the bounding aquifers, and time and storage effects can be important (Frind, 1983). However, lack of knowledge of aquitard properties often forces us to use a simplified approach.

4.4 Examples of Solutions

4.4.1 Dupuit Discharge Formula

Consider steady flow through a pervious homogeneous and isotropic dam with vertical walls and impervious horizontal base, as shown in Figure 4.8. The dam separates two reservoirs, so that the flow will be directed from the reservoir with the highest water level on the left to the reservoir with the lower level on the right, and bounded vertically by the impervious base and the water table. In addition, there will be a seepage face at the right-end side above the reservoir where groundwater seeps out freely in the atmosphere under zero pressure.

The flow equation, given by Equation 4.61, reduces to

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial z^2} = 0 \quad (4.99)$$

If the groundwater potential is measured from the impervious base, the boundary conditions can be written as follows: for the left boundary

$$h(0, z) = h_1 \quad (4.100)$$

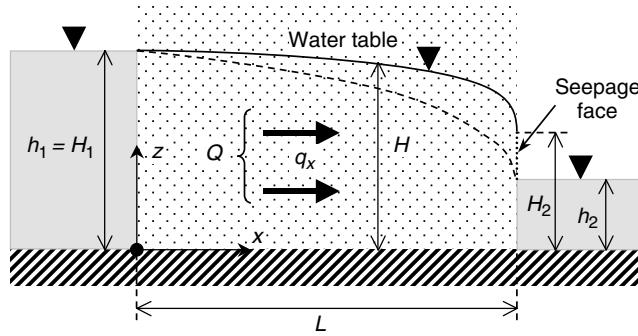

FIGURE 4.8 Steady state flow through a porous dam with vertical walls, situated between two reservoirs with constant water levels; the flow is vertically contained between the impervious base and water table and partially exists in the atmosphere through a seepage face; the dashed line represents the approximate position of the water table as obtained from the Dupuit equation.

where h_1 is the water depth in the left reservoir, for the right boundary at the contact between dam and reservoir

$$h(L, z \leq h_2) = h_2 \quad (4.101)$$

where h_2 is the water depth in the right reservoir, and L the width of the dam, while for the seepage face above the reservoir

$$h(L, z > h_2) = z \quad (4.102)$$

and for the impervious base

$$\left. \frac{\partial h}{\partial z} \right|_{z=0} = 0 \quad (4.103)$$

and finally for the water table Equation 4.70, which here becomes

$$\left(\frac{\partial h}{\partial x} \right)^2 + \left(\frac{\partial h}{\partial z} \right)^2 - \frac{\partial h}{\partial z} = 0 \quad (4.104)$$

An exact solution is very difficult to obtain because the position of the water table is unknown and the condition given by Equation 4.104 is nonlinear. A solution is given by Polubarinova-Kochina (1962) but is very complicated and hard to apply in practice. Hence, a simplified approach using the hydraulic approximation seems more appropriate. In this case Equation 4.96 applies, which reduces to

$$\frac{\partial^2 H^2}{\partial x^2} = 0 \quad (4.105)$$

where H is the average potential and, at the same time, the water table position measured from the base. The solution is

$$H^2 = C_1 x + C_2 \quad (4.106)$$

with C_1 and C_2 , integration constants, that have to be determined from the boundary conditions. Because the water table starts at h_1 , the water level of the left reservoir at $x = 0$, it follows that $C_2 = h_1^2$. At the right

end side, there is a problem, because we do not know the position of the water table due to the presence of the seepage face. Hence, we are forced to ignore the seepage face, and impose $H = h_2$ for $x = L$, which enables to determine C_1 , resulting in the following solution

$$H^2 = \frac{1}{L}(h_2^2 - h_1^2)x + h_1^2 \quad (4.107)$$

This equation implies that the water table has a parabolic shape, as depicted by the dashed line in Figure 4.8, which obviously deviates from reality (although differences will be small if L is large compared to h_1). The amount of flow Q , from the left reservoir to the right reservoir can be calculated with Equation 4.79, or

$$Q = -K \frac{\partial}{\partial x} \left(\frac{H^2}{2} \right) \quad (4.108)$$

Calculating the derivative using Equation 4.107 results in

$$Q = K \frac{h_1^2 - h_2^2}{2L} \quad (4.109)$$

This is the famous Dupuit equation, which is extensively used in practice to calculate ground water flow in phreatic aquifers. One would be tempted to question its validity or accuracy in view of the horizontal flow assumption. Hence, we return to the 2D flow problem, given by Equation 4.99 to Equation 4.103, and calculate the flow from by integrating the horizontal flux component q_x along a vertical from the base of the dam to the water table

$$Q = \int_0^H q_x dz = -K \int_0^H \frac{\partial h}{\partial x} dz \quad (4.110)$$

When the integration and derivative is interchanged, this becomes

$$Q = -K \frac{\partial}{\partial x} \left(\int_0^H h dz - \frac{1}{2} H^2 \right) \quad (4.111)$$

Integration with respect to x gives

$$xQ = -K \left(\int_0^H h dz - \frac{1}{2} H^2 \right) + C_3 \quad (4.112)$$

The integration constant, C_3 , is determined by equating terms at $x = 0$, for which we make use of Equation 4.100, so that

$$C_3 = K \left(\int_0^{h_1} h dz - \frac{1}{2} h_1^2 \right) = K \left(h_1^2 - \frac{1}{2} h_1^2 \right) = \frac{1}{2} K h_1^2 \quad (4.113)$$

Equation 4.112 now becomes

$$xQ = \frac{1}{2} K h_1^2 - K \left(\int_0^H h dz - \frac{1}{2} H^2 \right) \quad (4.114)$$

Next, all terms are equated at $x = L$, for which we use Equation 4.101 and Equation 4.102, yielding

$$\begin{aligned} LQ &= \frac{1}{2}Kh_1^2 - K \left(\int_0^{h_2} h_2 dz + \int_{h_2}^{H_2} zdz - \frac{1}{2}H_2^2 \right) \\ &= \frac{1}{2}Kh_1^2 - K \left(h_2^2 + \frac{1}{2}H_2^2 - \frac{1}{2}h_2^2 - \frac{1}{2}H_2^2 \right) = \frac{1}{2}K(h_1^2 - h_2^2) \end{aligned} \quad (4.115)$$

Surprisingly, the final result does not depend upon H_2 , although the seepage face contributes to the total flow, and we obtain back Equation 4.109. This remarkable finding is due to Charny (1951). Hence, it appears that although the shape of the water table is not correctly predicted by the Dupuit approach, the equation for the flux is nevertheless exact. Obviously the errors introduced by the parabolic shape of the water table and the disregard of the seepage face cancel out.

4.4.2 Hvorslev Slug Test Equation

Consider a piezometer, with a screen of length L and radius R , installed in an aquifer, as shown in Figure 4.9a. We assume that the screen is small compared to the aquifer dimensions, so that seen from the piezometer screen the aquifer can be considered infinite in all directions. The groundwater potential h_0 is revealed by the water level in the piezometer. We will assume that this potential is present everywhere in the aquifer. The question arises as to what will be the groundwater inflow through the screen into the piezometer if the water level inside the piezometer is artificially lowered by an amount, Δh . No exact solution has been found for this problem. Hence, some simplifications are needed. First, consider steady flow to a point sink as shown in Figure 4.9b. Using spherical coordinates and because of spherical symmetry, the flux directed to the sink q_r at a distance r can be found by dividing the total flow Q by the surface of a sphere with radius, r , or

$$q_r = -K \frac{\partial h}{\partial r} = \frac{-Q}{4\pi r^2} \quad (4.116)$$

which enables to find h , as function of r

$$h = \frac{-Q}{4\pi Kr} + C_1 \quad (4.117)$$

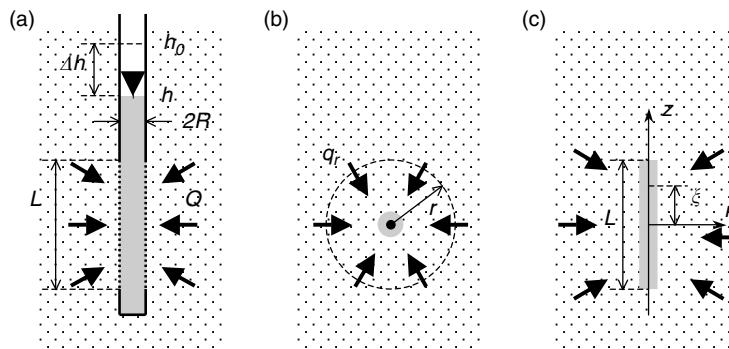

FIGURE 4.9 Groundwater flow through a piezometer screen when the water level in the piezometer is artificially lowered: (a) actual situation, (b) approximation by a point sink, and (c) approximation by a line sink.

The integration constant can be obtained by imposing that far from the sink, $r \rightarrow \infty$, the potential remains unchanged, that is, $h = h_0$, yielding

$$h = h_0 - \frac{Q}{4\pi Kr} \quad (4.118)$$

or

$$\Delta h = h_0 - h = \frac{Q}{4\pi Kr} \quad (4.119)$$

As a point sink is not a good representation of a piezometer screen, we now consider a line source sink, as shown in Figure 4.9c. The line sink has a length L and extracts a total flow Q , to mimic the piezometer screen as well as possible. To find the potentials, we use cylindrical coordinates and consider the line sink to be composed of an infinite series of point sinks distributed along z -axis. We use for this an additional coordinate ξ which runs from $-L/2$ to $L/2$ as shown in Figure 4.9c. Hence, each point sink extracts an elementary flow $Qd\xi/L$ and the distance from any point to a sink is given by $\sqrt{(z - \xi)^2 + r^2}$. The resulting potential distribution can be obtained by summing up all the contributions of each point sink, that is,

$$\Delta h = \int dh = \int_{-L/2}^{L/2} \frac{Q}{4\pi KL\sqrt{(z - \xi)^2 + r^2}} d\xi = \frac{Q}{4\pi KL} \left[\sinh^{-1} \left(\frac{L/2 + z}{r} \right) + \sinh^{-1} \left(\frac{L/2 - z}{r} \right) \right] \quad (4.120)$$

Finally, the potential drop in the piezometer is approximated by equating the above formula for $z = 0$ and $r = R$ yielding

$$\Delta h = \frac{Q}{2\pi KL} \sinh^{-1} \left(\frac{L}{2R} \right) = \frac{Q}{2\pi KL} \ln \left[\frac{L}{2R} + \sqrt{1 + \left(\frac{L}{2R} \right)^2} \right] \quad (4.121)$$

which for $L/R > 8$ can be approximated as

$$\Delta h = \frac{Q}{2\pi KL} \ln \left(\frac{L}{2R} \right) \quad (4.122)$$

This equation was presented by Hvorslev (1951) and forms the basis for the so-called piezometer or slug test, to determine the hydraulic conductivity in the field. As explained by Hvorslev (1951) and Freeze and Cherry (1979), the potential difference and the flow rate can be obtained by measuring the change in water level inside the piezometer, and used to calculate the hydraulic conductivity.

4.4.3 Theis Well Flow Equation

Consider a fully penetrating well in a homogeneous and perfect horizontal, and infinite in radial, extend confined aquifer, as shown in Figure 4.10. Initially the groundwater potential is constant and equal to h_0 . At time $t = 0$, pumping starts with a constant rate Q . The problem is described by the 3D groundwater flow equation, given by Equation 4.56. As the problem is axial-symmetric, it can best be described in cylindrical coordinates (r, φ, z) , as in Equation 4.59, but the term in φ disappears because of the axial symmetry and in z because the flow to the well is strictly horizontal; hence the flow equation reduces to

$$S_s \frac{\partial h}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left(r K_h \frac{\partial h}{\partial r} \right) \quad (4.123)$$

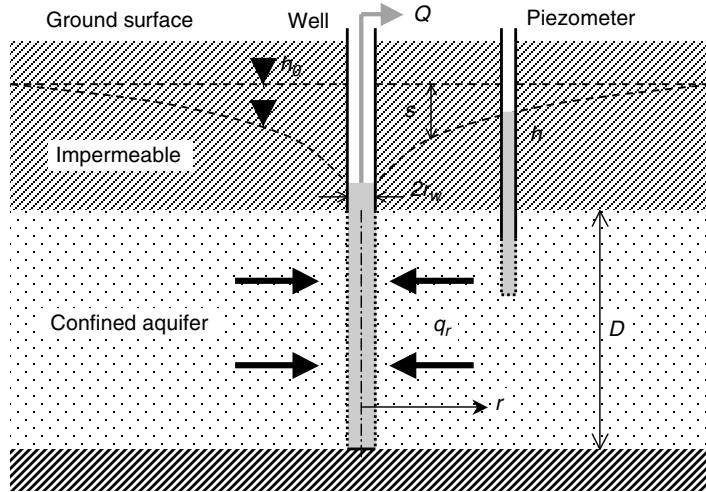

FIGURE 4.10 Groundwater flow in a confined aquifer to a fully penetrating well.

The **initial condition** is given by

$$h(r, 0) = h_0 \quad (4.124)$$

and the **boundary conditions** are: at infinity the given initial potential

$$h(\infty, t) = h_0 \quad (4.125)$$

and at the well screen the given radial flux

$$q_r(r_w, t) = -K_h \frac{\partial h}{\partial r} \Big|_{r=r_w} = -\frac{Q}{2\pi r_w D} \quad (4.126)$$

where r_w is the radius of the well screen. Notice that the term on the right-hand side is negative, because the flow is directed out of the aquifer. However, the boundary condition at the well is rather complicated; hence, this will be simplified by assuming that the radius of the well tends to zero, or

$$\lim_{r \rightarrow 0} \left(r \frac{\partial h}{\partial r} \right) = \frac{Q}{2\pi D K_h} \quad (4.127)$$

The solution is obtained by means of the Boltzmann transform $h(\lambda) = h(r, t)$, with $\lambda = r^2/t$. The transformation formulae are

$$\frac{\partial h}{\partial t} = \frac{dh}{d\lambda} \frac{\partial \lambda}{\partial t} = -\frac{r^2}{t^2} \frac{dh}{d\lambda} = -\frac{\lambda}{t} \frac{dh}{d\lambda} \quad (4.128)$$

$$r \frac{\partial h}{\partial r} = r \frac{dh}{d\lambda} \frac{\partial \lambda}{\partial r} = \frac{2r^2}{t} \frac{dh}{d\lambda} = 2\lambda \frac{dh}{d\lambda} \quad (4.129)$$

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial h}{\partial r} \right) = \frac{1}{r} \frac{\partial}{\partial r} \left(2\lambda \frac{dh}{d\lambda} \right) = \frac{1}{r} \frac{d}{d\lambda} \left(2\lambda \frac{dh}{d\lambda} \right) \frac{\partial \lambda}{\partial r} = \frac{4}{t} \frac{d}{d\lambda} \left(\lambda \frac{dh}{d\lambda} \right) \quad (4.130)$$

so that Equation 4.123 is transformed in

$$4K_h \frac{d}{d\lambda} \left(\lambda \frac{dh}{d\lambda} \right) + S_s \left(\lambda \frac{dh}{d\lambda} \right) = 0 \quad (4.131)$$

The boundary conditions for Equation 4.124 and Equation 4.125 become

$$\lim_{\lambda \rightarrow \infty} (h) = h_0 \quad (4.132)$$

and for Equation 4.127

$$\lim_{\lambda \rightarrow 0} \left(\lambda \frac{dh}{d\lambda} \right) = \frac{Q}{4\pi D K_h} \quad (4.133)$$

Equation 4.131 is a first order differential equation in $\lambda dh/d\lambda$, which can be solved as

$$\lambda \frac{dh}{d\lambda} = C_1 \exp \left(-\frac{S_s \lambda}{4K_h} \right) \quad (4.134)$$

where C_1 is an integration constant that can be determined with Equation 4.132, yielding

$$\lambda \frac{dh}{d\lambda} = \frac{Q}{4\pi D K_h} \exp \left(-\frac{S_s \lambda}{4K_h} \right) \quad (4.135)$$

This can be solved for h , as

$$h = \frac{Q}{4\pi D K_h} \int \lambda^{-1} \exp \left(-\frac{S_s \lambda}{4K_h} \right) d\lambda + C_2 \quad (4.136)$$

where C_2 is a second integration constant that can be determined with Equation 4.132, giving

$$h = h_0 - \frac{Q}{4\pi D K_h} \int_{r^2/t}^{\infty} \lambda^{-1} \exp \left(-\frac{S_s \lambda}{4K_h} \right) d\lambda \quad (4.137)$$

where we also have back-transformed $\lambda = r^2/t$. This equation was first derived by Theis (1935) through analogy with the flow and storage of heat in solids. It is usually written using the drawdown $s = h_0 - h$ [L], and overall aquifer properties transmissivity, T , and storativity, S , as

$$s = \frac{Q}{4\pi T} W \left(\frac{Sr^2}{4Tt} \right) \quad (4.138)$$

with the Theis well function, $W(u)$, given by

$$W(u) = \int_u^{\infty} \lambda^{-1} e^{-\lambda} d\lambda \quad (4.139)$$

The Theis well flow equation is probably the most commonly used and fundamental equation in groundwater flow, especially for the design of wells and the analysis of pumping tests.

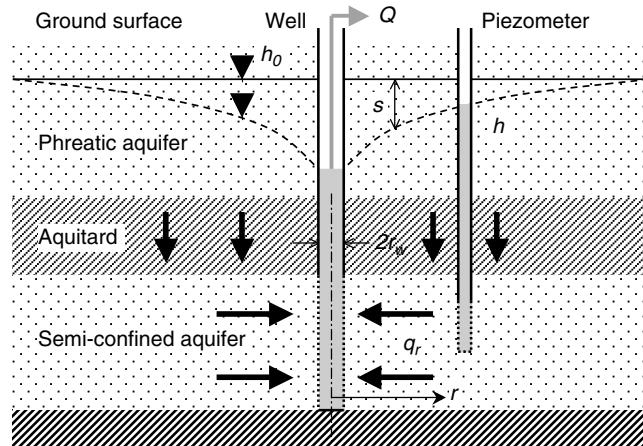

FIGURE 4.11 Groundwater flow in a semi-confined aquifer to a pumped, fully penetrating well and induced leakage through the overlying aquitard.

4.4.4 Hantush Leaky Well Flow Equation

Consider a fully penetrating well in a homogeneous and perfect horizontal semi-confined or leaky aquifer, as shown in Figure 4.11. The setting and conditions are very similar as for the confined aquifer considered in the previous case, but an essential difference is that the pumping of the well in the semi-confined aquifer will induce leakage through the aquitard. It is assumed that this water is coming from an aquifer on top, which can yield sufficient water without being depleted. Hence, it is assumed that initially the groundwater potential in both aquifers is constant and equal to h_0 , and that even when the well is pumping the potential in the top aquifer will remain unchanged.

The leakage through the aquitard will induce vertical flows in the semi-confined aquifer, resulting in a rather complex flow pattern. In order to simplify the problem, we will use the hydraulic approach for flow in the semi-confined aquifer, given by Equation 4.89, and for leakage through the aquitard, given by Equation 4.74. Because of axial symmetry, the flow equation becomes

$$S \frac{\partial h}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left(rT \frac{\partial h}{\partial r} \right) + C(h_0 - h) \quad (4.140)$$

The last term in this equation represents the leakage through the aquitard. The boundary conditions are similar as for the previous case, that is, Equations 4.124, 4.125, and 4.127. The flow equation can also be expressed in function of the drawdown, $s = h_0 - h$, as follows

$$S \frac{\partial s}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left(rT \frac{\partial s}{\partial r} \right) - Cs = T \frac{\partial^2 s}{\partial r^2} + \frac{T}{r} \frac{\partial s}{\partial r} - Cs \quad (4.141)$$

with initial condition

$$s(r, 0) = 0 \quad (4.142)$$

and boundary conditions

$$s(\infty, t) = 0 \quad (4.143)$$

$$\lim_{r \rightarrow 0} \left(r \frac{\partial s}{\partial r} \right) = -\frac{Q}{2\pi T} \quad (4.144)$$

The solution is obtained with the *Laplace transform*; let $\tilde{s}(r, p)$ be the Laplace transform of $s(r, t)$, where the tilde indicates the Laplace transform and p is the transform parameter. After transformation Equation 4.141 becomes

$$\frac{\partial^2 \tilde{s}}{\partial r^2} + \frac{1}{r} \frac{\partial \tilde{s}}{\partial r} - \frac{Sp + C}{T} \tilde{s} = 0 \quad (4.145)$$

where we have made use of the initial condition given by Equation 4.142. Equation 4.145 is the modified *Bessel equation* of order zero with general solution

$$\tilde{s} = C_1 I_0 \left(r \sqrt{\frac{Sp + C}{T}} \right) + C_2 K_0 \left(r \sqrt{\frac{Sp + C}{T}} \right) \quad (4.146)$$

where I_0 is the modified *Bessel function* of the first kind of order zero and K_0 the modified *Bessel function* of the second kind of order zero, and C_1 and C_2 are arbitrary constants, which have to be determined from the boundary conditions. The Laplace transform of Equation 4.143 is

$$\tilde{s}(\infty, p) = 0 \quad (4.147)$$

which implies that C_1 should be zero, since $I_0(\infty) = \infty$ and $K_0(\infty) = 0$. The Laplace transform of Equation 4.144 is

$$\lim_{r \rightarrow 0} \left(r \frac{\partial \tilde{s}}{\partial r} \right) = -\frac{Q}{2\pi T p} \quad (4.148)$$

and as the derivative of $K_0(x)$ is $K_1(x)$, the modified Bessel function of the second kind of order one, which tends to x^{-1} for $x \rightarrow 0$, the second constant can be determined and substituted in Equation 4.146, yielding

$$\tilde{s} = \frac{Q}{2\pi T p} K_0 \left(r \sqrt{\frac{Sp + C}{T}} \right) \quad (4.149)$$

Finally, making use of properties and tables of the Laplace transform (Abramowitz and Stegun, 1970; Zwillinger, 2002) to back-transform the solution, results in

$$s = \frac{Q}{4\pi T} \int_0^t \tau^{-1} \exp \left(-\frac{Sr^2}{4T\tau} - \frac{C\tau}{S} \right) d\tau \quad (4.150)$$

After substituting $\lambda = Sr^2/4T\tau$ as integration variable, this becomes

$$s = \frac{Q}{4\pi T} W \left(\frac{Sr^2}{4Tt}, \frac{r}{B} \right) \quad (4.151)$$

where $B = \sqrt{T/C}$ is the leakage factor [L], and $W(u, \beta)$ is the Hantush leaky well function, given by

$$W(u, \beta) = \int_u^\infty \lambda^{-1} \exp \left(-\lambda - \frac{\beta^2}{4\lambda} \right) d\lambda \quad (4.152)$$

This equation was first developed by Hantush and Jacob (1955), and is extensively used for design and analysis of wells in semi-confined aquifers. Although it resembles very much the Theis equation, it cannot be considered as a straightforward extension of the Theis equation, because the Theis equation is an exact solution of the 3D groundwater flow equation (albeit trivial because there are no vertical flow components), while the Hantush leaky well flow equation is based on the hydraulic flow approximation, where vertical flows are ignored, that is, the flow in the semi-confined aquifer is assumed to be horizontal and the leakage is uniformly distributed over the thickness of the aquifer. An exact solution of well flow in a semi-confined aquifer is much more difficult, but possible to obtain and has been given by Bruggeman (1999, p. 392), which in our notation becomes

$$s = \frac{Q}{2\pi T} \sum_{i=0}^{\infty} \frac{\sin \alpha_i}{\alpha_i + \sin \alpha_i \cos \alpha_i} W\left(\frac{Sr^2}{4Tt}, \frac{\alpha_i r}{D}\right) \cos\left(\frac{\alpha_i z}{D}\right) \quad (4.153)$$

where z is measured from the base of the aquifer, and α_i ($i = 0, 1, 2, \dots$) are the roots of $\alpha \tan \alpha = D^2/B^2$. Comparing Equation 4.153 with Equation 4.151 clearly illustrates the complexity which arises from considering full 3D groundwater flow vs. the hydraulic approximation.

Glossary

Bessel equation, Bessel function: Bessel's differential equation arises in many problems in physics, especially when using polar or cylindrical coordinates

$$x^2 \frac{d^2 y}{dx^2} + \frac{dy}{dx} \pm (x^2 \mp n^2)y = 0$$

The solutions of this equation $y(x, n)$ are called Bessel functions and have various and often interesting properties depending upon their type and order n . For more information consult standard mathematical books, as for instance Abramowitz and Stegun (1970) or Zwillinger (2002).

Boundary conditions: all partial differential equations have an infinite number of possible solutions, each of which corresponds to a particular case; to obtain from this multitude of possible solutions one particular solution corresponding to a certain specific case, it is necessary to provide supplementary information that is not contained in the partial differential equation; the supplementary information are termed boundary conditions and should include the initial state of the considered situation and how the considered domain interacts with its surroundings.

Conservation of mass: also termed continuity equation; a mathematical statement of the mass balance, that is, in the absence of mass-producing or mass-ingesting processes, the mass present in an arbitrary portion of a moving fluid remains constant.

Conservation of momentum: also termed Newton's second law of motion or momentum or impulse equation; a mathematical statement of the physical fact that forces are needed to induce deviation from uniform motion or to change motion; the law states that the time rate of change of an arbitrary portion of a moving fluid is equal to the resulting forces acting upon the considered portion.

Del operator: symbolic notation of a differential vector operator; several important operations as gradient, divergence, and curl can be described with this operator in a coordinate-independent way.

Elementary control volume: a volume of infinitesimal size, which is used to equate some physical property or process; when the size of the volume is taken in the limit going to zero, a mathematical equation is obtained that describes the property or process in every point of the continuum.

Navier–Stokes equation: equation describing the motion of a Newtonian fluid, that is, a viscous fluid for which the viscous stress components are linearly related to the deformation; when the Navier–Stokes equation is put in dimensionless form the Reynolds number appears, which expresses the ratio of inertia to viscous forces; for very small Reynolds numbers the inertia terms can be

neglected and the Navier–Stokes equation reduces to the Stokes equation describing a situation called Stokes flow, or creeping motion; the movement of groundwater under natural conditions is always considered to be creeping because of the very small groundwater flow velocities.

Land subsidence: a phenomenon that involves the lowering or settling of the land surface due to various factors, mostly under the impact of man's activities; often the extensive exploitation of groundwater resources have been accompanied in many places by significant land subsidence; in each case the ground layers consist of a sequence of sand and gravel intermixed with poorly consolidated and highly compressible clays or peat; the pumping of water from the conductive layers induces a drop in water potentials and gradual drainage of water from the clays or peat, which leads to compaction of the formations and sinking of the land surface.

Laplace transform: integral transformation that can reduce a differential equation to a simpler form or even to an algebraic expression; it is usually applied to time variables to eliminate time derivative, that is, if $f(t)$ is a function of t , the Laplace transform $\tilde{f}(p)$ is defined by

$$\tilde{f}(p) = L\{f(t); t \rightarrow p\} = \int_0^{\infty} f(t)e^{-pt} dt$$

where p is a complex parameter; the Laplace transform of the derivative df/dt becomes

$$L\left\{\frac{df}{dt}; t \rightarrow p\right\} = p\tilde{f}(p) - f(0)$$

Hence, the derivation becomes a multiplication. This reduces the complexity of a differential equation and can often enable to obtain the solution of the differential equation, whereby the true solution can be obtained by back transformation, which is usually achieved by look-up tables, as for instance given in Abramowitz and Stegun (1970) or Zwillinger (2002).

Piezometer: observation well tapping a saturated porous formation at a certain position and depth, indicating the groundwater potential present in the formation at that point.

Potential flow problem: potential flow is used to denote movement of fluids, without rotations in the driving force, which is a sufficient condition for the existence of a potential function, such that the gradient of that function gives the direction and magnitude of the driving force; in a homogeneous medium, potential functions are harmonic functions as they are solutions of the Laplace equation; there many mathematical techniques to solve these type of problems, especially for 2D flow problems that can be solved with the theory of complex functions.

Taylor series expansion: let $f(x)$ be a differentiable function of x , then the following series expansion holds

$$\begin{aligned} f(x) &= \sum_{n=0}^{\infty} \frac{x - x_0}{n!} \frac{d^n f(x_0)}{dx^n} \\ &= f_0 + \Delta x \frac{df_0}{dx} + \frac{(\Delta x)^2}{2} \frac{d^2 f_0}{dx^2} + \frac{(\Delta x)^3}{6} \frac{d^3 f_0}{dx^3} + \dots \end{aligned}$$

where $\Delta x = x - x_0$, and $f_0 = f(x_0)$.

Further Information

A standard reference in the field of mathematical aspects related to groundwater hydrology is Bear (1972). This work gives a comprehensive coverage of the dynamics of fluid flow through porous media. This book has been reprinted (Bear, 1988) and is highly recommended for scientists and engineers. Also parts that have been revised or updated and republished, as (Bear, 1979) dealing with principles of regional groundwater management and with special emphasis on the hydraulic approach to groundwater flow, and Bear and Verruijt (1987) in which especially mathematical and numerical modeling of groundwater flow and pollution transport are discussed.

Another classic work is Polubarnova-Kochina (1962), which gives an extensive overview of mathematical aspects of groundwater flow, with many analytical solutions to practical problems. Other notable works are McWhorter and Sunada (1977), Freeze and Cherry (1979), Todd (1980), and de Marsily (1986). A mathematical in-depth discussion of groundwater flow is Zijl and Nawalany (1993). Stochastic groundwater flow approach is discussed by Dagan (1989), Dagan and Neuman (1997), and Rubin (2003). A very comprehensive overview of analytical solutions of geohydrological problems and analytical solution methods is Bruggeman (1999).

New developments can be found in journals. Well known is *Water Resources Research*, published by the American Geophysical Union; this journal covers all scientific hydrology subjects. Also well known is the *Journal of Hydrology* of the European Geophysical Society, published by Elsevier. This journal also covers all aspects of hydrology. The most specialized journal in the field of mathematical groundwater hydrology as well as flow and transport through porous media for non-hydrological applications is *Transport in Porous Media*, edited by J. Bear and published by Kluwer Academic Publishers. Other interesting journals are *Journal of Groundwater* of the U.S. National Ground Water Association, and *Hydrogeology Journal* of the International Association of Hydrogeologists; these journals cover all aspects of hydrogeology.

5.1 Introduction

Figure 5.1 shows the pore space available for flow in two highly idealized soil models: *regular cubic* and *rhombohedral*. It is seen that even for these special cases, the pore space is not regular, but consists of cavernous cells interconnected by narrower channels. Pore spaces in real soils can range in size from molecular interstices to tunnel-like caverns. They can be spherical (as in concrete) or flat (as in clays), or display irregular patterns that defy description. Add to this the fact that pores may be *isolated* (inaccessible) or *interconnected* (accessible from both ends) or may be *dead-ended* (accessible through one end only).

In spite of the apparent irregularities and complexities of the available pores, there is hardly an industrial or scientific endeavor that does not concern itself with the passage of matter, solid, liquid, or gaseous, into, out of, or through porous media. Contributions to the literature can be found among such diverse fields (to name only a few) as soil mechanics, groundwater hydrology, petroleum, chemical and metallurgical engineering, water purification, materials of construction (ceramics, concrete, timber, paper), chemical

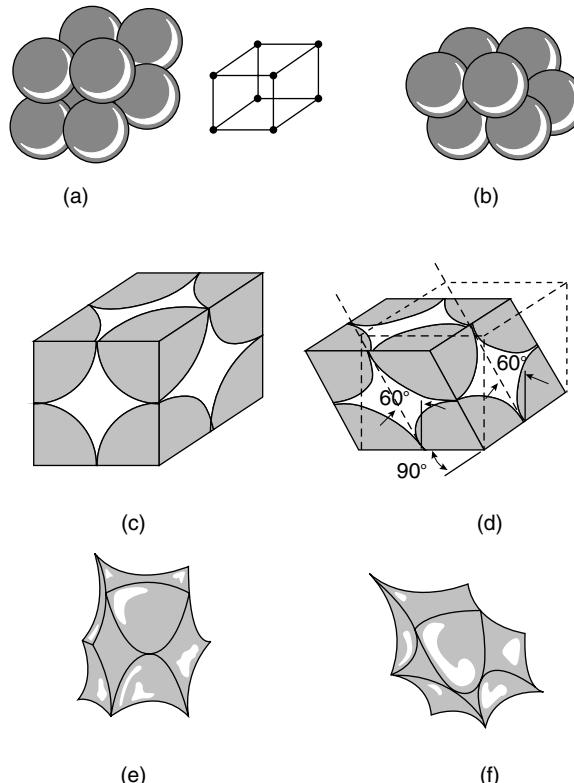

FIGURE 5.1 Idealized void space.

industry (absorbents, varieties of contact catalysts, and filters), pharmaceutical industry, traffic flow, and agriculture.

In no field of engineering are practitioners faced with more complex and uncertain sets of conditions than those concerned with groundwater systems. Unlike their colleagues in other engineering disciplines, who have the advantage of observing the performance of many prototypes under relatively known states of input, groundwater engineers generally deal with systems that are custom-built and tailored to special demands and specific locations. Add to these the very size of projects and the expense of underground sampling and data acquisition.

This chapter was written with the following main objectives:

1. To provide the groundwater engineer with an organized, logical, and systematic body of knowledge for the solution of groundwater and seepage problems.
2. To provide the groundwater engineer with probabilistic concepts and techniques to account for uncertainty in designs and to illustrate their relevance with application to practical problem situations.

5.2 Some Groundwater Fundamentals

The literature is replete with derivations and analytical excursions of the basic equations of steady-state groundwater flow (Polubarnova-Kochina, 1952; Harr, 1962; Cedergren, 1967; Bear, 1972; Domenico and Schwartz, 1990; to name only a few). A summary and brief discussion of these will be presented below for the sake of completeness.

5.2.1 Bernoulli's Equation

Underlying the analytical approach to groundwater flow is the representation of the actual physical system by a tractable mathematical model. In spite of their inherent shortcomings, many such analytical models have demonstrated considerable success in simulating the action of their prototypes.

As is well known from fluid mechanics, for steady flow of nonviscous incompressible fluids, Bernoulli's equation (Lamb, 1945)

$$\frac{p}{\gamma_w} + z + \frac{\bar{v}^2}{2g} = \text{constant} = h \quad (5.1)$$

where h = total head, ft, p = pressure, lb/ft², γ_w = unit weight of fluid, lb/ft³, g = gravitational constant, 32.2 ft/sec², \bar{v} = seepage velocity, ft/sec demonstrates that the sum of the *pressure head*, p/γ_w , *elevation head*, z , and *velocity head*, $\bar{v}^2/2g$, at any point within the region of flow is a constant.

To account for the loss of energy due to the viscous resistance within the individual pores, Bernoulli's equation is taken as

$$\frac{p_A}{\gamma_w} + z_A + \frac{\bar{v}_A^2}{2g} = \frac{p_B}{\gamma_w} + z_B + \frac{\bar{v}_B^2}{2g} + \Delta h \quad (5.2)$$

where Δh represents the total head loss (energy loss per unit weight of fluid) of the fluid over the distance Δs . The ratio

$$i = - \lim_{\Delta s \rightarrow 0} \frac{\Delta h}{\Delta s} = - \frac{dh}{ds} \quad (5.3)$$

is called the *hydraulic gradient* and represents the space rate of energy dissipation per unit weight of fluid (a pure number).

In most problems of interest the velocity heads (the kinetic energy) are so small they can be neglected. For example, a velocity of 1 ft/sec, which is large compared to typical seepage velocities through soils, produces a velocity head of only 0.015 ft. Hence, Equation 5.2 can be simplified to

$$\frac{P_A}{\gamma_w} + z_A = \frac{P_B}{\gamma_w} + z_B + \Delta h$$

and the total head at any point in the flow domain is simply

$$h = \frac{P}{\gamma_w} + z \quad (5.4)$$

5.2.2 Darcy's Law

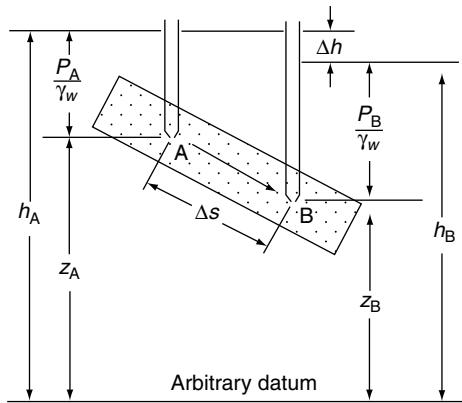

The flow of groundwater is taken to be governed by *Darcy's law*, which states that the velocity of the flow is directly proportional to the hydraulic gradient. A similar statement in an electrical system is *Ohm's law* and in a thermal system, *Fourier's law*. The grandfather of all such relations is *Newton's law of motion*. Table 5.1 presents some other points of similarity.

Prior to 1856, the formidable nature of the flow through porous media defied rational analysis. In that year, Henry Darcy published a simple relation based on his experiments on the flow of water in vertical sand filters in *Les Fontaines Publiques de la Ville de Dijon*, namely,

$$v = ki = -k \frac{dh}{ds} \quad (5.5)$$

TABLE 5.1 Some Similarities of Flow Models

Form of Energy	Name of Law	Quantity	Storage	Resistance
Electrical	Ohm's law	Current (voltage)	Capacitor	Resistor
Mechanical	Newton's law	Force (velocity)	Mass	Damper
Thermal	Fourier's law	Heat flow (temperature)	Heat capacity	Heat resistance
Fluid	Darcy's law	Flow rate (pressure)	Liquid storage	Permeability

**FIGURE 5.2** Heads in Bernoulli's equation.

Equation 5.5, commonly called Darcy's law, demonstrates a linear dependency between the hydraulic gradient and the *discharge velocity* v . The discharge velocity, $v = n\bar{v}$, is the product of the porosity n and the seepage velocity, \bar{v} . The coefficient of proportionality k in Equation 5.5 is called by many names depending on its use; among these are the *coefficient of permeability*, *hydraulic conductivity*, and *permeability constant*. As shown in Equation 5.5, k has the dimensions of a velocity. It should be carefully noted in this equation that flow is a consequence of differences in total head and not of pressure gradients. This is demonstrated in Figure 5.2 where the flow is directed from A to B, even though the pressure at point B is greater than that at point A.

Defining Q as the total volume of flow per unit time through a cross-sectional area A , Darcy's law takes the form

$$Q = Av = Aki = -Ak \frac{dh}{ds} \quad (5.6)$$

Darcy's law offers the single parameter k to account for both the characteristics of the medium and the fluid. It has been found that k is a function of γ_w , the unit weight of the fluid, μ , the coefficient of viscosity, and n , the porosity, as given by

$$k = C \frac{\gamma_w n}{\mu} \quad (5.7)$$

where C (dimensionally an area) typifies the structural characteristics of the media independent of the fluid properties. The principal advantage of Equation 5.7 lies in its use when dealing with more than one fluid or with temperature variations. When employing a single relatively incompressible fluid subjected to small changes in temperature, such as in groundwater and seepage-related problems, it is more convenient to use k as a single parameter. Some typical values for k are given in Table 5.2.

Although Darcy's law was obtained initially from considerations of one-dimensional macroscopic flow, its practical utility lies in its generalization into two or three spatial dimensions. Accounting for the

TABLE 5.2 Some Typical Values of Coefficient of Permeability

Soil Type	Coefficient of Permeability <i>k</i> , cm/sec
Clean gravel	1.0 and greater
Clean sand (coarse)	1.0–0.01
Sand (mixtures)	0.01–0.005
Fine sand	0.05–0.001
Silty sand	0.002–0.0001
Silt	0.0005–0.00001
Clay	0.000001 and smaller

directional dependence of the coefficient of permeability, Darcy's law can be generalized to

$$v_s = -k_s \frac{\partial h}{\partial s} \quad (5.8)$$

where k_s is the coefficient of permeability in the "s" direction, and v_s and $\partial h/\partial s$ are the components of the velocity and the hydraulic gradient, respectively, in that direction.

5.2.3 Reynolds Number

There remains now the question of the determination of the extent to which Darcy's law is valid in actual flow systems through soils. Such a criterion is furnished by the Reynolds number R (a pure number relating inertial to viscous force), defined as

$$R = \frac{vd\rho}{\mu} \quad (5.9)$$

where v = discharge velocity, cm/sec, d = average of diameter of particles, cm, ρ = density of fluid, g/(mass)/cm³, μ = coefficient of viscosity, g-sec/cm²

The critical value of the Reynolds number at which the flow in aggregations of particles changes from laminar to turbulent flow has been found by various investigators (see Muskat, 1937) to range between 1 and 12. However, it will generally suffice to accept the validity of Darcy's law when the Reynolds number is taken as equal to or less than unity, or

$$\frac{vd\rho}{\mu} \leq 1 \quad (5.10)$$

Substituting the known values of ρ and μ for water into Equation 5.10 and assuming a conservative velocity of 1/4 cm sec, we have d equal to 0.4 mm, which is representative of the average particle size of coarse sand.

5.2.4 Homogeneity and Isotropy

If the coefficient of permeability is independent of the direction of the velocity, the medium is said to be isotropic. Moreover, if the same value of the coefficient of permeability holds at all points within the region of flow, the medium is said to be *homogeneous* and *isotropic*. If the coefficient of permeability is dependent on the direction of the velocity and if this directional dependence is the same at all points of the flow region, the medium is said to be *homogeneous* and *anisotropic* (or *aleotropic*).

5.2.5 Streamlines and Equipotential Lines

Physically, all flow systems extend in three dimensions. However, in many problems the features of the motion are essentially planar, with the flow pattern being substantially the same in parallel planes. For these problems, for steady-state incompressible, isotropic flow in the xy plane, it can be shown (Harr, 1962) that the governing differential equation is

$$k_x \frac{\partial^2 h}{\partial x^2} + k_y \frac{\partial^2 h}{\partial y^2} = 0 \quad (5.11)$$

Here the function $h(x, y)$ is the distribution of the total head (of energy available to do work) within and on the boundaries of a flow region, and k_x and k_y are the coefficients of permeability in the x - and y -directions, respectively. If the flow system is isotropic, $k_x = k_y$, and Equation 5.11 reduces to

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} = 0 \quad (5.12)$$

Equation 5.12, called *Laplace's equation*, is the governing relationship for steady-state, laminar-flow conditions (Darcy's law is valid). The general body of knowledge relating to Laplace's equation is called *potential theory*. Correspondingly, incompressible steady-state fluid flow is often called *potential flow*. The correspondence is more evident upon the introduction of the *velocity potential* ϕ , defined as

$$\phi(x, y) = -kh + C = -k \left(\frac{p}{\gamma_w} + z \right) + C \quad (5.13)$$

where h is the total head, p/γ_w is the pressure head, z is the elevation head, and C is an arbitrary constant. It should be apparent that, for isotropic conditions,

$$v_x = \frac{\partial \phi}{\partial x} \quad v_y = \frac{\partial \phi}{\partial y} \quad (5.14)$$

and, Equation 5.12 will produce

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0 \quad (5.15)$$

The particular solutions of Equation 5.12 or Equation 5.15 which yield the locus of points within a porous medium of equal potential, curves along with $h(x, y)$ or $\phi(x, y)$ are equal to a series of constants, are called *equipotential lines*.

In analyses of groundwater flow, the family of flow paths is given by the function $\psi(x, y)$, called the *stream function*, defined in two dimensions as (Harr, 1962)

$$v_x = \frac{\partial \psi}{\partial y} \quad v_y = -\frac{\partial \psi}{\partial x} \quad (5.16)$$

where v_x and v_y are the components of the velocity in the x - and y -directions, respectively.

Equating the respective potential and stream functions of v_x and v_y produces

$$\frac{\partial \phi}{\partial x} = \frac{\partial \psi}{\partial y} \quad \frac{\partial \phi}{\partial y} = -\frac{\partial \psi}{\partial x} \quad (5.17)$$

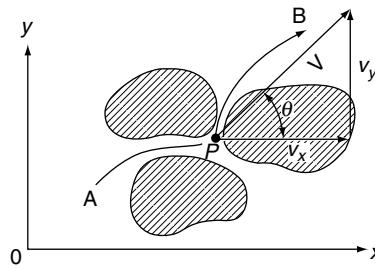

FIGURE 5.3 Path of flow.

Differentiating the first of these equations with respect to y and the second with respect to x and subtracting, we obtain Laplace's equation

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = 0 \quad (5.18)$$

We shall examine the significance of this relationship following a little more discussion of the physical meaning of the stream function.

Consider AB of Figure 5.3 as the path of a particle of water passing through point P with a tangential velocity v . We see from the figure that

$$\frac{v_y}{v_x} = \tan \theta = \frac{dy}{dx}$$

and hence

$$v_y dx - v_x dy = 0 \quad (5.19)$$

Substituting Equation 5.16, it follows that

$$\frac{\partial \psi}{\partial x} dx + \frac{\partial \psi}{\partial y} dy = 0$$

which states that the total differential $d\psi = 0$ and

$$\psi(x, y) = \text{constant}$$

Thus, we see that the family of curves generated by the function $\psi(x, y)$ equal to a series of constants are tangent to the resultant velocity at all points in the flow region and hence define the path of flow.

The potential, $\phi = -kh + \text{constant}$, is a measure of the energy available at a point in the flow region to move the particle of water from that point to the tailwater surface. Recall the locus of points of equal energy, say $\phi(x, y) = \text{constants}$, are called equipotential lines. The total differential along any curve, $\phi(x, y) = \text{constant}$, produces

$$d\phi = \frac{\partial \phi}{\partial x} dx + \frac{\partial \phi}{\partial y} dy = 0$$

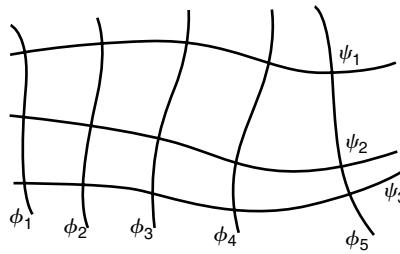

FIGURE 5.4 Streamlines and equipotential lines.

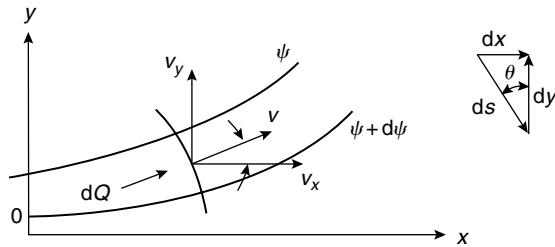

FIGURE 5.5 Flow between streamlines.

Substituting for $\partial\phi/\partial x$ and $\partial\phi/\partial y$ from Equation 5.16, we have

$$v_x dx + v_y dy = 0$$

and

$$\frac{dy}{dx} = -\frac{v_x}{v_y} \quad (5.20)$$

Noting the negative reciprocal relationship between their slopes, Equation 5.19 and Equation 5.20, we see that, within the flow domain, the families of streamlines $\psi(x, y) = \text{constants}$ and equipotential lines $\phi(x, y) = \text{constants}$ intersect each other at right angles. It is customary to signify the sequence of constants by employing a subscript notation, such as $\phi(x, y) = \phi_i$, $\psi(x, y) = \psi_j$ (Figure 5.4).

As only one streamline may exist at a given point within the flow medium, streamlines cannot intersect one another if flow is to occur between them. Consequently, if the medium is saturated, any pair of streamlines acts to form a flow channel between them.

Consider the flow between the two streamlines ψ and $\psi + d\psi$ in Figure 5.5; v represents the resultant velocity of flow. The quantity of flow through the flow channel per unit length normal to the plane of flow (say, cubic feet per second per foot) is

$$\begin{aligned} dQ &= v_x ds \cos \theta - v_y ds \sin \theta \\ &= v_x dy - v_y dx \\ &= \frac{\partial \psi}{\partial y} dy + \frac{\partial \psi}{\partial x} dx \end{aligned}$$

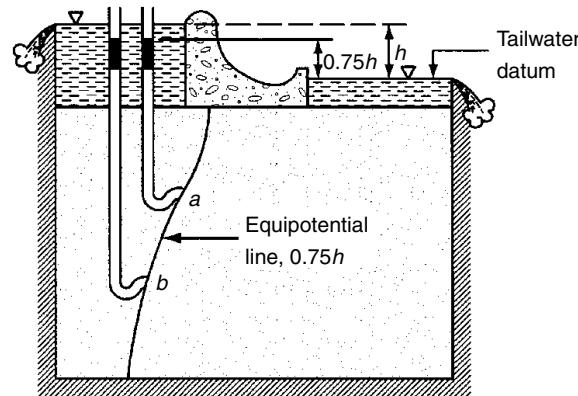

FIGURE 5.6 Pressure head along equipotential line.

and

$$dQ = d\psi \quad (5.21)$$

Hence, the quantity of flow (also called the *quantity of discharge* and *discharge quantity*) between any pair of streamlines is a constant whose value is numerically equal to the difference in their respective ψ values. Thus, once a sequence of streamlines of flow has been obtained, with neighboring ψ values differing by a constant amount, their plot will not only show the expected direction of flow but the relative magnitudes of the velocity along the flow channels; that is, the velocity at any point in the flow channel varies inversely with the streamline spacing in the vicinity of that point.

An equipotential line was defined previously as the locus of points where there is an expected level of available energy sufficient to move a particle of water from a point on that line to the tailwater surface. Thus, it is convenient to reduce all energy levels relative to a tailwater datum. For example, a piezometer located anywhere along an equipotential line, say at $0.75h$ in Figure 5.6, would display a column of water extending to a height of $0.75h$ above the tailwater surface. Of course, the pressure in the water along the equipotential line would vary with its elevation, Equation 5.4. This will be illustrated in Section 5.4.

5.3 Some Probabilistic Fundamentals

Within the context of engineering usage there are two primary definitions of the concept of probability: *relative frequency* and *subjective interpretation*. Historically, the measure first offered for the probability of an outcome was its *relative frequency*. If an outcome A can occur T times in N equally likely trials, the probability of the outcome A is

$$P[A] = \frac{T}{N} \quad (5.22a)$$

Implied in Equation 5.22a is that the probability of an outcome A equals the number of outcomes favorable to A (within the meaning of the experiment) divided by the total number of possible outcomes, or

$$P[A] = \frac{\text{Favorable outcomes}}{\text{Total possible outcomes}} \quad (5.22b)$$

Example 5.1

Find the probability of drawing a red card from an ordinary well-shuffled deck of 52 cards.

Solution. Of the 52 equally likely outcomes, there are 26 favorable (red card) outcomes. Hence,

$$P[\text{drawing red card}] = \frac{26}{52} = \frac{1}{2}$$

Understood from the example is that if one were to repeat the process a very large number of times, a red card would appear in one half of the trials. This is an example of the relative frequency interpretation. Now, what meaning could be associated with the statement, the probability of the failure of a proposed dam is 2% ($P[\text{failure}] = 0.02$)? The concept of repeated trials is meaningless: the structure will be built only *once* and it will either fail or be successful during its design lifetime. It cannot do both. Here, we have an example of the *subjective interpretation* of probability. It is a measure of information as to the likelihood of the occurrence of an outcome.

Subjective probability is generally more useful than the relative frequency concept in engineering applications. However, the basic rules governing both are identical. As an example, we note that both concepts specify the probability of an outcome to range between and to include numerical values from zero to one. The lower limit indicates there is *no* likelihood of occurrence: the upper limit corresponds to a *certain* outcome.

$$\langle \text{Axiom I} \rangle \quad 0 \leq P[A] \leq 1 \quad (5.23a)$$

The certainty of an outcome C is a probability of unity

$$\langle \text{Axiom II} \rangle \quad P[C] = 1 \quad (5.23b)$$

Equations 5.23 provide two of the three axioms of the theory of probability. The third axiom requires the concept of *mutually exclusive* outcomes. Outcomes are mutually exclusive if they cannot occur simultaneously. The third axiom states the probability of the occurrence of the sum of a number of mutually exclusive outcomes $A(1), A(2), \dots, A(N)$ is the sum of their individual probabilities (*addition rule*), or

$$\langle \text{Axiom III} \rangle \quad P[A(1) + A(2) + \dots + A(N)] = P[A(1)] + P[A(2)] + \dots + P[A(N)] \quad (5.23c)$$

As a very important application of these axioms, consider the proposed design of a spillway. After construction, only one of two outcomes can be obtained in the absolute structural sense: either it is successful or it fails. These are mutually exclusive outcomes. They are also exhaustive in that, within the sense of the example, no other outcomes are possible. Hence, the second axiom, Equation 5.23b, requires

$$P[\text{success+failure}] = 1$$

As they are mutually exclusive, the third axiom specifies that

$$P[\text{success}] + P[\text{failure}] = 1$$

The probability of the success of a structure is called its *reliability*, R . Symbolizing the probability of failure as $p(f)$, we have the important expression

$$R + p(f) = 1 \quad (5.24)$$

5.3.1 Moments

Consider a system of *discrete* parallel (vertical) forces, $P(1), P(2), \dots, P(N)$, acting on a rigid beam at the respective distances $x(1), x(2), \dots, x(N)$ (Figure 5.7a). From statics we have that the magnitude of the *equilibrant* M , is

$$M = \sum_{i=1}^N P(i) \quad (5.25a)$$

and its point of application, \bar{x} , is

$$\bar{x} = \frac{\sum_{i=1}^N x(i)P(i)}{\sum_{i=1}^N P(i)} \quad (5.25b)$$

For a *continuously* distributed parallel force system (Figure 5.7b) over a finite distance, say from $x(a)$ to $x(b)$, the corresponding expressions are

$$M = \int_{x(a)}^{x(b)} p(x)dx \quad (5.26a)$$

and

$$\bar{x} = \frac{\int_{x(a)}^{x(b)} xp(x)dx}{M} \quad (5.26b)$$

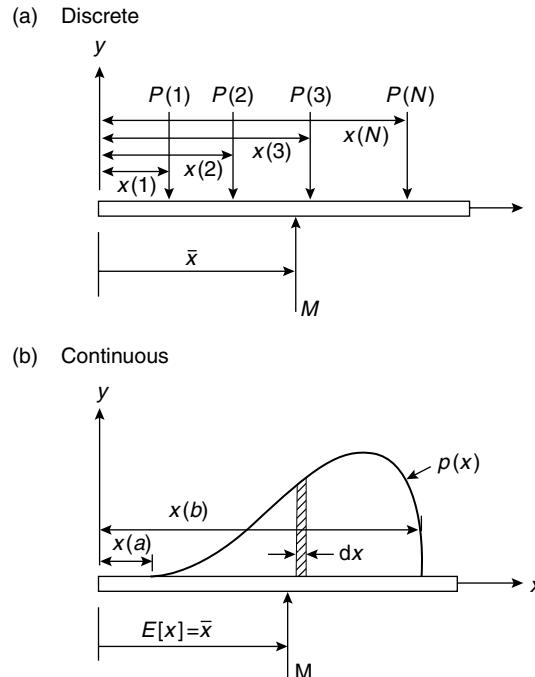

FIGURE 5.7 Equilibrant for discrete and continuous distributions.

Suppose that the discrete forces $P(i)$ in Figure 5.7a represent the frequencies of the occurrence of the N outcomes $x(1), x(2), \dots, x(N)$. As the distribution is exhaustive, from Axiom II, Equation 5.23b, the magnitude of the equilibrant must be unity, $M = 1$. Hence, Equation 5.25b becomes

$$\text{(Discrete)} \quad E[x] = \bar{x} = \sum_{i=1}^N x(i)P(i) \quad (5.27a)$$

Similarly, for the continuous distribution (Figure 5.7b), as all probabilities $p(x)dx$ must lie between $x(a)$ and $x(b)$, in Equation 5.26a $M = 1$. Hence, Equation 5.26b becomes

$$\text{(Continuous)} \quad E[x] = \bar{x} = \int_{x(a)}^{x(b)} xp(x)dx \quad (5.27b)$$

The symbol $E[x]$ in Equations 5.27 is called the *expected value* or the *expectation* or simply the *mean* of the variable x . As is true of the equilibrant, it is a measure of the central tendency, the *center of gravity* in statics.

Example 5.2

What is the expected value of the number of dots that will appear if a fair die is tossed?

Solution. Here, each of the possible outcomes 1, 2, 3, 4, 5, and 6 has the equal probability of $P(i) = 1/6$ of appearing. Hence, from Equation 5.27a

$$E[\text{toss of a fair die}] = \frac{1}{6}[1 + 2 + 3 + 4 + 5 + 6] = 3.5$$

We note in the above example that the expected value of 3.5 is an impossible outcome. There is no face on the die that will show 3.5 dots; however, it is still the best measure of the central tendency.

Example 5.3

Find the expected value of a continuous probability distribution wherein all values are equally likely to occur (called a *uniform distribution* [Figure 5.8]) between $y(a) = 0$ and $y(b) = 1/2$.

Solution. From Equation 5.26a as $M = 1$ and $p(y) = C$ is a constant, we have

$$1 = C \int_0^{1/2} dy, \quad C = 2$$

From Equation 5.27b, $E[y] = 2 \int_0^{1/2} y dy = 1/4$, as expected.

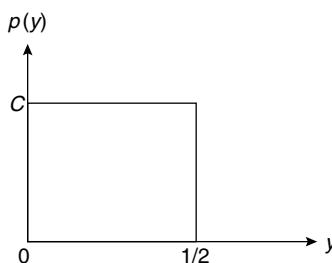

FIGURE 5.8 Uniform distribution.

As the variables x and y in the above examples are determined by the outcomes of random experiments they are said to be *random variables*. In classical probability theory, random variables are generally represented by capital letters, such as X and Y . The individual values are customarily denoted by their corresponding lowercase letters x and y ; however, no such distinction will be made here.

The expected value (mean) provides the locus of the central tendency of the distribution of a random variable. To characterize other attributes of the distribution, recourse is had to higher moments. Again, returning to statics, a measure of the dispersion of the distribution of the force system about the centroidal axis, at $x = E[x]$ in Figure 5.7b, is given by the *moment of inertia* (the *second central moment*),

$$I(y) = \int_{x(a)}^{x(b)} (x - \bar{x})^2 p(x) dx \quad (5.28)$$

The equivalent measure of the scatter (variability) of the distribution of a random variable is called its *variance*, denoted in this text as $\nu[x]$ (lowercase “ ν ”) and defined as

$$\langle \text{Discrete} \rangle \quad \nu[x] = \sum_{\text{all } x(i)} [x(i) - \bar{x}]^2 P(i) \quad (5.29a)$$

$$\langle \text{Continuous} \rangle \quad \nu[x] = \int_{x(a)}^{x(b)} (x - \bar{x})^2 p(x) dx \quad (5.29b)$$

In terms of the expectation these can be written as

$$\nu[x] = E[(x - \bar{x})^2] \quad (5.30)$$

which, after expansion, leads to a form more amenable to computations,

$$\nu[x] = E[x^2] - (E[x])^2 \quad (5.31)$$

This expression is the equivalent of the *parallel-axis theorem* for the moment of inertia.

Example 5.4

Find the expected value, and the variance of the *exponential distribution*, $p(x) = a \exp(-ax)$, $x > 0$, a is a constant.

Solution. We first show that $p(x)$ is a valid probability distribution

$$\int_0^\infty p(x) dx = a \int_0^\infty e^{-ax} dx = 1$$

The expected value is

$$E[x] = a \int_0^\infty x e^{-ax} dx = \frac{1}{a}$$

Continuing,

$$E[x^2] = a \int_0^\infty x^2 e^{-ax} dx = \frac{1}{a^2}$$

whence, using Equation 5.31,

$$\nu[x] = \frac{2}{a^2} - \left(\frac{1}{a}\right)^2 = \frac{1}{a^2}$$

The variance has the units of the square of those of the random variable. A more meaningful measure of dispersion of a random variable (x) is the positive square root of its variance (compare with *radius of gyration* of mechanics) called the *standard deviation*, $\sigma[x]$,

$$\sigma[x] = \sqrt{\nu[x]} \quad (5.32)$$

From the results of the previous example, it is seen that the standard deviation of the exponential distribution is $\sigma[x] = 1/a$.

An extremely useful relative measure of the scatter of a random variable $\sigma[x]$ is its *coefficient of variation* $V(x)$, capital "V" with parenthesis, usually expressed as a percentage,

$$V(x) = \frac{\sigma[x]}{E[x]} \times 100(%) \quad (5.33)$$

For the exponential distribution we found, $\sigma[x] = 1/a$ and $E[x] = 1/a$, hence V (exponential distribution) = 100%. In Table 5.3 are given representative values of the coefficients of variation. Original sources should be consulted for details.

The coefficient of variation expresses a measure of the reliability of the central tendency. For example, given a mean value of a parameter of 10 with a coefficient of variation of 10% would indicate a standard deviation of 1, whereas a similar mean with a coefficient of variation of 20% would demonstrate a standard deviation of 2. The coefficient of variation has been found to be a fairly stable measure of variability for homogeneous conditions. Additional insight into the standard deviation and the coefficient of variation as measures of uncertainty is provided by *Chebyshev's inequality* (for the derivation see Lipschutz, 1965).

The spread of a random variable is often spoken of as its *range*, the difference between the largest and smallest outcomes of interest. Another useful measure is the range between the mean plus-and-minus- h -standard deviations, $\bar{x} \pm h\sigma[x]$, called the *h-sigma bounds* (Figure 5.9). If x is a random variable with mean value \bar{x} and standard deviation σ , then Chebyshev's inequality states

$$P[(\bar{x} - h\sigma) \leq x \leq (\bar{x} + h\sigma)] \geq \frac{1}{h^2} \quad (5.34)$$

In words, it asserts that for any probability distribution (with finite mean and standard deviation) the probability that random values of the variate will lie within h -sigma bounds is at least $(1 - 1/h^2)$. Some numerical values are given in Table 5.4. It is seen that quantitative probabilistic statements can be made without complete knowledge of the probability distribution function: only its expected value and coefficient of variation (or standard deviation) are required. In this regard, the values for the coefficients of variation given in the table may be used in the absence of more definitive information.

Example 5.5

The expected value for the ϕ -strength parameter of a sand is 30° . What is the probability that a random sample of this sand will have a ϕ -value between 20° and 40° ?

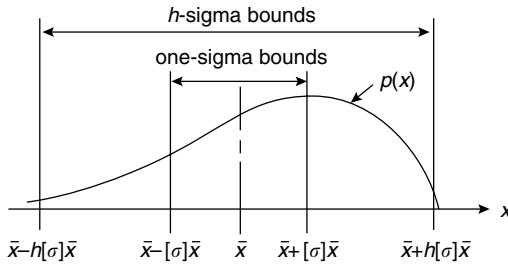

FIGURE 5.9 Range in h -sigma bounds.

TABLE 5.4 Probabilities for Range of Expected Values $\pm h$ -Sigma Bounds

h	Chebyshev's Inequality	Gauss's Inequality	Exact Exponential Distribution	Exact Normal Distribution	Exact Uniform Distribution
1/2	0	0	0.78	0.38	0.29
1	0	0.56	0.86	0.68	0.58
2	0.75	0.89	0.95	0.96	1.00
3	0.89	0.95	0.982	0.9973	1.00
4	0.94	0.97	0.993	0.999934	1.00

Solution. From Table 5.3, $V(\phi) = 12\%$ for sand; hence, $\sigma[\phi]$ is estimated to be $(0.12)(30) = 3.6^\circ$ and $h = (\bar{\phi} - \phi)/\sigma = 10^\circ/3.6^\circ = 2.8$. Hence, $P[20^\circ \leq \phi \leq 40^\circ] \geq 1 - (1/2.8)^2 \geq 0.87$. That is, the probability is at least 0.87 that the ϕ -strength parameter will be between 20° and 40° .

If the unknown probability distribution function is symmetrical with respect to its expected value and the expected value is also its maximum value (said to be *unimodal*), it can be shown that (Freeman, 1963)

$$P[(\bar{x} - h\sigma) \leq x \leq (\bar{x} + h\sigma)] \geq 1 - \frac{4}{9h^2} \quad (5.35)$$

This is sometimes called *Gauss' inequality*. Some numerical values are given in the third column of Table 5.4.

Example 5.6

Repeat the previous example if it is assumed that the distribution of the ϕ -value is symmetrical with its maximum at the mean value ($\bar{\phi} = 30^\circ$).

Solution. For this case, Gauss' inequality asserts

$$P[20^\circ \leq \phi \leq 40^\circ] \geq 1 - \frac{4}{9(2.8)^2} \geq 0.94$$

Recognizing symmetry we can also claim $P[\phi \leq 20^\circ] = P[\phi \geq 40^\circ] = 0.03$.

Example 5.7

Find the general expression for the probabilities associated with h -sigma bounds for the exponential distribution, $h \geq 1$.

Solution. From Example 5.4, we have (with $E[x] = 1/a$, $\sigma[x] = 1/a$)

$$P[(\bar{x} - h\sigma) \leq x \leq (\bar{x} + h\sigma)] = \int_0^{(h+1)/a} ae^{-ax} dx = 1 - e^{-(h+1)}$$

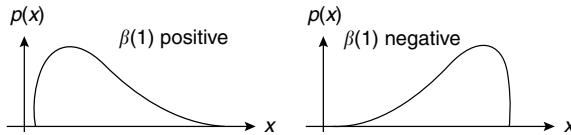

FIGURE 5.10 Coefficient of skewness.

Some numerical values are given in Table 5.4. The normal distribution noted in this table will be developed subsequently.

The results in Table 5.4 indicate that, lacking information concerning a probability distribution beyond its first two moments, from a practical engineering point of view, it may be taken to range within 3-sigma bounds. That is, in Figure 5.7b, $x(a) \approx \bar{x} - 3\sigma[x]$ and $x(b) \approx \bar{x} + 3\sigma[x]$.

For a symmetrical distribution all moments of odd order about the mean (central moments) must be zero. Consequently, any odd-ordered moment may be used as a measure of the degree of *skewness* or *asymmetry* of a probability distribution. The fourth central moment $E[(x - \bar{x})^4]$ provides a measure of the peakedness (called *kurtosis*) of a distribution.

As the units of the third central moment are the cube of the units of the variable, to provide an absolute measure of skewness, Pearson [1894, 1895] proposed that its value be divided by the standard deviation cubed to yield the dimensionless *coefficient of skewness*,

$$\beta(1) = \frac{E[(x - \bar{x})^3]}{(\sigma[x])^3} \quad (5.36)$$

If $\beta(1)$ is positive, the long tail of the distribution is on the right side of the mean: if it is negative the long tail is on the left side (Figure 5.10). Pearson also proposed the dimensionless *coefficient of kurtosis* $\beta(2)$ as a measure of peakedness

$$\beta(2) = \frac{E[(x - \bar{x})^4]}{(\sigma[x])^4} \quad (5.37)$$

5.3.2 Probability Distributions

In Figure 5.11 are shown the regions occupied by a number of probability distribution types identified by their coefficients of skewness and kurtosis. Examples of the various types are also shown schematically. We note in the figure that the type IV distribution and the symmetrical type VII are unbounded (infinite) below and above. From the point of view of practical groundwater engineering applications, this represents an extremely unlikely distribution. For example, *all* parameters or properties (see Table 5.3) are positive numbers (including zero).

The type V (the *lognormal distribution*), type III (the gamma), and type VI distributions are unbounded above. Hence, their use would be confined to those variables with an extremely large range of possible values. Some examples are the coefficient of permeability, the state of stress at various points in a body, distribution of annual rainfall, and so on.

The *normal (Gaussian) distribution* [$\beta(1) = 0, \beta(2) = 3$], even though it occupies only a single point in the universe of possible distributions, is the most frequently used probability model. Some associated properties were given in Table 5.4. The normal distribution is the well-known symmetrical bell-shaped curve (Figure 5.12). Some tabular values are given in Table 5.5. The table is entered by forming the standardized variable z , for the normal variate x as

$$z = \left| \frac{x - \bar{x}}{\sigma[x]} \right| \quad (5.38)$$

Tabular values yield the probabilities associated with the shaded areas shown in the figure: area = $\psi(z)$.

3.9	.499952	.499954	.499956	.499958	.499959	.499961	.499963	.499964	.499966	.499967

Solution. The standard deviation is $\sigma[s] = (0.14)(6000) = 840$ psi. Hence (see Figure 5.12),

- (a) $z = |(7000 - 6000)/840| = 1.19$; hence, from Table 5.5 $\psi(1.19) = 0.383$.
- (b) By symmetry, $P[5000 \leq s \leq 6000] = 0.383$.
- (c) $P[s \geq 7000] = 0.500 - 0.383 = 0.117$.

As might be expected from its name, the *lognormal distribution* (type V) is related to the normal distribution. If x is a normal variate and $x = \ln y$ or $y = \exp(x)$, then y is said to have a lognormal distribution. It is seen that the distribution has a minimum value of zero and is unbounded above. The probabilities associated with lognormal variates can be obtained very easily from those of mathematically corresponding normal variates (Table 5.5). If $E(y)$ and $V(y)$ are the expected value and coefficient of variation of a lognormal variate, the corresponding normal variate x will have the expected value and standard deviation (Benjamin and Cornell, 1970).

$$(\sigma[x])^2 = \ln\{1 + [V(y)]^2\} \quad (5.39a)$$

$$E[x] = \ln E(y) - (\sigma[x])^2/2 \quad (5.39b)$$

Example 5.9

A live load of 20 tons acts on a footing. If the loading is assumed to be lognormally distributed, estimate the probability that a loading of 40 tons will be exceeded.

Solution. From Table 5.3 we have that the coefficient of variation for a live load, say L , can be estimated as 25%; hence, from Equations 5.39 we have for the corresponding normal variate, say x ,

$$\sigma[x] = \sqrt{\ln[1 + (0.25)^2]} = 0.25$$

and

$$E[x] = \ln 20 - (0.25)^2/2 = 2.96$$

As $x = \ln L$, the value of the normal variate x equivalent to 40 tons is $\ln 40 = 3.69$. We seek the equivalent normal probability $P[3.69 \leq x]$. The standardized normal variate is $z = (3.69 - 2.96)/0.25 = 2.92$. Hence, using Table 5.5:

$$P[40 \leq L] = 0.50 - \psi(2.92) = 0.500 - 0.498 = 0.002$$

Particular attention should be paid to the regions of Figure 5.11, labeled the beta distributions. It is seen that many distributions (such as the normal, lognormal, uniform, and exponential) can be obtained as special cases of the very versatile beta distribution. Inherent in selecting a probability distribution to characterize a random variable is the imposition of the limits or range of its applicability. For example, for the normal it is required that the variable range from $-\infty$ to $+\infty$; the range of the lognormal and the exponential is from 0 to $+\infty$. Such assignments may not be critical if knowledge of distributions are desired in the vicinity of their expected values and their coefficients of variation are not excessive (say, less than 25%). On the other hand, many probabilistic assessments (such as reliability or the probability of failure) are vested in the tails of distributions. It is in such characterizations that the beta distribution is of great value.

The beta distribution is treated in great detail by Harr (1977, 1987). The latter reference also contains FORTRAN programs for beta probability distributions. This writer modified Pearson's beta distribution by fitting it to the four parameters: the expected value, the standard deviation, the minimum, and the

maximum values. Pearson's original work used the coefficients of skewness and kurtosis instead of the minimum and maximum values. Motivating the change was the sensitivity of the distribution to the coefficients. On the other hand, from an engineering point of view, one generally has a feel for the extremes of a design variable. Often, zero is the optional minimum value. In the event that limits are not defined, the specification of a range as the mean plus or minus, say, three standard deviations, generally places the generated beta distribution well within the accuracy required for most groundwater engineering applications (see Table 5.4).

We next return to groundwater and seepage.

5.4 The Flow Net

The graphical representation of special members of the families of streamlines and corresponding equipotential lines within a flow region form a *flow net*. The orthogonal network shown in Figure 5.13 represents such a system. Although the construction of a flow net often requires tedious trial-and-error adjustments, it is one of the more valuable methods employed to obtain the solutions for two-dimensional flow problems. Of additional importance, even a hastily drawn flow net will often provide a check on the reasonableness of solutions obtained by other means. Noting that, for steady-state conditions, Laplace's equation also models the action of (see Table 5.1) thermal, electrical, acoustical, odoriferous, torsional, and other systems, the flow net is seen to be a significant tool for analysis.

If, in Figure 5.13, Δw denotes the distance between a pair of adjacent streamlines and Δs is the distance between a pair of adjacent equipotential lines in the near vicinity of a point within the region of flow, the approximate velocity (in the mathematical sense) at the point, according to Darcy's law, will be

$$v \approx \frac{k\Delta h}{\Delta s} = \frac{\Delta \psi}{\Delta w} \quad (5.40)$$

As the quantity of flow between any two streamlines is a constant, ΔQ , and equal to $\Delta \psi$ (Equation 5.21) we have

$$\Delta Q \approx k \frac{\Delta w}{\Delta s} \Delta h \quad (5.41)$$

Equation 5.40 and Equation 5.41 are approximate. However, as the distances Δw and Δs become very small, Equation 5.40 approaches the velocity at a point and Equation 5.41 yields the quantity of discharge through the flow channel.

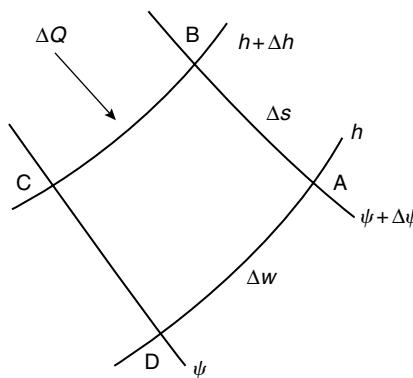

FIGURE 5.13 Flow at point.

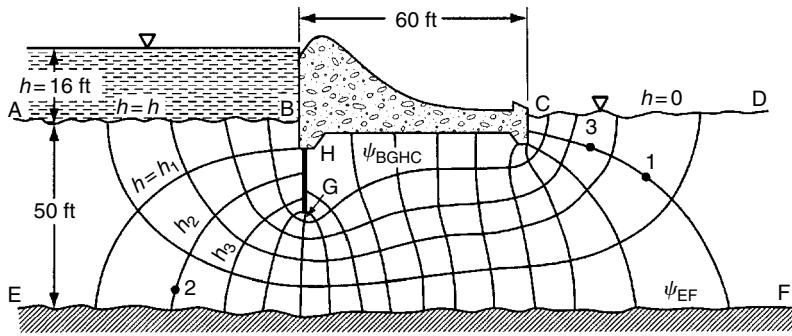

FIGURE 5.14 Example of flow net.

In Figure 5.14 is shown the completed flow net for a common type of structure. We first note that there are four boundaries: the bottom impervious contour of the structure $BGHC$, the surface of the impervious layer EF , the headwater boundary AB , and the tailwater boundary CD . The latter two boundaries designate the equipotential lines $h = h$ and $h = 0$, respectively. For steady-state conditions the quantity of discharge through the section Q , and the head loss ($h=16$ ft) must be constant. If the flow region is saturated, it follows that the two impervious boundaries are not only streamlines but their difference must be identically equal to the discharge quantity

$$Q = \psi_{BGHC} - \psi_{EF}$$

From among the infinite number of possible streamlines between the impervious boundaries, we sketch only a few specifying the same quantity of flow between neighboring streamlines. Designating N_f as the number of flow channels, we have, from above,^{*}

$$Q = N_f \Delta Q = k N_f \frac{\Delta w}{\Delta s} \Delta h$$

Similarly, from among the infinite number of possible equipotential lines between headwater and tailwater boundaries, we sketch only a few and specify the same drop in head, say Δh , between adjacent equipotential lines. If there are N_e equipotential drops along each of the channels,

$$h = N_e \Delta h$$

and

$$Q = k \frac{N_f}{N_e} \frac{\Delta w}{\Delta s} h \quad (5.42)$$

If, now, we also require that the ratio $\Delta w/\Delta s$ be the same at all points in the flow region, for convenience, and as a square is most sensitive to visual inspection, we take this ratio to be unity,

$$\frac{\Delta w}{\Delta s} = 1$$

and obtain

$$Q = k \frac{N_f}{N_e} h \quad (5.43)$$

^{*}There is little to be gained by retaining the approximately equal sign \approx .

Recalling that Q , k , and h are all constants, Equation 5.43 demonstrates that the resulting construction, with the obvious requirement that everywhere within the flow domain streamlines and equipotential lines meet at right angles, will yield a unique value for the ratio of the number of flow channels to the number of equipotential drops, N_f/N_e . In Figure 5.14, N_f equals about 5 and N_e equals 16; hence, $N_f/N_e = 5/16$.

The graphical technique of constructing flow nets by sketching was first suggested by Prasil (1913) although it was developed formally by Forchheimer (1930); however, the adoption of the method by engineers followed Casagrande's classical paper in 1940. In this paper and in the highly recommended flow nets of Cedergren (1967) are to be found some of the best examples of the art of drawing flow nets. Harr (1962) also warrants a peek!

Unfortunately, there is no "royal road" to drawing a good flow net. The speed with which a successful flow net can be drawn is highly contingent on the experience and judgment of the individual. In this regard, the beginner will do well to study the characteristics of well-drawn flow nets: *labor omnia vincit*.

In summary, a flow net is a sketch of distinct and special streamlines and equipotential lines that preserve right-angle intersections within the flow regime, satisfy the boundary conditions, and form curvilinear squares.* The following procedure is recommended:

1. Draw the boundaries of the flow region to a scale so that all sketched equipotential lines and streamlines terminate on the figure.
2. Sketch lightly three or four streamlines, keeping in mind that they are only a few of the infinite number of possible curves that must provide a smooth transition between the boundary streamlines.
3. Sketch the equipotential lines, bearing in mind that they must intersect all streamlines, including boundary streamlines, at right angles and that the enclosed figures must form curvilinear rectangles (except at singular points) with the same ratio of $\Delta s/\Delta s$ along a flow channel. Except for partial flow channels and partial head drops, these will form curvilinear squares with $\Delta w = \Delta s$.
4. Adjust the initial streamlines and equipotential lines to meet the required conditions. Remember that the drawing of a good flow net is a trial-and-error process, with the amount of correction being dependent upon the position selected for the initial streamlines.

Example 5.10

Obtain the quantity of discharge, Q/kh , for the section shown in Figure 5.15.

Solution. This represents a region of horizontal flow with parallel horizontal streamlines between the impervious boundaries and vertical equipotential lines between reservoir boundaries. Hence, the flow net will consist of perfect squares, and the ratio of the number of flow channels to the number of drops will be $N_f/N_e = a/L$ and $Q/kh = a/L$.

Example 5.11

Find the pressure in the water at points A and B in Figure 5.15.

Solution. For the scheme shown in Figure 5.15, the total head loss is linear with distance in the direction of flow. Equipotential lines are seen to be vertical. The total heads at points A and B are both equal to $2h/3$ (datum at the tailwater surface). This means that a piezometer placed at these points would show a column of water rising to an elevation of $2h/3$ above the tailwater elevation. Hence, the pressure at each point is simply the weight of water in the columns above the points in question: $p_A = (2h/3 + h_1)\gamma_w$, $p_B = (2h/3 + h_1 + a)\gamma_w$.

*We except singular squares such as the five-sided square at point H in Figure 5.14 and the three-sided square at point G. (It can be shown [Harr, 1962, p. 84] that a five-sided square designates a point of turbulence.) With continued subdividing into smaller squares, the deviations, in the limit, act only at singular points.

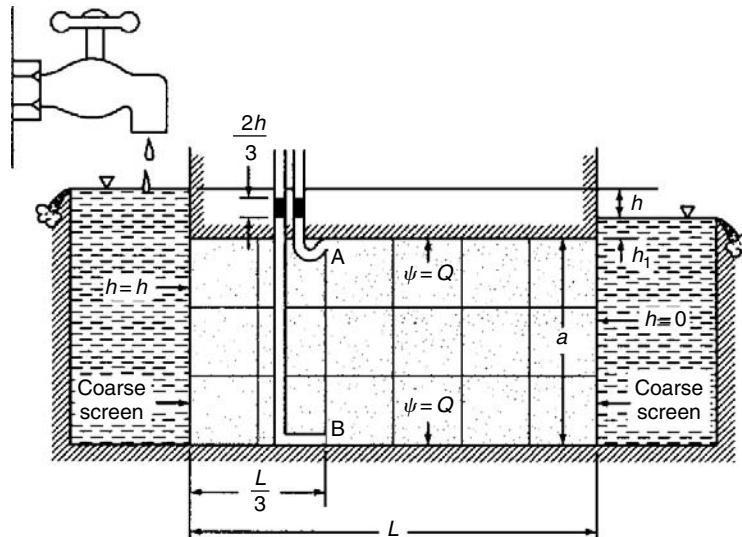

FIGURE 5.15 Example of flow regime.

Example 5.12

Using flow nets, obtain a plot of Q/kh as a function of the ratio s/T for the single impervious sheetpile shown in Figure 5.16a.

Solution. We first note that the section is symmetrical about the y axis, hence only one half of a flow net is required. Values of the ratio s/T range from 0 to 1; with 0 indicating no penetration and 1 complete cutoff. For $s/T = 1$, $Q/kh = 0$ (see point a in Figure 5.16b). As the ratio of s/T decreases, more flow channels must be added to maintain curvilinear squares and, in the limit as s/T approaches zero, Q/kh becomes unbounded (see arrow on Figure 5.16b). If $s/T = 1/2$ (Figure 5.16c), each streamline will evidence a corresponding equipotential line in the half-strip; consequently, for the whole flow region, $N_f/N_e = 1/2$ for $s/T = 1/2$ (point b in Figure 5.16b). Thus, without actually drawing a single flow net, we have learned quite a bit about the functional relationship between Q/kh and s/T . If Q/kh were known for $s/T=0.8$ we would have another point and could sketch, with some reliability, the portion of the plot in Figure 5.16b for $s/T \geq 0.5$. In Figure 5.16d is shown one half of the flow net for $s/T = 0.8$, which yields the ratio of $N_f/N_e = 0.3$ (point c in Figure 5.16b). As shown in Figure 5.16e, the flow net for $s/T=0.8$ can also serve, geometrically, for the case of $s/T=0.2$, which yields approximately $N_f/N_e=0.8$ (plotted as point d in Figure 5.16b). The portion of the curve for values of s/T close to 0 is still in doubt. Noting that for $s/T = 0$, $kh/Q = 0$, we introduce an ordinate scale of kh/Q to the right of Figure 5.16b and locate on this scale the corresponding values for $s/T=0, 0.2$, and 0.5 (shown primed). Connecting these points (shown dotted) and obtaining the inverse, Q/kh , at desired points, the required curve can be obtained.

A plot giving the quantity of discharge (Q/kh) for symmetrically placed pilings as a function of depth of embedment (s/T), as well as for an impervious structure of width $(2b/T)$, is shown in Figure 5.17. This plot was obtained by Polubarnova-Kochina (1952) using a mathematical approach. The curve labeled $b/T=0$ applies for the conditions in Example 5.12. It is interesting to note that this whole family of curves can be obtained, with reasonable accuracy,^{*} by sketching only two additional half flow nets (for special values of b/T).

* At least commensurate with the determination of the coefficient of permeability, k .

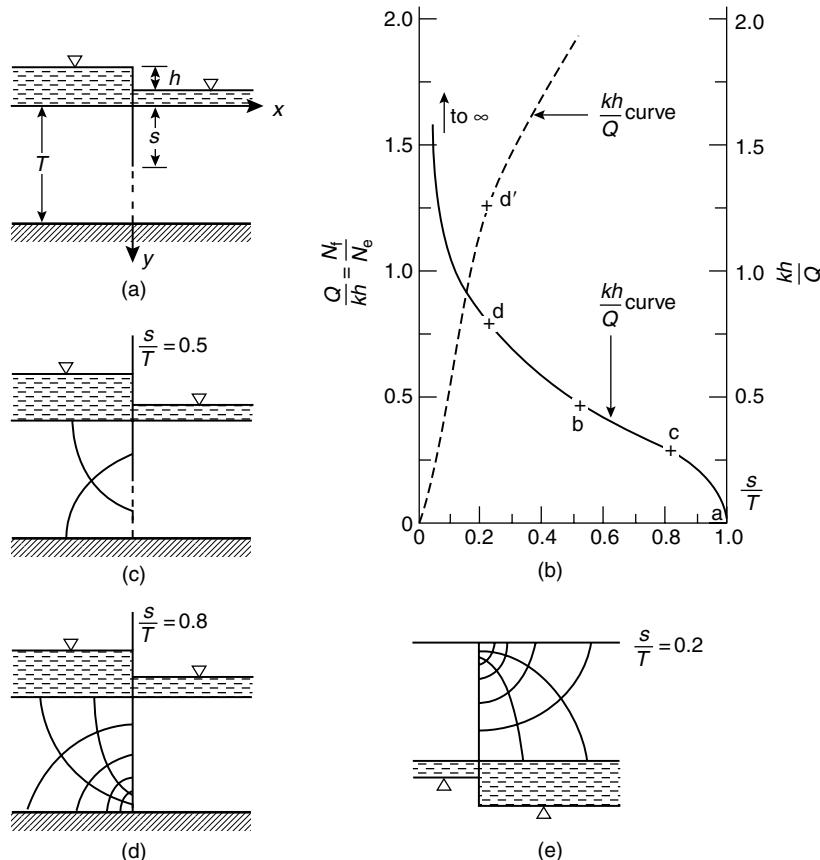

FIGURE 5.16 Example 5.12.

It was tacitly assumed in the foregoing that the medium was homogeneous and isotropic ($k_x = k_y$). Had isotropy not been realized, a transformation of scale* in the y direction of $Y = y(k_x/k_y)^{1/2}$ or in the x direction of $X = x(k_y/k_x)^{1/2}$ would render the system as an equivalent isotropic system (for details, see Harr, 1962, p. 29). After the flow net has been established, by applying the inverse of the scaling factor, the solution can be had for the anisotropic system. The quantity of discharge for a homogeneous and anisotropic section is

$$Q = \sqrt{k_x k_y} h \frac{N_f}{N_e} \quad (5.44)$$

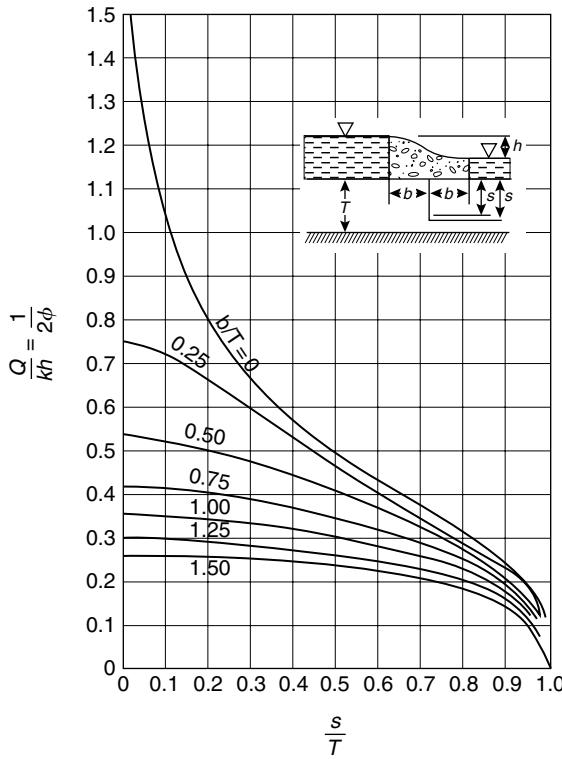

We next introduce some powerful probabilistic tools.

5.5 The Point Estimate Method (PEM)

5.5.1 One Random Variable

Many methods have been offered in the past to accommodate uncertainty. The most common, by far, is to assign single-valued point estimates that reflect central tendencies or implied levels of conservatism. Analyses are then reduced to deterministic treatments. More direct probabilistic methods employ Monte Carlo simulations or truncated Taylor series (Harr, 1987). However, analyses rapidly become exceedingly

*Here x and y are taken as the directions of maximum and minimum permeability.

$$\text{If } m = \cos \frac{\pi s}{2T} \sqrt{\tanh^2 \frac{\pi b}{2T} + \tan^2 \frac{\pi b}{2T}}$$

$$\text{for } m \leq 0.3, \frac{Q}{kh} = \frac{1}{\pi} \ln \frac{4}{m}$$

$$\text{for } m^2 \geq 0.3, \frac{Q}{kh} = \frac{-\pi}{2 \ln \left(\frac{1-m^2}{16} \right)}$$

FIGURE 5.17 Quantity of flow for given geometry.

difficult, if not impossible, for these methods for any but a very few uncorrelated random variables. A simple and very versatile procedure called the *point estimate method* is advocated by this writer and will be developed in some detail. This method, first presented by Rosenblueth (1975) and later extended by him in 1981, has since seen considerable use and expansion by this writer and his coauthors. The methodology is presented in considerable detail in Harr (1987).

Consider $y = p(x)$ to be the probability distribution of the random variable x , with expected value \bar{x} and standard deviation σ . With analogy to Figure 5.7, we replace the load on the beam by *two* reactions, $p(-)$ and $p(+)$ acting at $x(-)$ and $x(+)$, as shown in Figure 5.18.

Pleading symmetry, probabilistic arguments produce for a random variable x :

$$p(+) = p(-) = \frac{1}{2} \quad (5.45a)$$

$$x(+) = \bar{x} + \sigma[x] \quad (5.45b)$$

$$x(-) = \bar{x} - \sigma[x] \quad (5.45c)$$

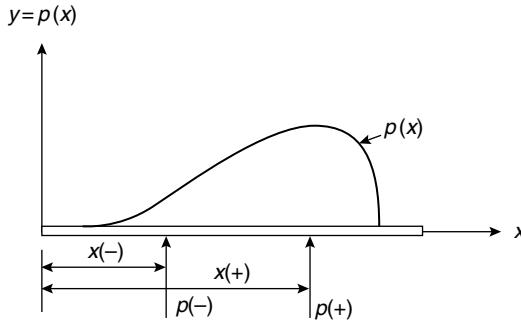

FIGURE 5.18 Point estimate approximations.

With the distribution $p(x)$ approximated by the point estimates $p(-)$ and $p(+)$, the moments of $y = p(x)$ are

$$E[y] = \bar{y} = p(-)y(-) + p(+)y(+) \quad (5.46a)$$

$$E[y^2] = p(-)y^2(-) + p(+)y^2(+) \quad (5.46b)$$

where $y(-)$ and $y(+)$ are the values of the function $p(x)$ at $x(-)$ and $x(+)$, respectively. These reduce to the simpler expressions

$$\bar{y} = \frac{y(+) + y(-)}{2} \quad (5.47a)$$

$$\sigma[y] = \left| \frac{y(+) - y(-)}{2} \right| \quad (5.47b)$$

Example 5.13

Estimate the expected value and the coefficient of variation for the well-known coefficient of active earth pressure $K_A = \tan^2(45 - \phi/2)$, if $E[\phi] = 30^\circ$.

Solution. With the standard deviation of the ϕ -parameter not given, we again return to Table 5.3, $V(\phi) = 12\%$, and $\sigma[\phi] = 3.6^\circ$. Hence, $\phi(+) = 33.6^\circ$, $\phi(-) = 26.4^\circ$. Therefore, $K_A(+) = 0.29$, $K_A(-) = 0.38$, and Equations 5.47 produce $\bar{K}_A = 0.34$, $\sigma[K_A] = 0.05$; hence, $V(K_A) = 13\%$.

Before proceeding with functions of many random variables, we shall first consider regression and correlation.

5.5.2 Regression and Correlation

We next study the functional relationship between random variables called *regression analysis*. It is regression analysis that provides the grist of being able to predict the value of one variable from that of another or of others. The measure of the degree of correspondence within the developed relationship belongs to *correlation analysis*.

Let us suppose we have N pairs of data $[x(1), y(1)], \dots, [x(N), y(N)]$ for which we postulate the *linear* relationship

$$y = Mx + B \quad (5.48)$$

where M and B are constants. Of the procedures available to estimate these constants (including *best fit by eye*), the most often used is the *method of least squares*. This method is predicated on minimizing the

sum of the squares of the distances between the data points and the corresponding points on a straight line. That is, M and B are chosen so that

$$\sum(y - Mx - B)^2 = \text{minimum}$$

This requirement is met by the expressions

$$M = \frac{N \sum xy - \sum x \sum y}{N \sum x^2 - (\sum x)^2} \quad (5.49a)$$

$$B = \frac{\sum x^2 \sum y - \sum x \sum xy}{N \sum x^2 - (\sum x)^2} \quad (5.49b)$$

It should be emphasized that a straight line fit was assumed. The reasonableness of this assumption is provided by the *correlation coefficient* ρ , defined as

$$\rho = \frac{\text{cov}[x, y]}{\sigma[x]\sigma[y]} \quad (5.50)$$

where $\sigma[x]$ and $\sigma[y]$ are the respective standard deviations and $\text{cov}[x, y]$ is their *covariance*. The covariance is defined as

$$\text{cov}[x, y] = \frac{1}{N} \sum_{i=1}^N [x(i) - \bar{x}][y(i) - \bar{y}] \quad (5.51)$$

With analogy to statics the covariance corresponds to the *product of inertia*.

In concept, the correlation coefficient is a measure of the tendency for two variables to vary together. This measure may be zero, negative, or positive; wherein the variables are said to be *uncorrelated*, *negatively correlated*, or *positively correlated*.

The variance is a special case of the covariance as

$$\text{cov}[x, x] = \nu[x] \quad (5.52)$$

Application of their definitions produces (Ditlevsen, 1981) the following identities (a, b, c are constants):

$$E[a + bx + cy] = a + bE[x] + cE[y] \quad (5.53a)$$

$$\nu[a + bx + cy] = b^2\nu[x] + c^2\nu[y] + 2bc \text{cov}[x, y] \quad (5.53b)$$

$$\text{cov}[x, y] \leq \sigma[x]\sigma[y] \quad (5.53c)$$

$$\nu[a + bx + cy] = b^2\nu[x] + c^2\nu[y] + 2bc\sigma[x]\sigma[y]\rho \quad (5.53d)$$

Equation 5.53c demonstrates that the correlation coefficient, Equation 5.50, must satisfy the condition

$$-1 \leq \rho \leq +1 \quad (5.54)$$

If there is perfect correlation between variables and in the same sense of direction, $\rho = +1$. If there is perfect correlation in opposite directions (one variable increases as the other decreases), $\rho = -1$. If some scatter exists, $-1 < \rho < +1$, with $\rho = 0$ if there is no correlation. Some examples are shown in Figure 5.19.

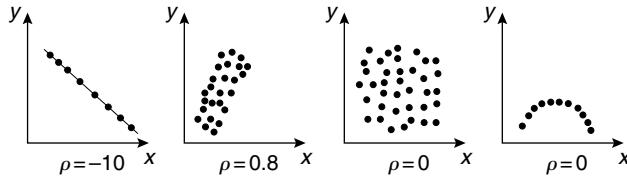

FIGURE 5.19 Example of scatter and correlation coefficients.

TABLE 5.6 Example of Extraction of Moments and Correlation Coefficients

Test	x_1	x_2	x_3	dx_1	dx_2	dx_3	ds_1	ds_2	ds_3
1	2	1	2	-5.25	-6.67	-4.92	-1.92	-1.85	-1.29
2	4	3	1	-3.25	-4.67	-5.92	-1.18	-1.30	-1.55
3	6	7	5	-1.25	-0.67	-1.92	-0.46	-0.19	-0.50
4	7	6	3	-0.25	-1.67	-3.92	-0.09	-0.46	-1.02
5	5	4	7	-2.25	-3.67	0.08	-0.82	-1.02	0.02
6	8	9	6	0.75	1.33	-0.92	0.27	0.37	-0.25
7	9	8	7	1.75	0.33	0.08	0.64	0.09	0.02
8	7	10	9	-0.25	2.33	2.08	-0.09	0.65	0.55
9	10	11	11	2.75	3.33	4.08	1.01	0.93	1.07
10	8	9	8	0.75	1.33	1.08	0.27	0.37	0.28
11	12	11	10	4.75	3.33	3.08	1.74	0.93	0.81
12	9	13	14	1.75	5.33	7.08	0.64	1.48	1.85
Expected value	7.25	7.67	6.92	0	0	0	0	0	0
Standard deviations	2.73	3.60	3.82	2.73	3.60	3.82	1	1	1

We shall next present an extension of the above correlation methodology that will accommodate very many random variables.

Suppose that 12 tests are performed and sample measurements of the three variables x_1 , x_2 , and x_3 yield the values in columns so labeled in Table 5.6. Also shown are the sample expected values (\bar{x}_i) obtained as

$$\bar{x}_i = E[x_i] = \frac{1}{12} \sum_{i=1}^{12} x_i, \quad i = 1, 2, 3 \quad (5.55)$$

Columns labeled dx_1 , dx_2 , and dx_3 are *mean-corrected*; that is, the respective expected values have been subtracted from the raw data,

$$dx_i = x_i - \bar{x}_i, \quad i = 1, 2, 3 \quad (5.56)$$

Designating the 12×3 matrix composed of the three columns (dx_1 , dx_2 , dx_3) as D , the *mean-corrected matrix*, and performing the matrix multiplication, D' is the transpose of the matrix D , produces the symmetrical *covariance matrix*, C :

$$C = \frac{1}{11} D'D = \begin{bmatrix} 7.48 & 8.73 & 7.84 \\ 8.73 & 12.97 & 12.24 \\ 7.84 & 12.24 & 14.63 \end{bmatrix} \quad (5.57a)$$

The elements on the principal diagonal, 7.48, 12.97, 14.63, are the respective variances of the variables x_1 , x_2 , and x_3 . Hence, the respective standard deviations are 2.73, 3.60, and 3.82.

$$\sigma_1 = 2.73, \quad \sigma_2 = 3.60, \quad \sigma_3 = 3.82 \quad (5.57b)$$

The off-diagonal elements are the respective covariances; for example, $8.73 = \sigma_1\sigma_2\rho_{1,2}$, where $\rho_{1,2}$ is the correlation coefficient between the variables x_1 and x_2 . Hence, $\rho_{1,2} = 8.73/(2.73 \times 3.60) = 0.89$. In general, dividing a row and column of the covariance matrix by the corresponding standard deviations produces the symmetrical *correlation matrix*, K , which for the example at hand becomes

$$K = \begin{bmatrix} 1.00 & 0.89 & 0.75 \\ 0.89 & 1.00 & 0.89 \\ 0.75 & 0.89 & 1.00 \end{bmatrix} \quad (5.58)$$

It should be noted that the correlation matrix could also have been obtained directly from the raw data, the columns of x_1 , x_2 , and x_3 in Table 5.6. The respective standard deviations (σ_i) are given by (Note: $12 - 1 = 11$):

$$\sigma_i^2 = \frac{1}{11} \sum_{i=1}^{12} (x_i - \bar{x})^2, \quad i = 1, 2, 3 \quad (5.59)$$

The last three columns of Table 5.6, labeled ds_1 , ds_2 , and ds_3 are *standardized variates*, obtained by subtracting the expected values and dividing by the standard deviations, respectively; that is

$$ds_i = \frac{x_i - \bar{x}_i}{\sigma_i} \quad (5.60)$$

Then, forming the 12×3 matrix D_s , with the columns the same as the last three columns of Table 5.6, the correlation matrix is obtained as

$$K = \frac{1}{11} D_s' D_s \quad (5.61)$$

Thus, the data in Table 5.6 have been reduced to provide the expected values, standard deviations, and correlation coefficients of the three uncertain variables. It should be apparent that the foregoing concepts can be readily extended to m test results for n variables to produce the $n \times n$ correlation matrix and the respective expected values and standard deviations of the n -variates. The coefficient in Equation 5.59 and Equation 5.61 would be $1/(m - 1)$. Computer software abounds that readily produces these results.

5.5.3 Point Estimate Method — Several Random Variables

Rosenblueth (1975) generalized his earlier methodology to any number of correlated variables. For example, for a function of three random variables; say, $y = y[x(1), x(2), x(3)]$; where $\rho(i, j)$ is the correlation coefficient between variables $x(i)$ and $x(j)$ he obtained:

$$E[y^N] = p(++)y^N(++) + p(+-)y^N(+-) + \dots + p(--y^N--) \quad (5.62a)$$

where

$$y(\pm \pm \pm) = y[\bar{x}(1) \pm \sigma[x1], \bar{x}(2) \pm \sigma[x2], \bar{x}(3) \pm \sigma[x3]] \quad (5.62b)$$

$$p(+++)=p(---)=\frac{1}{2^3}[1+\rho(1,2)+\rho(2,3)+\rho(3,1)]$$

$$p(++-)=p(-+)=\frac{1}{2^3}[1+\rho(1,2)-\rho(2,3)-\rho(3,1)]$$

$$p(+--)=p(-+-)=\frac{1}{2^3}[1-\rho(1,2)-\rho(2,3)+\rho(3,1)]$$

$$p(+--)=p(-++)=\frac{1}{2^3}[1-\rho(1,2)+\rho(2,3)-\rho(3,1)] \quad (5.62c)$$

where $\sigma[xi]$ is the standard deviation of $x(i)$. The sign of $\rho(i,j)$ is determined by the multiplication rule of i and j ; that is, if the sign of $i = (-)$, and of $j = (+)$; $(i)(j) = (-)(+) = (-)$.

Equation 5.62a has $2^3 = 8$ terms, all permutations of the three +’s and –’s. In general, for M variables there are 2^M terms and $M(M - 1)/2$ correlation coefficients, the number of combinations of M objects taken two at a time. The coefficient on the right-hand side of Equation 5.62c, in general, is $(1/2)^M$.

Example 5.14

The recommendation of the American Concrete Institute (Galambos et al., 1982) for the design of reinforced concrete structures is (in simplified form)

$$R \geq 1.6D + 1.9L$$

where R is the strength of the element, D is the dead load, and L is the lifetime live load. If $E[D] = 10$, $E[L] = 8$, $V(D) = 10\%$, $V(L) = 25\%$, $\rho(D, L) = 0.75$ (a) Find the expected value and standard deviation of R for the case $R = 1.6I + 1.9L$. (b) If the results in part (a) generate a normal variate and the maximum strength of the element R is estimated to be 40, estimate the implied probability of failure.

Solution. The solution is developed in Figure 5.20.

Generalizations of the point estimate method to more than three random variables is given by Harr (1987). We next return to groundwater and seepage.

5.6 Method of Fragments

In spite of its many uses, a graphical flow net provides the solution for a singular problem configuration only. Should one wish to investigate the influence of a range of characteristic dimensions (such as is generally the case in a design problem) many flow nets would be required. Consider, for example, the section shown in Figure 5.21, and suppose we wish to investigate the influence of the dimensions A, B, and C on the characteristics of flow, all other dimensions being fixed. Taking only three values for each of these dimensions would require 27 individual flow nets. As noted previously, a rough flow net should always be drawn as a check. In this respect it may be thought of as being analogous to a free-body diagram in mechanics, wherein the physics of a solution can be examined with respect to satisfying conditions of necessity.

An approximate analytical method of solution, directly applicable to design, was developed by Pavlovsky in 1935 (Pavlovsky, 1956) and was expanded and advanced by Harr (1962, 1977). The underlying assumption of the method, called the *method of fragments*, is that equipotential lines at various critical parts of the flow region can be approximated by straight vertical lines (as, for example, the dotted lines in Figure 5.22) that divide the region into sections or fragments. The groundwater flow region in the figure is shown divided into four fragments.

$$R = 1.6D + 1.9L$$

Variable,	\bar{x}	$\sigma[x]$	$x(+)$	$x(-)$
x				
D	10	1	11	9
L	8	2	10	6

$$\rho(D, L) = +0.75$$

	$R(ij)$	$R(ij)^2$
$R(++) :$	36.6	1340
$R(+-) :$	29.0	841
$R(-+) :$	33.4	1116
$R(--)$:	25.8	666

$$p(++) = 1/4(1 + \rho) = 0.44$$

$$E[R] = \bar{R} = \sum R(ij)p(ij)$$

$$p(+-) = 1/4(1 - \rho) = 0.06$$

$$= 0.44(36.6 + 25.8) + 0.06(29.0 + 33.4)$$

$$p(-+) = 1/4(1 - \rho) = 0.06$$

$$= 31.20$$

$$p(--)= 1/4(1 + \rho) = 0.44$$

$$E[R^2] = \sum R(ij)^2 p(ij)$$

$$v[R] = E[R^2] - (E[R])^2 = 1000.06 - (31.20)^2 = 26.62$$

$$= 0.44(1340 + 666) + 0.06(841 + 1116)$$

$$\sigma[R] = 5.16; \quad V(R) = 16.5\%$$

$$= 1000.06$$

$$P_f = P[R \geq 40] = \frac{1}{2} - \Psi\left[\frac{40 - 31.20}{5.16}\right] = \frac{1}{2} - \Psi[1.71] = 0.044 \text{ (Table 5.3)}$$

The exact solution is 0.043

FIGURE 5.20 Solution to Example 5.14.

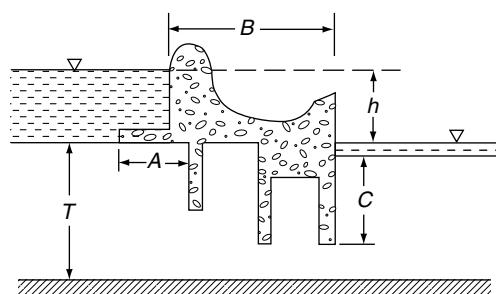

FIGURE 5.21 Example of a complicated structure.

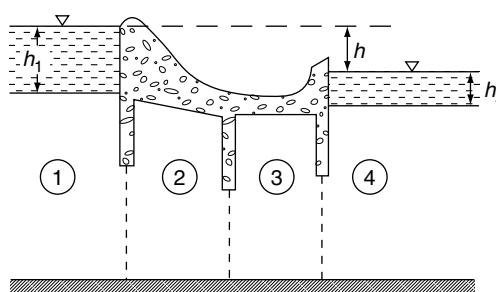

FIGURE 5.22 Four fragments.

Suppose, now, that one computes the discharge in the i th fragment of a structure with m such fragments as

$$Q = \frac{kh_i}{\Phi_i} \quad (5.63)$$

where h_i = head loss through the i th fragment, Φ_i = dimensional form factor in the i th fragment, $\Phi_i = N_e/N_f$ in Equation 5.43. Then, as the discharge through all fragments must be the same,

$$Q = \frac{kh_1}{\Phi_1} = \frac{kh_2}{\Phi_2} = \frac{kh_i}{\Phi_i} = \dots = \frac{kh_m}{\Phi_m}$$

whence

$$\Sigma h_i = \frac{Q}{k} \Sigma \Phi_i$$

and

$$Q = k \frac{h}{\sum_{i=1}^m \Phi_i} \quad (5.64)$$

where h (without subscript) is the total head loss through the section. By similar reasoning, the head loss in the i th fragment can be calculated from

$$h_i = \frac{h\Phi_i}{\Sigma \Phi} \quad (5.65)$$

Thus, the primary task is to implement this method by establishing a catalog of form factors. Following Pavlovsky, the various form factors will be divided into types. The results are summarized in tabular form, Figure 5.23, for easy reference. The derivation of the form factors is well documented in the literature (Harr, 1962, 1977).

Various entrance and emergence conditions for type VIII and IX fragments are shown in Figure 5.24. Briefly, for the entrance condition, when possible, the free surface will intersect the slope at right angles. However, as the elevation of the free surface represents the level of available energy along the uppermost streamline, at no point along the curve can it rise above the level of its source of energy, the headwater elevation. At the point of emergence the free surface will, if possible, exit tangent to the slope (Dachler, 1934). As the equipotential lines are assumed to be vertical, there can be only a single value of the total head along a vertical line, and, hence, the free surface cannot curve back on itself. Thus, where unable to exit tangent to a slope it will emerge vertical.

To determine the pressure distribution on the base of a structure (such as that along C'CC'' in Figure 5.25), Pavlovsky assumed that the head loss within the fragment is linearly distributed along the impervious boundary. Thus, if h_m is the head loss within the fragment, the rate of loss along E'C'CC'E'' will be

$$R = \frac{h_m}{L + s' + s''} \quad (5.66)$$

Once the total head is known at any point, the pressure can easily be determined by subtracting the elevation head, relative to the established (tailwater) datum.

Example 5.15

For the section shown in Figure 5.26a, estimate (a) the discharge and (b) the uplift pressure on the base of the structure.

III		$\Phi = \frac{L}{2} \left(\frac{kh}{Q} \right)$, Fig. 4.17	VII		$\Phi = \frac{2L}{h_1+h_2}$ $Q = k \frac{h_1-h}{\cot \alpha} \ln \frac{h_d}{h_d-h}$
IV		$b \leq s: \Phi = \ln(1 + \frac{b}{a})$ $b \geq s: \Phi = \ln(1 + \frac{s}{a}) + \frac{b-s}{T}$	VIII		$Q = k \frac{h_1-h}{\cot \alpha} \ln \frac{h_d}{h_d-h}$
			IX		$Q = k \frac{a_2}{\cot \beta} (1 + \ln \frac{a_2+h_2}{a_2})$

FIGURE 5.23 Summary of fragment types and form factors.

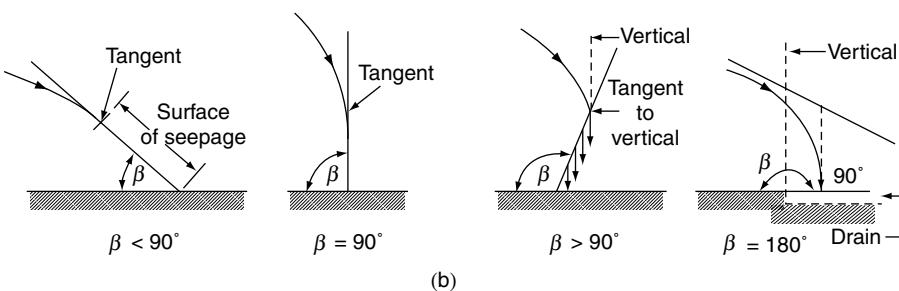

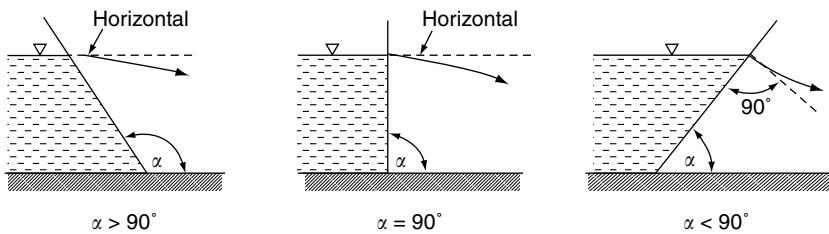

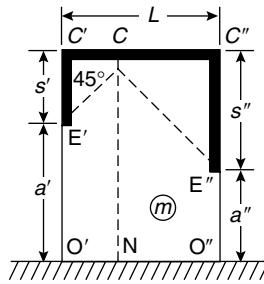

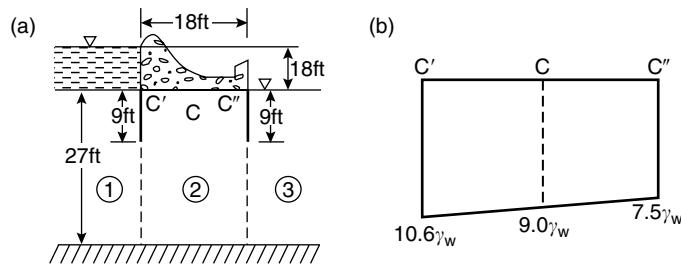

FIGURE 5.24 Entrance and emergence conditions.

**FIGURE 5.25** Illustration of Equation 5.66.**FIGURE 5.26** Example 5.15.

Solution. The division of fragments is shown on the figure. Regions 1 and 3 are both type II fragments, and the middle section is type V with $L = 2s$. For regions 1 and 3, we have, from Figure 5.17, with $b/T = 0$, $\Phi_1 = \Phi_3 = 0.78$.

For region 2, as $L = 2s$, $\Phi_2 = 2 \ln(1 + 18/36) = 0.81$. Thus, the sum of the form factors is

$$\Sigma \Phi = 0.78 + 0.81 + 0.78 = 2.37$$

and the quantity of flow (Equation 5.64) is $Q/k = 18/2.37 = 7.6$ ft.

For the head loss in each of the sections, from Equation 5.64 we find

$$h_1 = h_3 = \frac{0.78}{2.37} (18) = 5.9 \text{ ft}$$

$$h_2 = 6.1 \text{ ft}$$

Hence the head loss rate in region 2 is (Equation 5.65)

$$R = \frac{6.1}{36} = 17\%$$

and the pressure distribution along $C'C'C''$ is shown in Figure 5.26b.

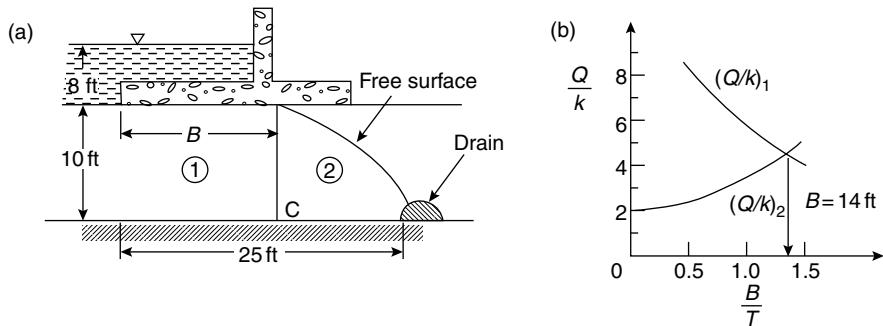

FIGURE 5.27 Example 5.16.

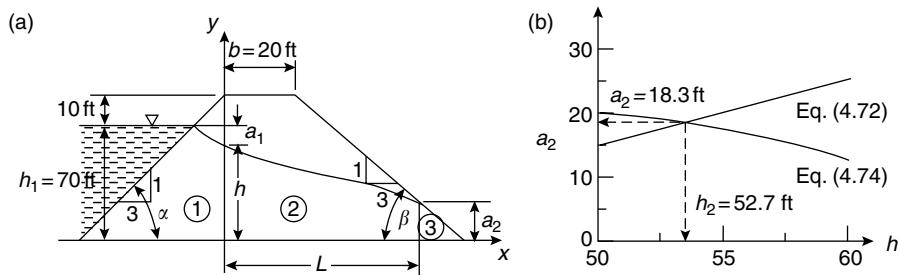

FIGURE 5.28 Example 5.17.

Example 5.16*

Estimate the quantity of discharge per foot of structure and the point where the free surface begins under the structure (point A) for the section shown in Figure 5.27a.

Solution. The vertical line AC in Figure 5.27a is taken as the vertical equipotential line that separates the flow domain into two fragments. Region 1 is a fragment of type III, with the distance B as an unknown quantity. Region 2 is a fragment of type VII with $L = 25 - B$, and $h_1 = 10 \text{ ft}$ and $h_2 = 0$. Thus, we are led to a trial-and-error procedure to find B . In Figure 5.27b are shown plots of Q/k vs. B/T for both regions. The common point is seen to be $B = 14 \text{ ft}$, which yields a quantity of flow of approximately $Q = 100k/22 = 4.5k$.

Example 5.17

Determine the quantity of flow for 100 ft of the earth dam section shown in Figure 5.28a, where $k = 0.002 \text{ ft/min}$.

Solution. For this case, there are three regions. For region 1, a type VIII fragment $h_1 = 70 \text{ ft}$, $\cot \alpha = 3$, $h_d = 80 \text{ ft}$, produces

$$\frac{Q}{k} = \frac{70 - h}{3} \ln \frac{80}{80 - h} \quad (5.67)$$

* For comparisons between analytical and experimental results for mixed fragments (confined and unconfined flow) see Harr and Lewis (1965).

For region 2, a type VII fragment

$$\frac{Q}{k} = \frac{h^2 - a_2^2}{2L} \quad (5.68)$$

With tailwater absent, $h_2 = 0$, the flow in region 3, a type IX fragment, with $\cot \beta = 3$ produces

$$\frac{Q}{k} = \frac{a_2}{3} \quad (5.69)$$

Finally, from the geometry of the section, we have

$$L = 20 + \cot \beta [h_d - a_2] = 20 + 3[80 - a_2] \quad (5.70)$$

The four independent equations contain only the four unknowns, h , a_2 , Q/k , and L , and hence provide a complete, if not explicit solution.

Combining Equations 5.68 and Equation 5.69 and substituting for L in Equation 5.70, we obtain, in general (b = crest width),

$$a_2 = \frac{b}{\cot \beta} + h_d - \sqrt{\left(\frac{b}{\cot \beta} + h_d\right)^2 - h^2} \quad (5.71)$$

and, in particular,

$$a_2 = \frac{20}{3} + 80 - \sqrt{\left(\frac{20}{3} + 80\right)^2 - h^2} \quad (5.72)$$

Likewise, from Equations 5.66 and Equation 5.68, in general,

$$\frac{a_2 \cot \alpha}{\cot \beta} = (h_1 - h) \ln \frac{h_d}{h_d - h} \quad (5.73)$$

and, in particular,

$$a_2 = (70 - h) \ln \frac{80}{80 - h} \quad (5.74)$$

Now, Equations 5.72 and 5.74, and 5.71 and 5.73 in general, contain only two unknowns (a_2 and h), and hence can be solved without difficulty. For selected values of h , resulting values of a_2 are plotted for Equation 5.72 and Equation 5.74 in Figure 5.28b. Thus, $a_2 = 18.3$ ft, $h = 52.7$ ft, and $L = 205.1$ ft. From Equation 5.69, the quantity of flow per 100 ft is

$$Q = 100 \times 2 \times 10^{-3} \times \frac{18.3}{3} = 1.22 \text{ ft}^3/\text{min} = 9.1 \text{ gal}/\text{min}$$

5.7 Flow in Layered Systems

Closed-form solutions for the flow characteristics of even simple structures founded in layered media offer considerable mathematical difficulty. Polubarinova-Kochina (1952) obtained closed-form solutions for the two-layered sections shown in Figure 5.29 (with $d_1 = d_2$). In her solution she found a cluster of parameters that suggested to Harr (1962) an approximate procedure whereby the flow characteristics of structures founded in layered systems can be obtained simply and with a great degree of reliability.

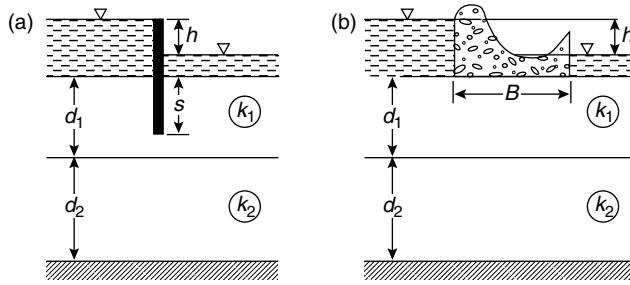

FIGURE 5.29 Example of two-layered systems.

The flow medium in Figure 5.29a consists of two horizontal layers of thickness d_1 and d_2 , underlain by an impervious base. The coefficient of permeability of the upper layer is k_1 and of the lower layer, k_2 . The coefficients of permeability are related to a dimensionless parameter ε by the expression

$$\tan \pi \varepsilon = \sqrt{\frac{k_2}{k_1}} \quad (5.75^*)$$

Thus, as the ratio of the permeabilities varies from 0 to ∞ , ε ranges between 0 and 1/2. We first investigate the structures shown in Figure 5.29a for some special values of ε .

1. $\varepsilon = 0$. If $k_2 = 0$, from Equation 5.75 we have $\varepsilon = 0$. This is equivalent to having the impervious base at depth d_1 . Hence, for this case the flow region is reduced to that of a single homogeneous layer for which the discharge can be obtained directly from Figure 5.17.
2. $\varepsilon = 1/4$. If $k_1 = k_2$, the sections are reduced to a single homogeneous layer of thickness $d_1 + d_2$, for which Figure 5.17 is again applicable.
3. $\varepsilon = 1/2$. If $k_2 = \infty$, $\varepsilon = 1/2$. This represents a condition where there is no resistance to flow in the bottom layer. Hence, the discharge through the total section under steady-state conditions is infinite, or $Q/k_1 h = \infty$. However, of greater significance is the fact that the inverse of this ratio $k_1 h/Q = 0$. It can be shown (Polubarinova-Kochina, 1952), that for $k_2/k_1 \rightarrow \infty$,

$$\frac{Q}{k_1 h} \approx \sqrt{\frac{k_2}{k_1}} \quad (5.76)$$

Thus, we see that for the special values of $\varepsilon = 0$, $\varepsilon = 1/4$, and $\varepsilon = 1/2$ measures of the flow quantities can be easily obtained. The essence of the method then is to plot these values, on a plot of $k_1 h/Q$ vs. ε , and to connect the points with a smooth curve, from which intermediate values can be had.

Example 5.18

In Figure 5.29a, $s = 10$ ft, $d_1 = 15$ ft, $d_2 = 20$ ft, $k_1 = 4k_2 = 1 \times 10^{-3}$ ft/min, $h = 6$ ft. Estimate $Q/k_1 h$.

Solution. For $\varepsilon = 0$, from Figure 5.17 with $s/T = s/d_1 = 2/3$, $b/T = 0$, $Q/k_1 h = 0.39$, $k_1 h/Q = 2.56$.

For $\varepsilon = 1/4$, from Figure 5.17 with $s/T = s/(d_1 + d_2) = 2/7$, $Q/k_1 h = 0.67$, $k_1 h/Q = 1.49$.

For $\varepsilon = 1/2$, $k_1 h/Q = 0$.

The three points are plotted in Figure 5.30, and the required discharge, for $\varepsilon = 1/\Pi \tan^{-1}(1/4)^{1/2} = 0.15$, is $k_1 h/Q = 1.92$ and $Q/k_1 h = 0.52$; whence

$$Q = 0.52 \times 1 \times 10^{-3} \times 6 = 3.1 \times 10^{-3} \text{ ft}^3/(\text{min})(\text{ft})$$

* π is in radian measure.

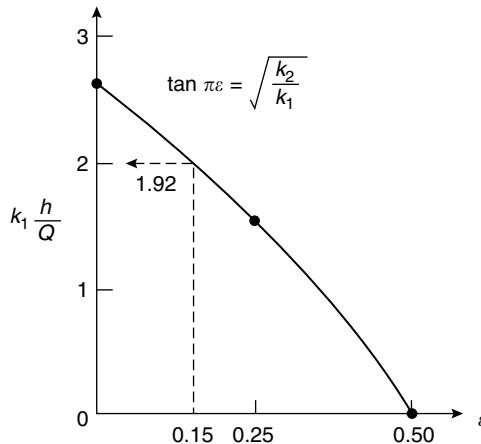

FIGURE 5.30 Example 5.18.

In combination with the method of fragments, approximate solutions can be had for very complicated structures.

Example 5.19

Estimate (a) the discharge through the section shown in Figure 5.31a, $k_2 = 4k_1 = 1 \times 10^{-3}$ ft/day and (b) the pressure in the water at the point P.

Solution. The flow region is shown divided into four fragments. However, the form factors for regions 1 and 4 are the same. In Figure 5.31b are given the resulting form factors for the listed conditions. In Figure 5.31c is given the plot of $k_1 h/Q$ vs. ε . For the required condition ($k_2 = 4k_1$), $\varepsilon = 0.35$, $k_1 h/Q = 1.6$ and hence $Q = (1/1.6) \times 0.25 \times 10^{-3} \times 10 = 1.6 \times 10^{-3}$ ft³/(day)(ft).

The total head at point P is given in Figure 5.31b as Δh for region 4; for $\varepsilon = 0$, $h_p = 2.57$ ft and for $\varepsilon = 1/4$, $h_p = 3.00$. We require h_p for $k_2 = \infty$; theoretically, there is assumed to be no resistance to the flow in the bottom layer for this condition. Hence, the boundary between the two layers (AB) is an equipotential line with an expected value of $h/2$. Thus, $h_p = 10/2 = 5$ for $\varepsilon = 1/2$. In Figure 5.31d is given the plot of h_p vs. ε . For $\varepsilon = 0.35$, $h_p = 2.75$ ft, and the pressure in the water at point P is $(3.75 + 5)\gamma_w = 8.75\gamma_w$. The above procedure may be extended to systems with more than two layers.

Example 5.20

Given the weir section shown in Figure 5.32a. There are four random variables: the soil permeability, the thickness of the pervious layer, and the effective depth of both sheetpiles. The coefficient of variation for the soil permeability will be taken as 100%, with a mean value of 1×10^{-3} cm/sec. A coefficient of variation of 30% will be used for the sand layer thickness. A coefficient of variation of 15% will be assumed for the depth of the sheetpiles. Determine the expected value and standard deviation for the quantity of flow per unit of the section shown.

Solution. AB and CD in Figure 5.32a are taken as equipotential lines; hence, the flow regime is divided into three regions or fragments. In general, with four variables, 16 permutations would be required; however, as the form factors are not functions of soil permeability, only eight form factor terms are necessary for this example.

Region 1 is a type III fragment. This fragment contains both an impervious partial cutoff; say (s_1) and top blanket. The top blanket width of 10 ft is considered to be known in this example (no uncertainty). The form factor is a function of the ratios of b and s_1 to the pervious layer thickness (T). These ratios are entered in Figure 5.17 to determine the term $1/2\phi$ which is then used to calculate ϕ . In the PEM the

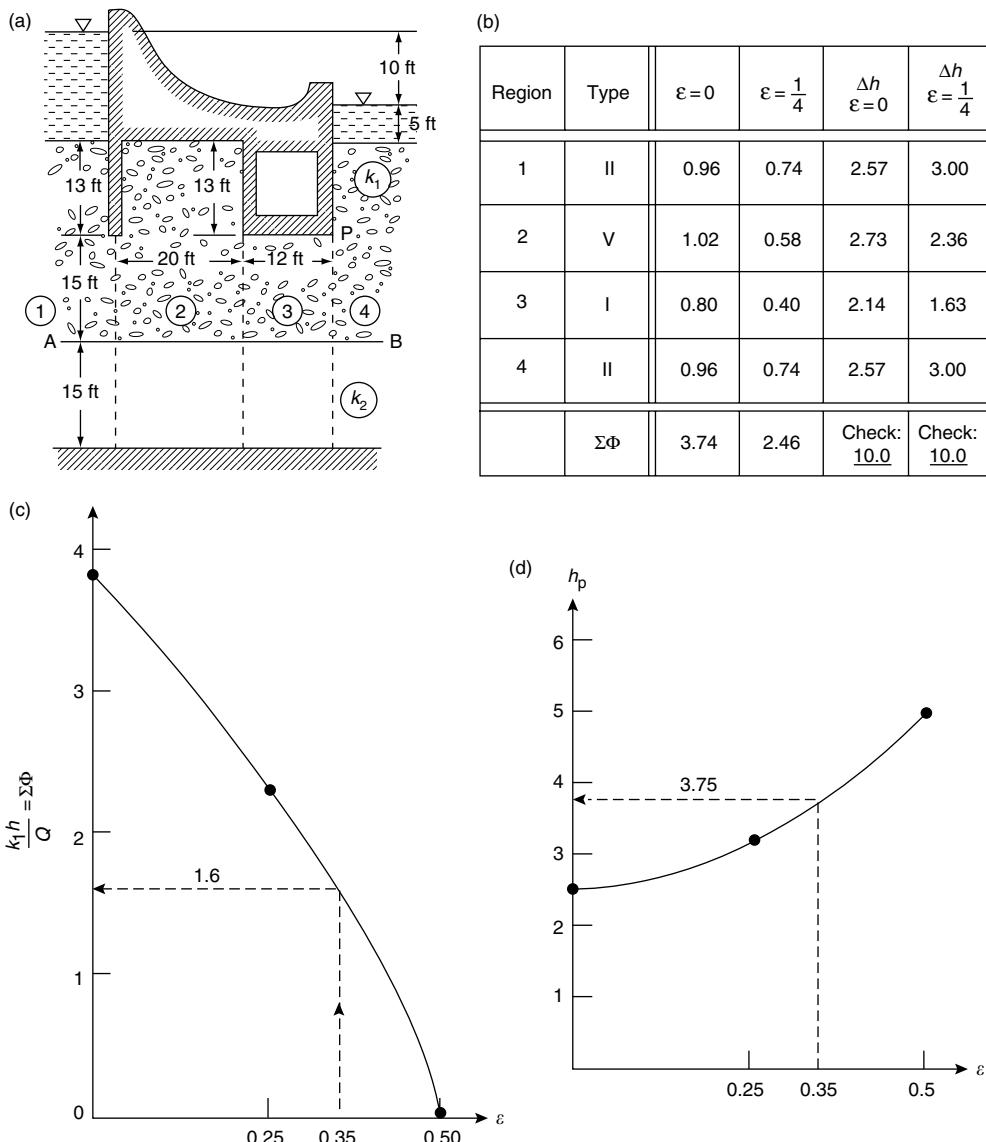

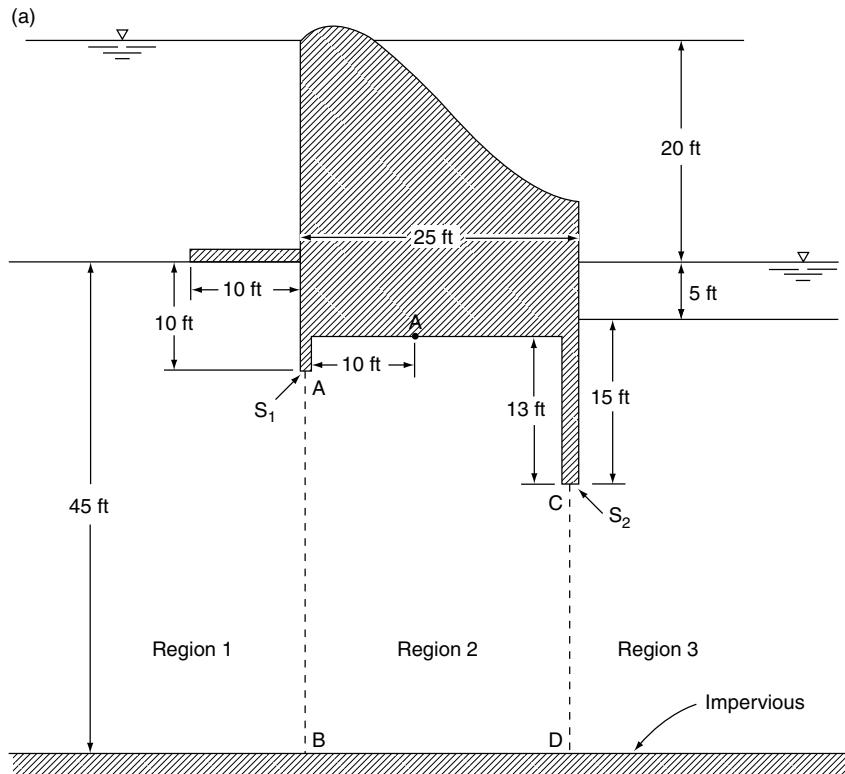

FIGURE 5.31 Example 5.19.

variability in s_1 and T are represented by two plus and minus terms. There are two b/T ratio terms (b/T_+ , and b/T_-) and four s/T ratio terms (s_+/T_+ , s_-/T_+ , s_+/T_- , s_-/T_-) used to determine the four form factors. The corresponding PEM values for Region 1 are shown in Figure 5.32b.

Region 2 is a type VI fragment for which there are three variables. The corresponding PEM plus and minus terms are shown in Figure 5.32c. For this fragment type the equation for the form factor is dependent on the relationship between the length (L) and the sum of the partial cutoffs ($s_1 + s_2$). For the present example the length is greater than the sum of the cutoffs. Thus, the following equation is used (Figure 5.23):

$$\phi = \ln \left[\left(1 + \frac{s_1}{a_1} \right) \left(1 + \frac{s_2}{a_2} \right) \right] + \frac{L - (s_1 + s_2)}{T} \quad (5.77)$$

(b) Type III Fragment

$$b = 10 \text{ ft}$$

$$\bar{s}_1 = 10 \text{ ft}, V_{S_1} = 15\%, \delta_{s_1} = 1.5 \text{ ft}$$

$$S_{1+} = 11.5 \text{ ft } S_{1-} = 8.5 \text{ ft}$$

$$\frac{Q}{kh} = \frac{1}{2\Phi}$$

$$\bar{T} = 45 \text{ ft}, V_T = 30\%, S_T = 13.5 \text{ ft}$$

FIGURE 5.32 (a) Cross section for Example 5.20. (b) Region 1 variables and form factors.

The necessary eight form factors are shown in the figure.

Region 3 is a type II fragment that consists of only a partial cutoff (s_2). The graph in Figure 5.17 is used again to determine the form factor based on the s_2/T ratio. The plus and minus terms of the ratio and the resulting form factors are shown in Figure 5.32d. As there are two random variables, only four form factors are required for this fragment.

(c) Type VI Fragment

$$\begin{aligned}\bar{S}_1 &= 3 \text{ ft}, V_{S_1} = 15\%, \delta_{S_1} = 0.45 \text{ ft} & S_+ &= 3.45 \text{ ft} & S_{1-} &= 2.65 \text{ ft} \\ \bar{a}_1 &= 35 \text{ ft} & a_{1+} &= 34.55 \text{ ft} & a_{1-} &= 35.33 \text{ ft} \\ \bar{S}_2 &= 13 \text{ ft}, V_{S_2} = 15\%, \delta_{S_2} = 1.95 \text{ ft} & S_{2+} &= 14.95 \text{ ft} & S_{2-} &= 11.05 \text{ ft} \\ \bar{a}_2 &= 25 \text{ ft} & a_{2+} &= 23.05 \text{ ft} & a_{2-} &= 26.95 \text{ ft} \\ T &= 38 \text{ ft}, V_T = 30\%, \delta_T = 11.4 \text{ ft} & T_+ &= 49.4 \text{ ft} & T_- &= 26.6 \text{ ft} \\ L &= 25 \text{ ft} \\ L \text{ is always } &> S_1 + S_2\end{aligned}$$

$$\Phi_2 = \ln[(1 + S_1/a_1)(1 + S_2/a_2)] + \frac{L - (S_1 + S_2)}{T}$$

$$\Phi_{+++} = \ln \left[\left(1 + \frac{3.45}{34.55} \right) \left(1 + \frac{14.95}{23.05} \right) \right] + \frac{25 - (3.45 + 14.95)}{49.4} = 0.729$$

$$\Phi_{-++} = 0.722$$

$$\Phi_{+-+} = 0.651$$

$$\Phi_{--+} = 0.645$$

$$\Phi_{++-} = 0.843$$

$$\Phi_{-+-} = 0.851$$

$$\Phi_{+-} = 0.834$$

$$\Phi_{--} = 0.841$$

(d) Type II Fragment

$$\bar{S}_2 = 15 \text{ ft}, V_{S_2} = 15\%, \delta_{S_2} = 2.25 \text{ ft} \quad S_{2+} = 17.25 \text{ ft} \quad S_{2-} = 12.75 \text{ ft}$$

$$\bar{T} = 40 \text{ ft}, V_T = 30\%, \delta_T = 12 \text{ ft} \quad T_+ = 52 \text{ ft} \quad T_- = 28 \text{ ft}$$

$$b = 0 \text{ thus } b/T = 0$$

$$\frac{S_+}{T_+} = 0.332, \frac{1}{2\Phi} = 0.64 \quad \Phi_{++} = 0.781$$

$$\frac{S_-}{T_+} = 0.245, \frac{1}{2\Phi} = 0.73 \quad \Phi_{-+} = 0.685$$

$$\frac{S_+}{T_-} = 0.616, \frac{1}{2\Phi} = 0.41 \quad \Phi_{+-} = 1.220$$

$$\frac{S_-}{T_-} = 0.455, \frac{1}{2\Phi} = 0.53 \quad \Phi_{--} = 0.943$$

FIGURE 5.33 Sum of form factors.

Figure 5.33 shows the summation of the appropriate ϕ terms. Equation 5.64 is then used to calculate the quantity of flow for the sixteen permutations of plus and minus terms required for four random variables. Whereas the coefficient of variation of the soil permeability was taken to be 100%, the plus term is twice the mean value and the minus term is zero (Figure 5.34). Thus, half of the flow values will be zero. The

mean value for the quantity of flow is seen to be 23.62 cubic feet per day with a standard deviation of 24.23 cubic feet per day. This results in a coefficient of variation of 102.6%.

Example 5.21

Obtain the probability distribution of the quantity of flow for the weir in Example 5.20.

Solution. With a coefficient of variation of 102.6%, the normal distribution would lead to the absurdity of negative, $P[Q < 0] = 17\%$, flow quantities! Consequently, the beta distribution will be used with a lower boundary of zero. The upper boundary will be taken to be three standard deviations above the mean. Thus, the bounds for the distribution are 0 to 96.32 cubic feet per day. The resulting distribution is shown in Figure 5.35. This example illustrates the necessity of using the beta distribution rather than the normal distribution when estimating the quantity of flow.

5.8 Piping: Reliability

By virtue of the viscous friction exerted on a liquid flowing through a porous medium, an energy transfer is effected between the liquid and the solid particles. The measure of this energy is the head loss h between the points under consideration. The force corresponding to this energy transfer is called the *seepage force*. It is this seepage force that is responsible for the phenomenon known as *quicksand*, and its assessment is of vital importance in the stability of structures founded in soils and subject to the action of flowing water (seepage).

The first rational approach to the determination of the effects of seepage forces was presented by Terzaghi (1922) and forms the basis for all subsequent studies. Consider all the forces acting on a volume of particulate matter through which a liquid flows.

1. The total weight per unit volume, the mass unit weight is

$$\gamma_m = \frac{\gamma_1(G + e)}{1 + e} \quad (5.78)$$

where e is the void ratio, G is the specific gravity of solids, and γ_1 is the unit weight of the liquid.

2. Invoking Archimedes' principle of buoyancy that *a body submerged in a liquid is buoyed up by force equal to the weight of the liquid displaced*, the effective unit weight of a volume of soil, called the *submerged unit weight*, is

$$\gamma'_m = \gamma_m - \gamma_1 = \frac{\gamma_1(G - 1)}{1 + e} \quad (5.79)$$

To gain a better understanding of the meaning of the submerged unit weight, consider the flow condition shown in Figure 5.36a. If the water column (AB) is held at the same elevation as the discharge face CD($h = 0$), the soil will be in a submerged state and the downward force acting on the screen will be

$$F \downarrow = \gamma'_m LA \quad (5.80)$$

where $\gamma'_m = \gamma_m - \gamma_w$. Now, if the water column is slowly raised (shown dotted to A'B'), water will flow up through the soil. By virtue of this upward flow, work will be done to the soil and the force acting on the screen will be reduced.

3. The change in force through the soil is due to the increased pressure acting over the area or

$$F \uparrow = h \gamma_w A$$

$$Q = \frac{kh}{\Sigma \Phi} \quad \text{Random Variables } k, \Phi(S_1, S_2, T) \\ (\text{thus } 2^4 \text{ or 16 terms})$$

$$h = 20 \text{ ft}$$

$$\bar{k} = 1 \times 10^{-3} \text{ cm/sec} = 2.83 \text{ ft/day}, V_k = 100\%, S_k = 2.83 \text{ ft/day}$$

$$k_+ = 5.66 \text{ ft/day} \quad k_- = 0.0$$

$$E[Q] = \sum_{i=1}^{16} P_{xi} Q_{xi}^2 \quad P_{xi} = \frac{1}{16} \text{ since all terms are taken to be uncorrelated}$$

$$\sigma_Q^2 = \sum_{i=1}^{16} P_{xi} Q_{xi}^2 - (E[Q])^2$$

S_1	S_2	T	k	Q_i	Q_i^2
+	+	+	+	51.950	2698.85
-	+	+	+	52.627	2769.57
+	-	+	+	56.431	3184.43
-	-	+	+	57.258	3278.53

-	-	-	-	0.0	0.0
				$\Sigma = 377.955$	$18324.0 \quad \Sigma/16 = 1145.25$

$$E[Q] = 23.62 \text{ ft}^3/\text{day}$$

$$\sigma_Q^2 = 1145.25 - (23.62)^2 = 587.24$$

$$\sigma_Q = 24.23 \text{ ft}^3/\text{day}$$

$$V_Q = 1.026 \text{ or } 102.6\%$$

FIGURE 5.34 Flow quantities.

Hence, the change in force, granted steady-state conditions, is

$$\Delta F = \gamma'_m LA - h \gamma_w A \quad (5.81)$$

Dividing by the volume AL , the resultant force per unit volume acting at a point within the flow region is

$$R = \gamma'_m - i \gamma_w \quad (5.82)$$

where i is the hydraulic gradient. The quantity $i \gamma_w$ is called the seepage force (force per unit volume). In general, Equation 5.81 is a vector equation, with the seepage force acting in the direction of flow (Figure 5.36b). Of course, for the flow condition shown in Figure 5.36a, the seepage force will be directed vertically upward (Figure 5.36c). If the head h is increased, the resultant force R in Equation 5.81 is seen to decrease. Evidently, should h be increased to the point at which $R = 0$, the material would be at the point of being washed upward. Such a state is said to produce a *quick* (meaning alive) condition. From

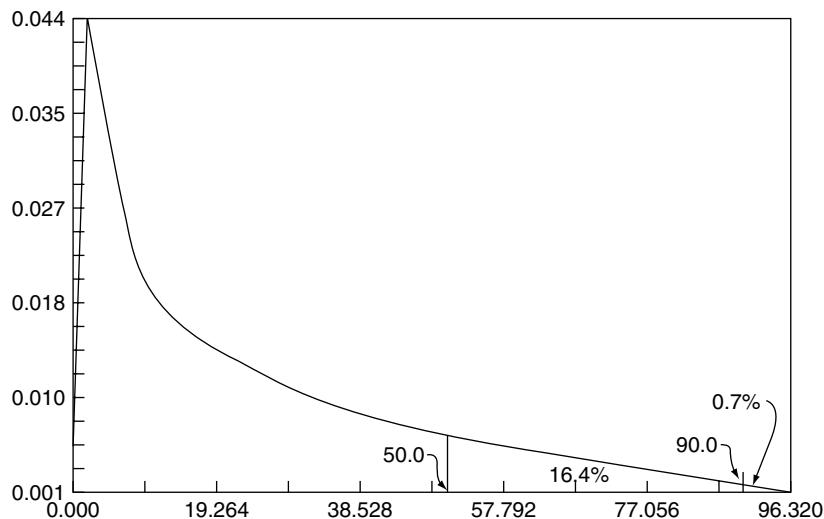

FIGURE 5.35 Beta distribution of flow quantity for Example 5.20.

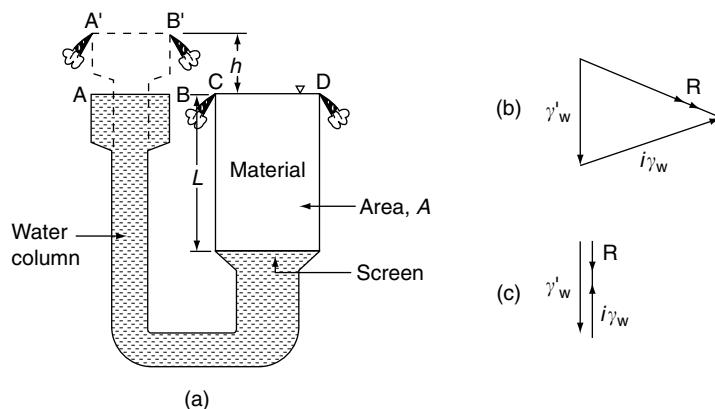

FIGURE 5.36 Development of seepage force concept.

Equation 5.81 it is evident that a quick condition is incipient if

$$i_{cr} = \frac{\gamma'_m}{\gamma_w} = \frac{G - 1}{1 + e} \quad (5.83)$$

Substituting typical values of $G = 2.65$ (quartz sand) and $e = 0.65$ (for sand $0.57 \leq e \leq 0.95$), we see that as an average value the critical gradient can be taken as

$$i_{cr} \approx 1 \quad (5.84)$$

When information is lacking as to the specific gravity and void ratio of the material, the critical gradient is generally taken as unity.

At the critical gradient, there is no interparticle contact ($R = 0$); the medium possesses no intrinsic strength and will exhibit the properties of liquid of unit weight

$$\gamma_q = \left(\frac{G + e}{1 + e} \right) \gamma_1 \quad (5.85)$$

Substituting the above values for G , e , and $\gamma_1 = \gamma_w$, $\gamma_q = 124.8 \text{ lb/ft}^3$. Hence, contrary to popular belief, a person caught in quicksand would not be sucked down, but would find it almost impossible to avoid floating.

Many hydraulic structures, founded on soils, have failed as a result of the initiation of a local quick condition which, in a chain-like manner, led to severe internal erosion called *piping*. This condition occurs when erosion starts at the exit point of a flow line and progresses backward into the flow region, forming pipe-shaped watercourses that may extend to appreciable depths under a structure. It is characteristic of piping that it needs to occur only locally and that once begun it proceeds rapidly, and is often not apparent until structural failure is imminent.

Equation 5.82 and Equation 5.83 provide the basis for assessing the safety of hydraulic structures with respect to failure by piping. In essence, the procedure requires the determination of the maximum hydraulic gradient along a discharge boundary, called the *exit gradient*, which will yield the minimum resultant force (R_{\min}) at this boundary. This can be done analytically, as will be demonstrated below, or from flow nets after a method proposed by Harza (1935).

In the graphical method, the gradients along the discharge boundary are taken as the macrogradient across the contiguous squares of the flow net. As the gradients vary inversely with the distance between adjacent equipotential lines, it is evident that the maximum (exit) gradient is located where the vertical projection of this distance is a minimum, such as at the toe of the structure (point C) in Figure 5.14. For example, the head lost in the final square of Figure 5.14 is one-sixteenth of the total head loss of 16 ft, or 1 ft, and as this loss occurs in a vertical distance of approximately 4 ft, the exit gradient at point C is approximately 0.25. Once the magnitude of the exit gradient has been found, Harza recommended that the factor of safety be ascertained by comparing this gradient with the critical gradient of Equation 5.82 and Equation 5.83. For example, the factor of safety with respect to piping for the flow conditions of Figure 5.14 is $1.0/0.25$ or 4.0. Factors of safety of 4 to 5 are generally considered reasonable for the graphical method of analysis.

The analytical method for determining the exit gradient is based on determining the exit gradient for the type II fragment, at point E in Figure 5.23. The required value can be obtained directly from Figure 5.37 with h_m being the head loss in the fragment.

Example 5.22

Find the exit gradient for the section shown in Figure 5.26a.

Solution. From the results of Example 15.5, the head loss in fragment 3 is $h_m = 5.9 \text{ ft}$. With $s/T = 1/3$, from Figure 5.37 we have $I_E s/h_m = 0.62$; hence,

$$I_E = \frac{0.62 \times 5.9}{9} = 0.41 \quad \text{or} \quad FS = 1/0.41 = 2.44$$

To account for the deviations and uncertainties in nature, Khosla, et al. (1954) recommend that the following factors of safety be applied as critical values of exit gradients; gravel, 4 to 5; coarse sand, 5 to 6; and fine sand, 6 to 7.

The use of reverse filters on the downstream surface, or where required, serves to prevent erosion and to decrease the probability of piping failures. In this regard, the Earth Manual of the U.S. Bureau of Reclamation, Washington, 1974, is particularly recommended.

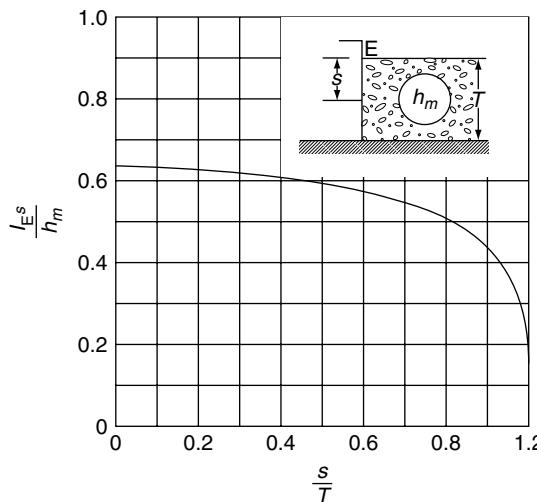

FIGURE 5.37 Exit gradient.

Glossary

Capacity The ability to resist an induced demand; resistance or strength of entity.

Coefficient of Permeability Coefficient of proportionality between Darcy's velocity and the hydraulic gradient.

Correlation Coefficient Measure of the compliance between two variables.

Demand Applied loading or energy.

Expected Value, Expectation Weighted measure of central tendency of a distribution.

Flow Net Trial-and-error graphical procedure for solving seepage problems.

Hydraulic Gradient Space rate of energy dissipation.

Method of Fragments Approximate analytical method for solving seepage problems.

Piping Development of a "pipe" within soil by virtue of internal erosion.

Probability Quantitative measure of a state of knowledge.

Quick Condition Condition when soil "liquefies."

Random Variable An entity whose measure cannot be predicted with certainty.

Regression Means of obtaining a functional relationship among variables.

Reliability Probability of an entity (or system) performing its required function adequately for a specified period of time under stated conditions.

Standard Deviation Square root of variance.

Variance Measure of scatter of variable.

6.1 Introduction

The *unsaturated zone*, sometimes called the *vadose zone*, is the zone between the ground surface and the water table. The term unsaturated zone is somewhat of a misnomer as the capillary fringe above the groundwater or the rain-saturated top soil are portions that are saturated. For this reason some authors (e.g., Bouwer, 1978) prefer the term vadose zone. The unsaturated zone is the hydrological connection between the surface water component of the hydrologic cycle and the groundwater component (Figure 6.1).

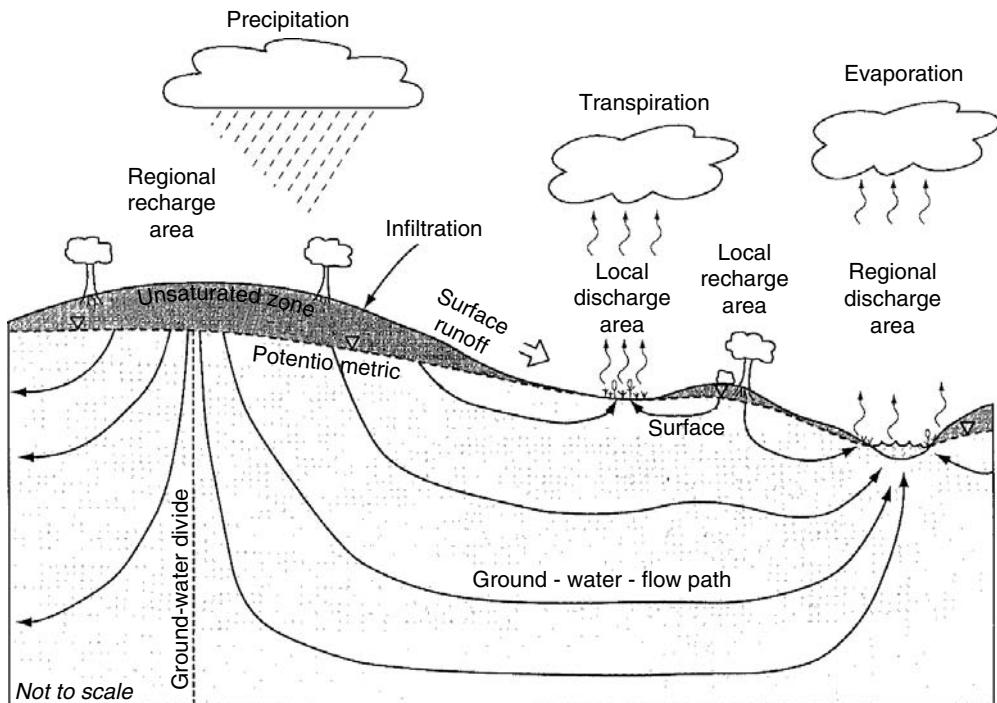

FIGURE 6.1 The unsaturated and saturated zones in the hydrological cycle.

The surface water component includes the precipitation as it reaches the land surface and artificial water application such as irrigation, surface runoff, stream flow, lakes, and artificial impoundments. The rainfall may infiltrate and some of the surface water may percolate through the unsaturated zone. Recharge of the groundwater usually occurs through the unsaturated zone. The unsaturated zone may lose water through evaporation, evapotranspiration, and drainage.

The unsaturated zone plays a crucial role in the transfer of pollutants. Many constituents present in the surface waters eventually find their way into the groundwater through the unsaturated zone. Accident spills of chemicals, application of fertilizers and pesticides on the land surface, leaks from gasoline storage tanks, septic tank drainage, leaching from landfills are examples of anthropogenic activities that contribute to the leaching of contaminants through the unsaturated zone into the groundwater (see Figure 3.22). Chapter 22 develops the multiphase, multi-species equations used to represent the soil, water, and air interactions in the unsaturated zone addressing the principal contaminant sources and pathways in the soil-chemical system.

An introduction to water in the unsaturated zone is given in Section 2.5. Chapter 6 is concerned with the movement of moisture in the unsaturated zone. It covers the conceptual aspects of unsaturated soil water flow related to soil physical properties and soil water characteristics. In Section 6.2 we deal with the soil physical properties, the soil hydraulic properties, and the choice of the functional relationships used to describe the soil hydraulic characteristics. Additionally, we also present some of the measurement and prediction techniques used for the estimation of the soil hydraulic characteristics parameters. We then address the conceptual aspects of the different unsaturated soil water transfer equations used in subsurface hydrology (Section 6.3). An overview of the most significant analytical solutions is presented in Section 6.4; the empirical infiltration laws are discussed in detail in Chapter 7. Section 6.5 sets out the details of a new scaling approach of the water transfer equation (Richards, 1931) and its implications for the soil characteristic scale parameters. Concluding remarks are given in Section 6.6, followed by the references, and a glossary and parameter notation.

6.2 Physical and Hydraulic Soil Properties

6.2.1 Soil Phases

Soils comprise three phases: the solid, the liquid, and the gaseous phases. The *solid phase* includes the mineral particles of gravel, sands, silts, and clays. Gravel, sand, and silt have a dense spherical or angular shape. Clays, on the other hand, have a plate-like structure (with dimensions between 1 and 2 μm) and their capability to adsorb sodium or calcium controls whether they are disperse or flocculent. Particle-size properties are determined from the size distribution of individual particles in a soil sample. Soil particles smaller than 2 mm are divided into the three soil texture groups: sand, silt, and clay. Particles larger than 2 mm are grouped into the gravel class. Figure 6.2 shows the particle-size limits according to the U.S. Department of Agriculture (USDA) (Soil Survey Laboratory Staff, 1992) and the International Soil Science Society (Yong and Warkentin, 1966). Figure 6.3 shows the USDA soil textural triangle that allows for the classification of soils as a function of their particle-size distribution. For example, a soil consisting of 30% sand, 40% silt, and 30% clay by weight is a clay loam. Another grouping is the Unified Soil Classification System (USCS). It is based on particle size, the plasticity index, and the liquid limit and is described in geotechnical engineering texts, such as Lambe and Whitman (1979). The mineral particles, along with the interconnecting pores, form the *soil matrix*. The solid phase may also include organic material such as peat.

The fluids in the soil comprise liquids and gases. The *liquid phase* usually consists of water that can move through the pores of the soil. The water can include numerous dissolved minerals and organic

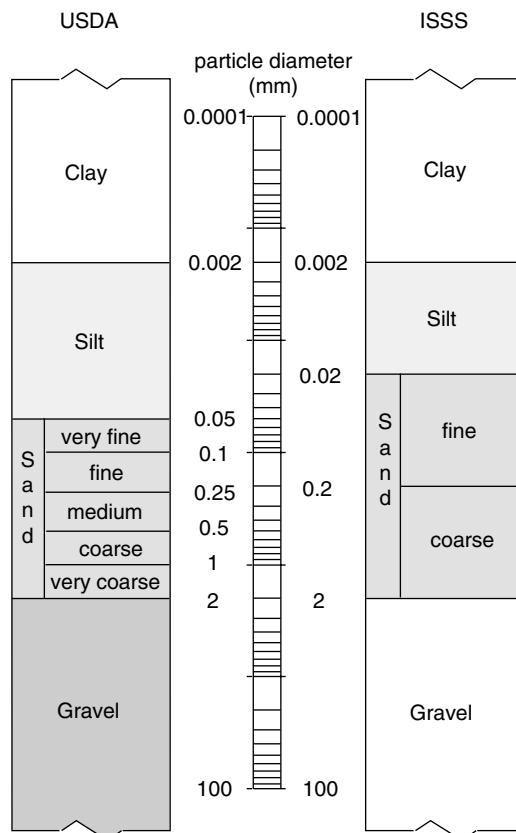

FIGURE 6.2 Particle-size limits according to the USDA and ISSS soil classification schemes.

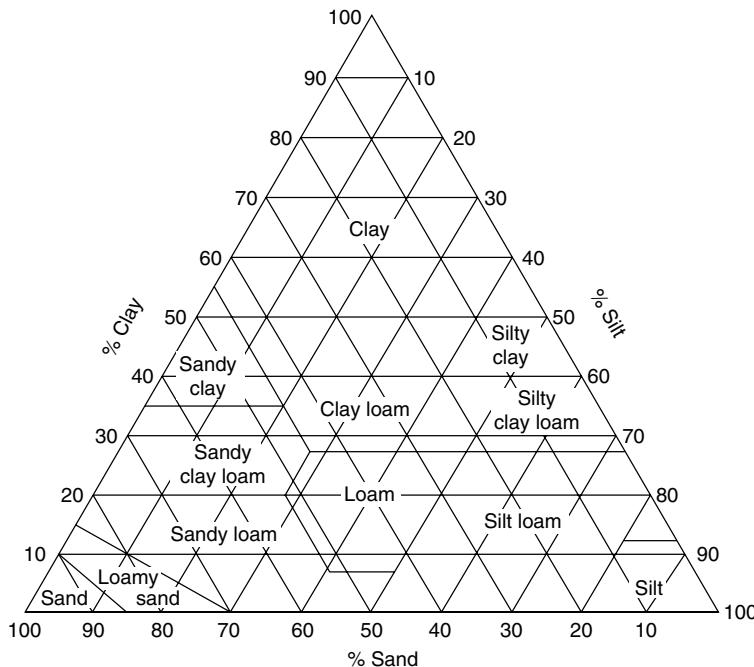

FIGURE 6.3 USDA soil textural classification chart showing the percentages of clay (below 2 μm), silt (2 to 50 μm), and sand (50 to 2000 μm).

compounds. Other liquids may be present. They may be miscible or immiscible in water and generally result from agricultural and industrial activities or accidental spills.

The principal component of the *gaseous phase* is air. Like water, air can also move through the soil and contains other dissolved gases like water vapor and volatile components, usually of pollutants. The principal characteristics of the unsaturated zone depend on the proportion of liquid and gas in the soil matrix. In this three phase system, water and air can flow simultaneously.

6.2.2 Physical Properties of Soils

Let V_s , V_l , V_g , V_t , M_s , M_l , M_g , M_t and W_s , W_l , W_g , W_t be the volumes, masses, and weights of solid, liquid, gas, and total, respectively. Then the density of the solid particles (ρ_s), the dry bulk density (ρ_d), and the porosity (ε) are given by:

$$\rho_s = \frac{M_s}{V_s} = \frac{W_s}{gV_s} \quad (6.1)$$

$$\rho_d = \frac{M_s}{V_t} = \frac{W_s}{gV_t} \quad (6.2)$$

and

$$\varepsilon = \frac{V_l + V_g}{V_t} = \frac{V_t - V_s}{V_t} = 1 - \frac{\rho_d}{\rho_s} \quad (6.3)$$

where g is gravitational acceleration ($\approx 9.82 \text{ m/sec}^2$). The particle density (ρ_s) is normally assumed to be equal to 2.65 g/cm^3 . The void ratio (e) is useful when V_t is not constant due to swelling or shrinking and

is defined as:

$$e = \frac{V_l - V_g}{V_s} = \frac{\varepsilon}{1 - \varepsilon} \quad (6.4)$$

A detailed description of the matrix pore space and associated macropores is given in Chapter 22.

If the definition of Equation 6.3 is applied to a very small elementary volume, the porosity would be equal to one if the element is centered in a pore or would be equal to zero if the element is centered in the solid. The element under consideration has to be equal to or larger than a minimum volume called *representative elementary volume* (REV) to reach a stable value. The continuum approach is used in this chapter. That is to say, an REV is assumed such that the fluid flow can be represented as the product of a transfer coefficient and an energy gradient. For a detailed discussion of the concept of the REV, see Bear and Bachmat (1984).

When small stones and porous coarse fragments (diameter >2 mm) occur in the elementary volume, the whole soil dry bulk density (ρ_{ap}) measured over the whole soil sample is different from the fine soil dry bulk density. The correction formula is:

$$\rho_d = \frac{1 - a - b}{1/\rho_{ap} - a/\rho_s - b/\rho_c} \quad (6.5)$$

where ρ_d is the dry bulk density of the fine soil material; ρ_c is the specific weight of the porous coarse fragments; and a and b are the stone and porous rock weight fractions, respectively, of the whole soil sample. The whole soil porosity (ε_{ap}) and the porosity of the porous coarse fragments (ε_c) are then defined as:

$$\varepsilon_{ap} = 1 - \frac{\rho_{ap}}{\rho_s} \quad (6.6)$$

and

$$\varepsilon_c = 1 - \frac{\rho_c}{\rho_s} \quad (6.7)$$

Dry bulk density and soil porosity are important soil morphological parameters as they are closely related to soil structure. Hence, they influence the soil water transfer properties to a large extent.

6.2.3 Hydraulic Properties of Soils

Regardless of the scales involved, the soil hydraulic properties that affect the flow behavior are incorporated into two fundamental characteristics: (i) the soil water retention curve describing the relation between volumetric soil water content and soil water pressure; and (ii) the hydraulic conductivity function describing the relation between volumetric water content and hydraulic conductivity.

6.2.3.1 Soil Water Content

The soil water content can be expressed by mass (w) or by volume (θ):

$$w = \frac{M_l}{M_s} = \frac{W_l}{W_s} \quad (6.8)$$

and

$$\theta = \frac{V_l}{V_t} = \frac{w\rho_d}{\rho_w} \quad (6.9)$$

where ρ_w is the specific density of water ($\rho_w \approx 1 \text{ g/cm}^3$). In most hydrologic applications, volumetric soil water content is used in nondimensional form:

$$\theta^* = \frac{\theta - \theta_r}{\theta_s - \theta_r} \quad (6.10)$$

Conventionally, θ_s is referred to as the *volumetric soil water content at natural saturation* and θ_r as the *residual volumetric soil water content*. Due to air entrapment, θ_s seldom reaches saturation of the total pore space (ε), for example, Rogowski (1971) gives $\theta_s = 0.9\varepsilon$. Its value is soil-specific and physically well-defined (Haverkamp et al., 2005; Leij et al., 2005). On the contrary, the physical meaning of θ_r is ambiguous. Conceptually, the residual water content may be associated with the immobile water held (by adsorptive forces) within a dry soil profile in films on particle surfaces, in interstices between particles, and within soil pores. In practice, however, its value is generally estimated by fitting the water retention equation to measured data points reducing θ_r to an empirical fitting parameter restricted to the range of data points used. Recently, Haverkamp et al. (2002) explained the residual volumetric water content through the theory of *hysteresis* where θ_r is related to the wetting and drying history prior to the measurement of the water content data points. Most field studies presented in the literature choose a zero θ_r -value (e.g., Kool et al., 1987; van Genuchten et al., 1991; Leij et al., 1996).

When volumetric water content is expressed as the ratio to total pore space (ε), it is referred to as the degree of saturation (S):

$$S = \frac{V_l}{V_l + V_g} = \frac{\theta}{\varepsilon} \quad (6.11)$$

6.2.3.2 Soil Water Pressure

Matric potential or *capillary potential* (ϕ_c) is the measure of the energy status of water retained in a soil by capillarity and surface adsorption (see also Chapter 2, Section 2.4). It is one of the three prevalent components of *total soil water potential* (Φ) given by:

$$\Phi = \phi_g + \phi_c + \phi_o \quad (6.12)$$

where ϕ_g is the *gravitational potential* and ϕ_o is the *osmotic potential* (e.g., van Bavel, 1969). The total soil water potential (Φ) measures the energy per unit quantity (volume, mass, or weight) that is required to move a small volume of water from a pool of water at a datum elevation and at standard atmospheric pressure, to the soil at the point under consideration. The sum of the matric potential and the gravitational potential is often referred to as the *hydraulic potential*. When there is a density gradient of dissolved substances it is necessary to add an *osmotic potential*. Following the International Society of Soil Science (Bolt, 1976), two other components can be included: the *air potential* (ϕ_a), and the *envelope potential* (ϕ_e). The air potential accounts for the difference in pressure that can exist between the air inside the pores and the outside atmospheric pressure over the reference water. When the external pressure due to the overburden is transmitted by the water envelope around the particles, the envelope potential can be significant.

The potential can be expressed per unit volume, per unit mass, or per unit weight. If the potential is expressed in terms of volume, the units are joules per cubic meter or equivalently in units of pressure: Newtons per square meter or Pascals. If the potential is expressed per unit mass or per unit weight, the units are joules per kilogram and meters, respectively. The latter option is conventionally used for most hydrologic studies. When taken per unit weight, the gravitational potential corresponds to the elevation head and the *capillary* or *matric potential* is related to the *soil water pressure head* (h) by:

$$\phi_c = \rho_w gh \quad (6.13)$$

The pressure head h is positive below the water table and negative above it. In the unsaturated zone, the negative of the pressure is also called the *matric suction* or *tension* which, therefore, is expressed as a positive number. A comprehensive description of the different notations is given by Kutilek and Nielsen (1994). In dry soils the pressure head can reach extremely high values; for computational convenience its value is often expressed in the logarithmic mode:

$$pF = \log |h| \quad (6.14)$$

The value of $pF = 4.2$ (i.e., a pressure head of 15,000 cm of water) is the threshold pressure value below which plant transpiration can take place. This point which is referred to as the *wilting point* is sometimes associated with the volumetric soil water content value θ_r (van Genuchten, 1980).

6.2.3.3 Water Retention Characteristic

The variation of volumetric soil water content (θ) with soil water suction (h) is referred to as the *water retention characteristic* ($h(\theta)$). It describes the soil's ability to store or release water. The water retention characteristic is a highly nonlinear S-shaped curve. Figure 6.4 gives an illustration of the typical behavior of the water retention characteristic. It clearly shows that the water retention curve varies with soil structure. For sandy soils the shape of $h(\theta)$ is characterized by a typical step form; for clay soils, on the other hand, the water retention curve is rather steep. Hence, for identical pressure head values clay soils measure generally higher water content values than sandy soils.

The characteristic curves may be different for drying (desorbing) and wetting (absorbing) soils. This phenomenon, referred to as *hysteresis*, can schematically be explained by the "ink bottle effect," that is, the fact that the opening radius r at the top of any pore is generally smaller than the radius R of the main pore. Following Laplace's equation the capillary rise in a tube of radius r is known to be inversely proportional to the radius:

$$h = \frac{2\sigma_{LV} \cos(\omega)}{rg\rho_w} \quad (6.15)$$

where σ_{LV} is the liquid–vapor surface tension of water; and ω is the contact angle between liquid and solid (see also Chapter 2, Equation 2.7). At 20°C, with ρ_w equal to 1 g/cm³ and ω equal to zero, Equation 6.15 is reduced to:

$$h \approx \frac{0.149}{r} \quad (6.16)$$

where soil water suction (h) and pore radius (r) are expressed in cm (e.g., Rose, 1966). Upon drying, the pore remains full until the capillary rise surpasses $0.149/r$. For wetting, the water starts filling the pore when h drops to the lower value $0.149/R$. The water content of the drying pore thus surpasses that of the wetting pore causing the hysteresis. Theoretically, for a given soil geometry, it should be possible to predict hysteretic effects from first principles. However, this problem remains largely unsolved and our rather sketchy understanding of soil structure suggests that only a few soil models will yield to this approach. Instead, hysteresis in soils remains largely based on Poulovassilis' (1962) analysis obtained by applying the independent domain theory to soils (see also Topp, 1971; Mualem, 1974). Parlange (1976, 1980) proposed an alternative theory that has proven to be precise and robust in spite of its operational simplicity. It requires only one boundary curve of the hysteresis envelope to predict the other boundary and all scanning curves in between (see also Hogarth et al., 1988; Liu et al., 1995; Parlange et al., 1999). In a recent study, Haverkamp et al. (2002) proposed a useful extension of the Parlange prediction model based on theory and geometric scaling. Considering the water retention curve to be described by three parameters, where the first defines the shape of the curve and the two others scale the soil water pressure head and volumetric soil water content, the authors derived three geometrical scaling conditions. The first condition determines a shape parameter that is identical for all wetting and drying curves and

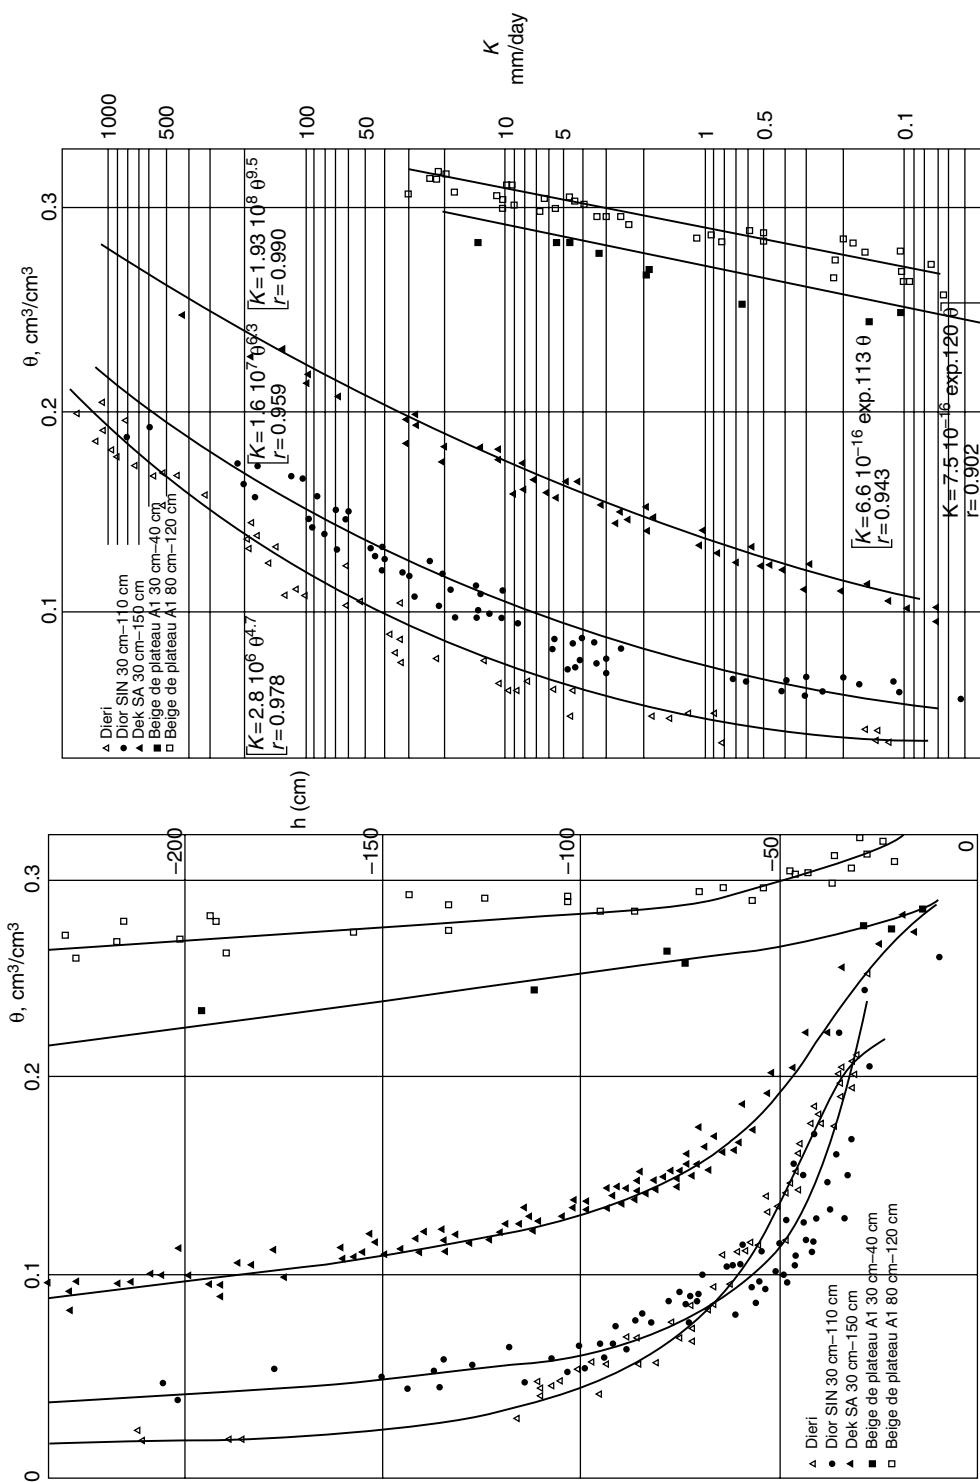

FIGURE 6.4 Water retention and hydraulic conductivity curves of five different soil types measured in Senegal. (Adapted from Hamon, G. 1980. Mise en oeuvre et critique de méthodes de caractérisation hydrodynamique de la zone non-saturée du sol. Applications aux sols de culture du Sénégal. *Thèse Docteur-Ingénieur*, Université Scientifique et Médicale de Grenoble, France. With permission.)

independent of their scanning order; the second defines the relation between the pressure head scale and the water content scale specific to each curve in wetting or drying; and the third condition determines specific water content scale parameters according to the points of departure and arrival of each scanning curve. The authors also derived equations necessary for the calculation of the different scale parameters. Given the saturated water content, all main, primary, and higher order scanning curves can hence be predicted from knowledge of only one curve, although in practice knowledge of a main or primary curve is desirable. Examples of four hysteresis-affected water retention curves measured in the laboratory are shown in Figure 6.5. The predicted main and primary drying curves are compared with measured data.

Hysteresis is more pronounced for sands than for clay soils, particularly for sands with low initial water content profiles prior to wetting (e.g., Vachaud and Thony, 1971). For convenience, hysteresis is usually ignored because its influence under field conditions is often masked by heterogeneities and spatial variability. However, many authors (e.g., Nielsen et al., 1986; Parker and Lenhard, 1987; Russo et al., 1989; Heinen and Raats, 1997; Otten et al., 1997; Whitmore and Heinen, 1999; Si and Kachanoski, 2000) have shown it to be important in simulations of water transfer, solute transport, multiphase flow, and microbial activities, and to disregard it leads to significant errors in predicted fluid distributions with concomitant effects on solute transport and contaminant concentrations (e.g., Hoa et al., 1977; Kool and Parker, 1987; Mitchel and Mayer, 1998).

6.2.3.4 Hydraulic Conductivity

The isothermal hydraulic conductivity was originally introduced by Darcy (1856) for saturated soils and extended to unsaturated soils by Buckingham (1907) and Richards (1931). The hydraulic conductivity is a measure of the ability of the soil to route water. From a theoretical view point $K(\theta)$ can be expressed as:

$$K(\theta) = k \frac{\rho_w g}{\mu_w} k_{rw}(\theta) \quad (6.17)$$

where k is intrinsic permeability; $k_{rw}(\theta)$ is relative water permeability (namely the ratio of the unsaturated to the saturated water permeabilities) that varies from 0 for completely dry soils to 1 for fully saturated soils; and μ_w is the water viscosity. Equation 6.17 shows that the soil conductivity depends on the soil matrix (k), the moving fluid (ρ_w and μ_w) and the fluid content in the soil ($k_{rw}(\theta)$). The dependence of K on θ is unaffected by hysteresis. The hydraulic conductivity at or above saturation ($h \geq 0$) is referred to as the *hydraulic conductivity at natural saturation* (K_s).

6.2.3.5 Hydraulic Conductivity Characteristic

When expressed as a function of the volumetric soil water content, the hydraulic conductivity function $K(\theta)$ is strongly nonlinear. Generally speaking, it behaves like a power function. For decreasing soil water content, the hydraulic conductivity decreases rapidly. Figure 6.4 illustrates the typical behavior of hydraulic conductivity. The hydraulic conductivity function highly depends on soil structure. For sandy soils, the hydraulic conductivity at natural saturation (K_s) is usually higher than that for clay soils, even though the porosity is higher in clay soils.

Besides the water retention and hydraulic conductivity functions, alternative combinations of soil characteristics can be chosen to characterize the soil moisture behavior of soils, such as $K(h)$ (e.g., Gardner, 1958; Rijtema, 1965), $D(\theta)$ (e.g., Childs and Collis-George, 1950), and/or $C(\theta)$ (e.g., Richards, 1931), where D refers to *diffusivity* defined by $D = K(\theta)dh/d\theta$ and C is *specific capacity* defined by $C(\theta) = d\theta/dh$. Both functions, $C(\theta)$ and $D(\theta)$, will be addressed in details in Section 6.3.1. The quintessence is that always two soil characteristics are required to model soil water movement in the vadose zone.

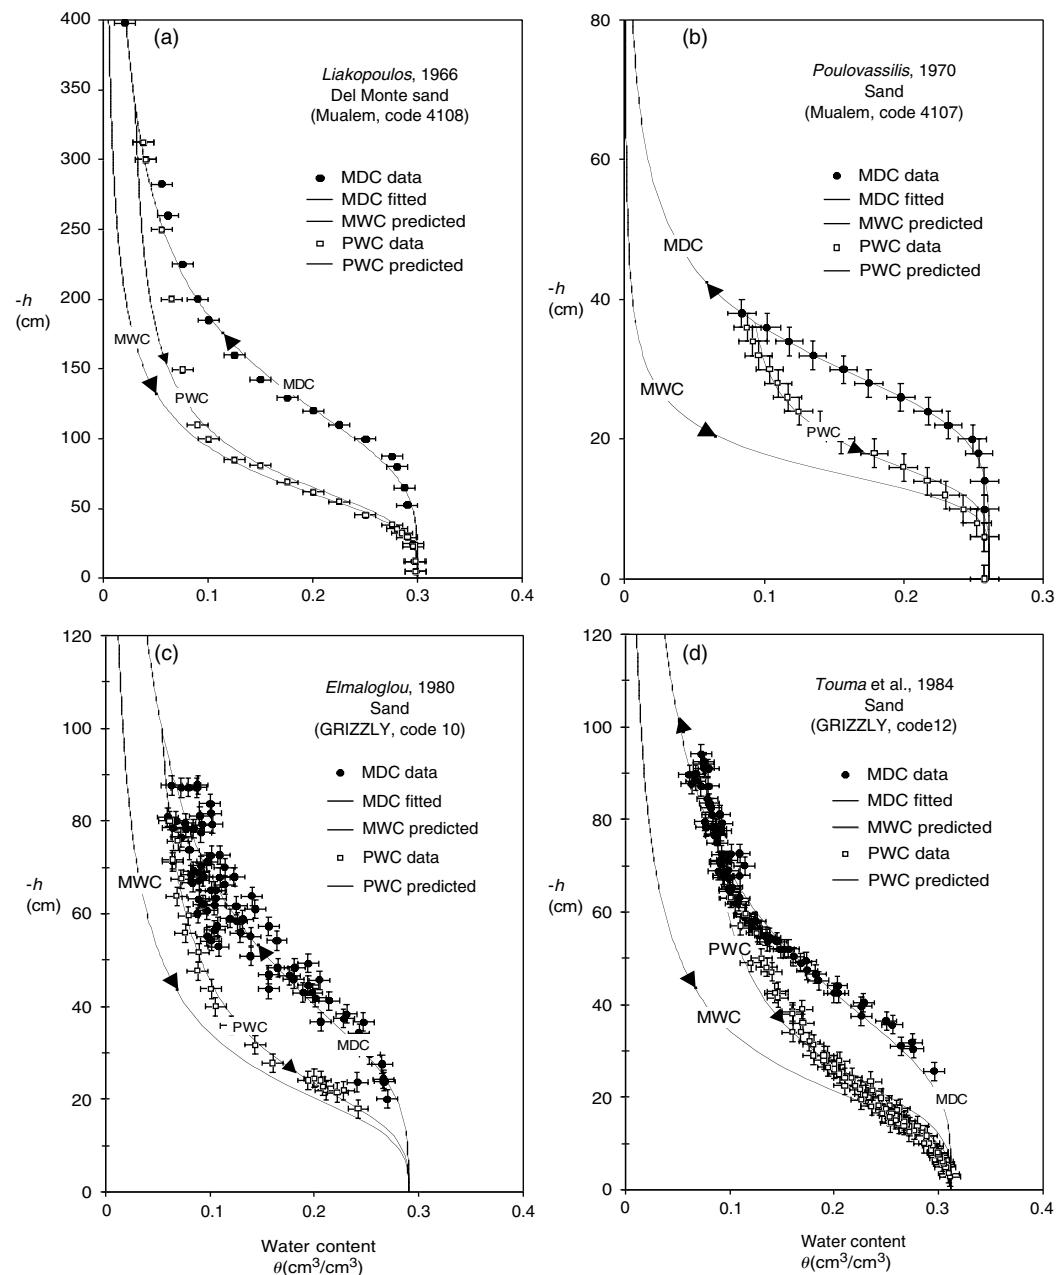

FIGURE 6.5 Main drying curve (MDC) fitted to measured drying data (\bullet) for four sands. The predicted main wetting curve (MWC) and primary wetting curve (PWC) are presented together with experimental primary wetting data (\square). The horizontal and vertical bars correspond to the measurement errors in water content and pressure head (i.e., $\pm 0.01 \text{ cm}^3/\text{cm}^3$ and $\pm 2 \text{ cm}$) associated with each observation. (Adapted from Haverkamp, R., Reggiani, P., Ross, P. J., and Parlange, J.-Y. 2002. Soil water hysteresis prediction model based on theory and geometric scaling. In *Environmental Mechanics: Water, Mass and Energy Transfer in the Biosphere*, Raats, P. A. C., Smiles, D., and Warrick, A. W. [Eds.], Geophysical Monograph 129, American Geophysical Union, Washington, DC, pp. 213–246.)

6.2.4 Functional Relationships

In the past, many different functional relations have been proposed in the literature. However, most refer to the hydraulic properties of soils and only little concern the physical properties of soils. Next, we present the most popular relations used for both groups of physical and hydraulic soil properties.

6.2.4.1 Particle-Size Distribution

The particle-size distribution describes the relation between the distribution frequency (F_p) expressed as a percentage of particle weight per unit sample mass and the effective diameter of soil particles (D_p). According to Haverkamp and Reggiani (2002), the cumulative distribution of particle weight (F_p) is described by an expression similar to that chosen for the water retention curve (see Equation 6.20 and Equation 6.21). Using the van Genuchten (1980) type-equation, $F_p(D_p)$ takes the form:

$$F_p = \left[1 + \left(\frac{D_{pg}}{D_p} \right)^N \right]^{-M} \quad (6.18)$$

where F_p varies from 0 for $D_p = 0 \mu\text{m}$ to 1 for $D_p = 2000 \mu\text{m}$; D_{pg} is a *particle-size scale parameter*; and M and N are the *particle-size shape parameters* assumed to be linked by the expression:

$$M = 1 - \frac{k_M}{N} \quad \text{with } N > k_M \quad (6.19)$$

The integer k_M is chosen identical to that used by the van Genuchten (1980) water retention equation (Equation 6.21). An example of $F_p(D_p)$ determined for a silt loam taken from the GRIZZLY soil database (Haverkamp et al., 1997), is shown in Figure 6.6.

The cumulative particle-size distribution function is of use for the determination of soil hydraulic properties through the use of Pedo-Transfer Functions or PTFs (Bouma and van Lanen, 1987). These

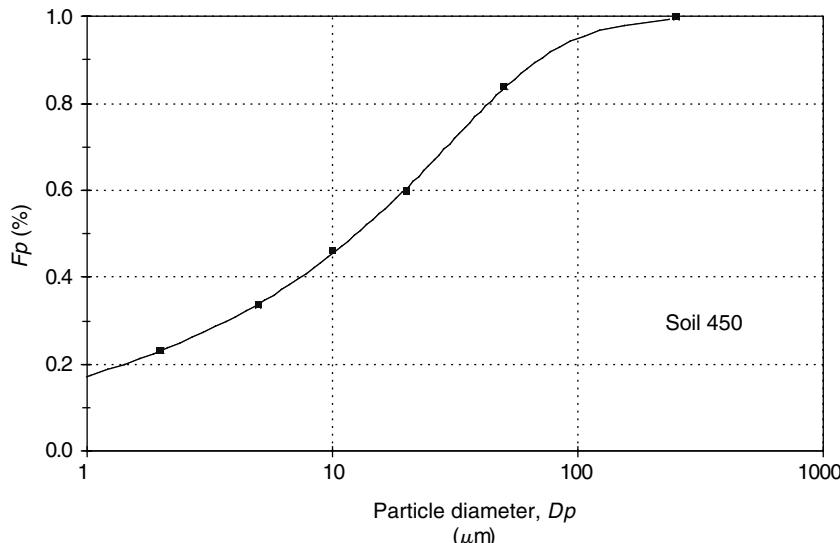

FIGURE 6.6 Cumulative particle-size distribution function $F_p(D_p)$ fitted to measured soil texture data observed for a silt loam. (Adapted from Haverkamp, R., Zammit, C., Bouraoui, F., Rajkai, K., Arrué, J. L., and Heckmann, N. 1997. Laboratoire d'Etude des Transferts en Hydrologie et Environnement [LTHE], Grenoble Cedex 9, France. With permission.)

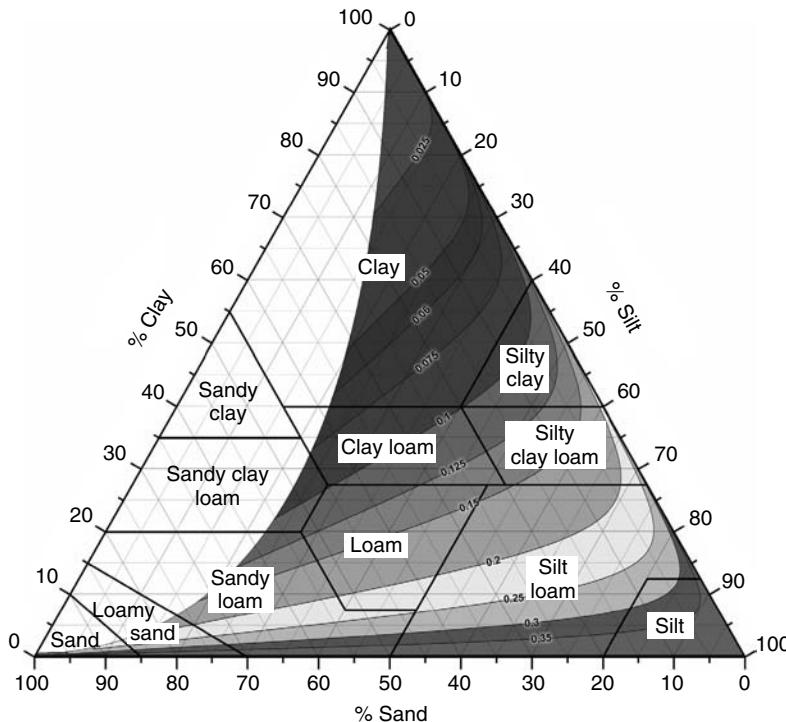

FIGURE 6.7 (See color insert following page 23-52) Contour lines of the particle-size shape parameter M plotted on the basis of the USDA soil texture triangle as a function of the different soil texture classes.

are generally empirical relationships that allow the hydraulic properties of a given soil to be predicted from more widely available data, such as texture (% of sand, silt, and clay) and bulk density (the PTFs are described in detail in Section 6.2.6). Among the PTFs proposed in the literature, some have been developed to predict the parameters of water retention equations of Brooks and Corey (Equation 6.20) or van Genuchten (Equation 6.21). For these PTFs, the direct conversion from particle-size shape parameters (M , N , and D_{pg}) to water retention parameters is a suitable choice. Using the USDA soil texture triangle (Figure 6.3) as classification chart, Figure 6.7 and Figure 6.8 show the contour lines of the particle-size shape (M) and scale (D_{pg}) parameters calculated for a mega number (10^6) of artificially generated soils.¹

As shown by Figure 6.6, Equation 6.18 describes a mono-modal function. This form is traditionally encountered for soils of temperate regions, where the silt fraction is present. As pointed out by Hodnett and Tomasella (2002), the weathering processes in temperate regions which have been going on for long periods of time, uninterrupted by ice ages, will have contributed to the large amounts of silty soils. When plotted on the USDA soil texture triangle, these soils correspond to the area covered by the colored contour plots of Figure 6.7 and Figure 6.8. They represent the bulk of soils of most soil databases such as UNSODA (Leij et al., 1996) and GRIZZLY (Haverkamp et al., 1997) used to derive the classical PTFs (e.g., Rawls and Brakensiek, 1985). However, when soils have low silt content, as is the case for tropical and subtropical soils, then the particle-size frequency curve shows a bimodal behavior (“camel” back behavior). These soils are situated in the blank area of Figure 6.7 and Figure 6.8. Obviously, the use of PTFs derived for the soils of temperate regions are inadequate for tropical soils and specific PTFs should be derived exclusively using data for tropical soils (e.g., Tomasella and Hodnett, 1998; Tomasella et al., 2000; Hodnett and Tomasella, 2002). Even though the complication of bimodal texture behavior has drawn very little attention in the literature, the consequences can be far-reaching. As there is shape similarity between the cumulative

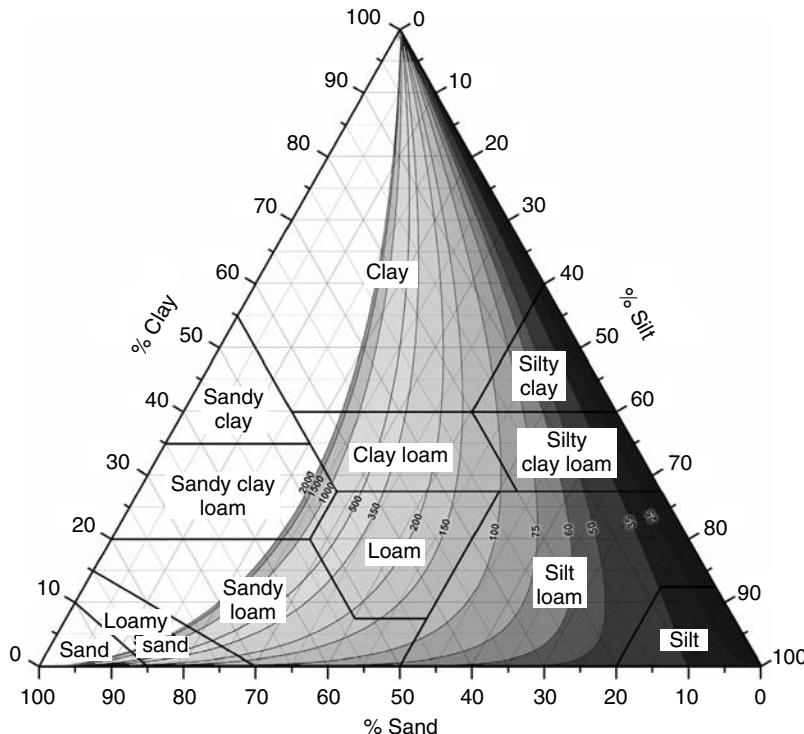

FIGURE 6.8 (See color insert following page 23-52) Contour lines of the particle-size scale parameter D_{p_8} (μm) plotted on the basis of the USDA soil textural triangle as a function of the different soil texture classes.

particle-size distribution and water retention functions (Haverkamp and Parlange, 1986), it follows that most tropical and subtropical soils show bimodal water retention characteristics (de Condappa et al., 2005).

The second category of functional relationships to be dealt with concerns the group of relations used to describe the hydraulic soil properties. Many different functions have been proposed in the literature based on various combinations of the dependent variables θ , h , and K , and a certain number of fitting parameters (e.g., Gardner, 1958; Brooks and Corey, 1964; Brutsaert, 1966; van Genuchten, 1980; Haverkamp and Vauclin, 1981). Independent of the correct physical meaning of the fitting parameters, their values are submitted to constraints imposed by the use of the transfer equations such as the Fokker-Planck or Richards' equation (see Section 6.4). The most frequently used in the literature are the following water retention and hydraulic conductivity expressions.

6.2.4.2 Water Retention Curves

The Brooks and Corey (1964) equation:

$$\begin{cases} \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left[\frac{h_{bc}}{h} \right]^\lambda & \text{for } h \leq h_{bc} \\ \theta = \theta_s & \text{for } h_{bc} \leq h \leq 0 \end{cases} \quad (6.20)$$

and the van Genuchten (1980) water retention equation:

$$\frac{\theta - \theta_r}{\theta_s - \theta_r} = \left[1 + \left(\frac{h}{h_g} \right)^n \right]^{-m} \quad (6.21)$$

where the water pressure head (h) is usually taken to be negative and is expressed in cm of water; h_{bc} is the Brooks and Corey *pressure scale parameter*; h_g is the van Genuchten *pressure scale parameter*; and λ , m , and n are *water retention shape parameters*. The water retention shape parameters m and n are frequently related according to:

$$m = 1 - \frac{k_m}{n} \quad \text{with } n > k_m \quad (6.22)$$

where k_m is an integer value referred to hereafter as the *user index* (Haverkamp et al., 2005) that was initially introduced by van Genuchten (1980) to calculate closed-form analytical expressions for the hydraulic conductivity function when substituted in the predictive conductivity models of Burdine (1953) or Mualem (1976) (see Equation 6.43). For the Mualem theory parameter k_m takes the value $k_m = 1$, and for the Burdine theory $k_m = 2$. The constraint $\theta_r = 0$ is frequently imposed.

The Brooks and Corey equation represents a limiting case of the van Genuchten equation. That is to say, Equation 6.21 reduces to Equation 6.20 for pressure heads very large compared with the scaling pressure (h_g). This explains that both shape parameters λ and mn are often assumed equal when used for converting purposes (e.g., Lenhard et al., 1989; Russo et al., 1991; Rawls et al., 1992; Morel-Seytoux et al., 1996). However, Haverkamp et al. (2005) showed in a recent study that the condition $\lambda = mn$ becomes totally incorrect for large values of λ and mn . They also showed a strong dependence of the shape parameter value on the residual water content θ_r and the user index k_m . This interdependency of parameter values is a potential problem with parameterization of retention data. To facilitate the interpretation, conversion, and optimization of retention parameters, the authors introduced a *water retention shape index* P_{wr} , which constitutes an integral measure of the slope of the water retention curve and which characterizes the retention behavior of a particular soil with a single number. The water retention shape index is constant for a given soil and provides a benchmark measure of texture. Its value which can be associated with the water retention fractal dimension, varies between 0 and 3 which is the maximum expected value for fractal behavior. In an associated study, Leij et al. (2005) applied the shape index concept to derive the conversion equation:

$$P_{wr} = \lambda_0 = \frac{mn_0}{1 + m_0} = \frac{mn_0(k_m + mn_0)}{k_m + 2mn_0} \quad (6.23)$$

where the subscript 0 indicates the constraint $\theta_r = 0$. When a nonzero θ_r -value is applied, the shape parameter values are directly affected. For the example of the Brooks and Corey water retention equation, the shape parameter λ changes according to:

$$P_{wr} = \lambda_0 = \lambda \left[1 + \frac{\theta_r}{\theta_s - \theta_r} \ln \left(\frac{\theta_r}{\theta_s} \right) \right] \quad (6.24)$$

As P_{wr} was shown to be independent of the parameterization, it follows $\lambda \geq \lambda_0$ (Equation 6.23).

The difference in λ and λ_0 compensates for the effect of θ_r . Leij et al. (2005) derived similar equations for the van Genuchten water retention shape factor mn and mn_0 . As an example, Figure 6.9a and b show the influence of θ_r on the shape factor mn (Figure 6.9a) and the water retention shape index P_{wr} (Figure 6.9b) calculated for 253 soil sample taken from the GRIZZLY soil database (Haverkamp et al., 1997) subject to the Burdine condition ($k_m = 2$). Obviously, the interdependency of the different parameter values leads to nonunique parameter sets. When used in soil databases regardless of the different regression constraints, these parameter sets may well lead to rather dubious PTF functions.

The problem of bi-modularity mentioned above for the case of the cumulative particle-size distribution function, also counts for the water retention curve. Apart from Ross and Smettem (1993) and Durner (1994) who use sums of monomodal water retention functions to describe bimodal water retention behavior, only few authors have dealt with the conceptualization of a bimodal water retention model.

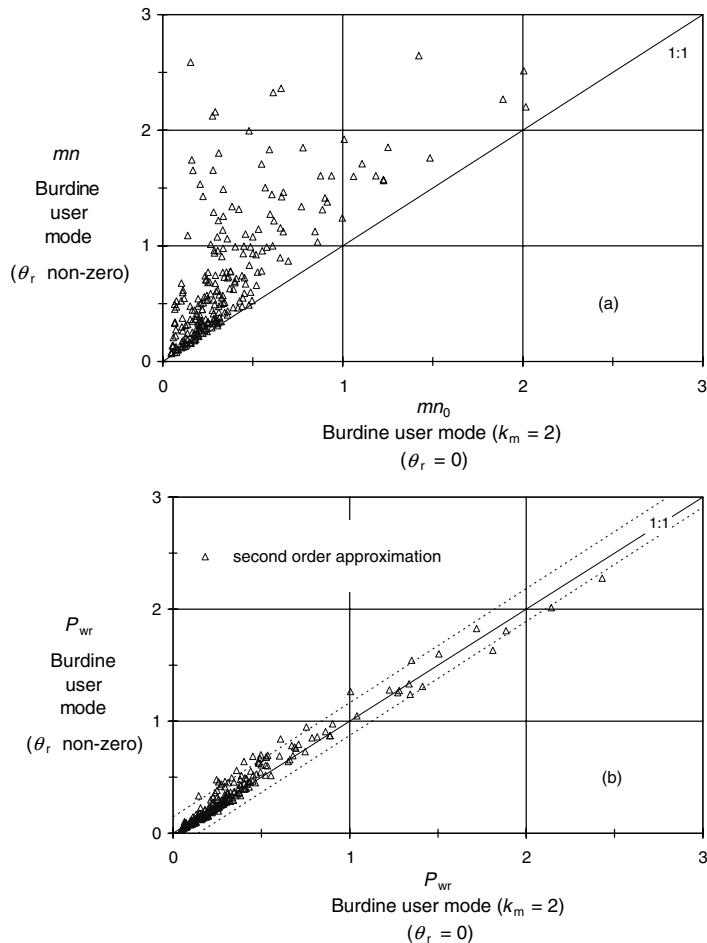

FIGURE 6.9 (a) The shape factor mn with θ_r optimized as a function of mn_0 with $\theta_r = 0$ for the van Genuchten equation for 253 soil samples from GRIZZLY subject to the Burdine condition. 6.2.4.3 Hydraulic Conductivity Functions

The Brooks and Corey (1964) equation:

$$\frac{K}{K_s} = \left[\frac{\theta - \theta_r}{\theta_s - \theta_r} \right]^\eta \quad (6.25)$$

and the van Genuchten (1980) hydraulic conductivity equation:

$$\frac{K}{K_s} = \left[\frac{\theta - \theta_r}{\theta_s - \theta_r} \right]^{1/2} \left[1 - \left\{ 1 - \left(\frac{\theta - \theta_r}{\theta_s - \theta_r} \right)^{1/m} \right\}^m \right]^2 \quad (6.26)$$

where η is a *conductivity shape parameter*.

Through an extensive study, Fuentes et al. (1992) concluded that only the combination of the van Genuchten water retention equation (Equation 6.21), $h(\theta)$, based on the Burdine theory ($m = 1 - 2/n$)

together with the Brooks and Corey conductivity equation (Equation 6.25) stays valid for all different types of soil encountered in practice without becoming inconsistent with the general water transfer theory. This is due to the rather limiting constraint that exists for shape parameter m when using the Mualem theory: $0.15 \leq m \leq 1$. As mentioned before, the value of θ_r is generally taken equal to zero.

For modeling purposes, the soil characteristic equations are often expressed in dimensionless form (e.g., Haverkamp and Vauclin, 1979; Warrick et al., 1985). The following dimensionless soil variables are used:

$$\theta^* = \frac{\theta}{\theta_s}; \quad h^* = \frac{h}{h_g}; \quad \text{and } K^* = \frac{K}{K_s} \quad (6.27)$$

where the superscript* refers to the nondimensional form of the different variables.

The use of Equations 6.20–6.26 combined with appropriate initial and boundary conditions allows the description of water transfer in the vadose zone of soil in a fully deterministic way (e.g., in the form of Richards [1931] equation, see Section 6.4). However, such a comprehensive approach has its price in complexity, as it requires the determination of five unknown soil parameters:

- The two dimensionless shape parameters (m and η); and
- The three scale parameters θ_s , h_g , and K_s .

Both shape parameters are strongly linked to the textural soil properties, whereas the scale parameters are related to soil structure (Haverkamp and Reggiani, 2002).

Before going to the following section on the measurements of soil characteristics it is important to underline two major difficulties in applying the foregoing formulism to field studies:

- Equations 6.20–6.26 only refer to the capillary water retention and hydraulic conductivity soil properties. Side effects due to *macroporosity*, such as soil cracks, root holes, worm channels, and large pores formed for various biological or mechanical reasons are not incorporated (see rather Chapter 9 and Chapter 22); and
- The soil characteristic equations only give point scale information (i.e., *local scale*) with a critical scale area of 1 m^2 . Consequently, when dealing with the modeling of soil moisture dynamics at field scales, there exists a clear mismatch between the scale at which the functional soil characteristics are defined (and measured!) and the characteristic spatial scale for which models are trying to make predictions.

6.2.5 Measurement of Soil Characteristics

Many experimental works have been devoted over the last decades to the development of measurement techniques for estimating soil hydraulic characteristics. Roughly speaking, two categories of methods can be distinguished for the determination of the unknown soil hydraulic parameters: (1) the measurement techniques (direct or indirect) and (2) the predictive methods. The first category of techniques has been developed mainly for the measurement of the soil hydraulic parameters at a local scale and is difficult to apply over large areas. The second category is more flexible and could possibly be used at larger scales. For that reason we have preferred to address the predictive methods separately in Section 6.2.6.

In general, the measurement techniques rely on precise and time-consuming experimental procedures that can be categorized as being either laboratory- or field-based. While laboratory methods allow accurate measurement of flow processes, they are performed on samples taken from the field, and as a result, their representativity of field conditions can be questioned. The presence of aggregates, stones, fissures, fractures, tension cracks, and root holes, commonly encountered in unsaturated soil profiles, is difficult to represent in small-scale laboratory samples. Field techniques can be more difficult to control, but they have the advantage of estimating *in situ* soil hydraulic properties that are more representative, which is of considerable value in the subsequent use of the hydraulic information. Therefore, it is desirable to aim at field methods that can ease, to some extent, the time-consuming constraints.

6.2.5.1 Soil Water Content

Soil water content is determined using direct or indirect methods. Direct techniques, such as the gravimetric method, involve the measurement of water losses through the process of evaporation, or drainage. Chemical reactions can also be used to displace water. Indirect methods, such as electrical or radiological techniques, estimate the physical properties of some factor known to have an influence on soil water content. Then through a calibration procedure, these properties are related to soil water content. A complete and detailed description of the different methods is given by Gardner (1986).

6.2.5.1.1 Gravimetric Method

This method usually involves the weighing of a wet soil sample, the removal of water by evaporation through oven drying or microwave heating, and then the reweighing of the dry sample. The soil water content is determined as the ratio of the net weights of the water removed to the dry sample. A high accuracy of soil water content can be achieved by drying the soil sample until a constant weight is reached. Even though it is a destructive and time-consuming approach, it is often used routinely because it does not require any calibration and it is easy to perform.

6.2.5.1.2 Electrical Resistance Methods

Electrical resistance methods are based on the strong correlation between the electrical resistance of a porous media and its water content. Two electrodes inserted in a porous block made of a variety of material, resistant to degradation once buried (e.g., gypsum, nylon, fiber glass), are placed into the soil. Once equilibrium is reached (identical matric potential for the porous block and the soil), the water content of the porous block is an indicator of the soil water content. This nondestructive technique is affected by hysteresis; due to technical limitations, only a drying calibration curve can be determined. The use of such techniques is highly limited because of a reduced accuracy, especially for high water contents.

6.2.5.1.3 Neutron Thermalization

The basis of this method is the property of hydrogen atoms to slow down and scatter fast, high energy colliding neutrons. The successive collisions result in a loss of energy until thermal equilibrium with the surrounding atoms is reached (*thermalization*). A source of fast neutrons is lowered in an access tube. Through collisions with the hydrogen atoms, these neutrons become thermalized. A counting system determines the concentration of thermal neutrons by calculating the number of particles emitted by the reaction of the low-energy neutrons and boron trifluoride present in a detector. Through calibration, the counts of the thermal neutrons are transformed to a water content. This method is nondestructive, but it requires calibration and its use is actually limited because of environmental regulations. Another limiting factor is the volume of measurement and its dependency on water content. Detailed information on the error analysis in estimating soil water content from neutron probe measurements are given by Haverkamp et al. (1984) and Vauclin et al. (1984).

6.2.5.1.4 Gamma Rays Attenuation Method

This nondestructive method consists of measuring the attenuation of intensity of a beam of gamma rays when crossing a soil column. The attenuation depends on the soil constituents and bulk density. Measuring the attenuation at two different gamma ray energies yields both the water content (θ) and dry bulk density (ρ_d). The apparatus includes a source of gamma rays and a scintillator detector. An accurate calibration is required.

6.2.5.1.5 Capacitance Method: Time Domain Reflectometry (TDR) Methods

These methods are based on the measurement of the dielectric constant of the soil. As the water has a very large dielectric constant compared to that of the solid phase and that of air, it has a large influence on the dielectric constant of the soil. TDR consists of measuring the transfer time of electromagnetic waves along the parallel metallic rods (two or more) of known length inserted in the soil:

$$C_e = \left[\frac{ct_{tr}}{2l} \right]^2 \quad (6.28)$$

where C_e is the relative dielectric constant of the soil; t_{tr} is the wave travel time from the entrance into the soil to the end of the rods; l is the length of the rods; and c is the light velocity. The next step is to calibrate the C_e vs. a known value of volumetric water content. The technique is described in a comprehensive paper by Topp et al. (1980). Although the authors suggested that the procedure is insensitive to variations in dry bulk density, temperature, mineral composition, and salinity (i.e., one single calibration curve could be applied to nearly all soils), it is evident that the sensitivity of the measurements depends on the dielectric constant of the material between or around the wire probes (e.g., Knight, 1992). Thus, local nonuniformities due to small air gaps or material of different density can cause considerable errors in the measured water content values. It complicates significantly the interpretation of the field water content measurements and often requires site-specific calibration curves. Haverkamp et al. (1996) proposed a procedure to correct the apparent (i.e., TDR) soil water content values for the effects of air gaps, small stones, and water-holding coarse fragments. The advantage of the TDR method is that it is nondestructive. As the use of the neutron probe is limited for environmental reasons, the TDR method is becoming more and more a standard.

6.2.5.1.6 Remote Sensing

Remote sensing involves airborne measurements, usually from satellite or airplanes, of the electromagnetic signature of a body or surface. For inferring soil moisture, measurements are usually done in the visible, infrared, and microwave spectra. Microwave sensors are of increasing interest as they measure the dielectric properties of a surface body without being affected by cloud cover. Two microwave sensors are used: passive sensors, also known as *radiometers*, which measure microwave emission, and active sensors or *radars*, which send a microwave signal and measure its reflection. One major advantage of remote sensing is that it integrates soil moisture over a certain area. However the measurements are limited to the very first centimeters of the soil and are affected by surface roughness and vegetation density. The calibration procedure is extremely difficult because of the temporal and spatial variability of ground measurement of soil moisture.

6.2.5.2 Soil Water Pressure Head

Depending on the pressure range measured, two different devices are most widely used: tensiometers and psychrometers.

6.2.5.2.1 Tensiometers

A tensiometer is composed of a porous cup, a connecting tube or barrel, and a pressure measuring device that can be a water manometer, mercury manometer, pressure transducer, or a vacuum gauge. The porous cup is filled with degased water and has to remain saturated for the whole soil water pressure range. The porous cup and the surrounding soil are in hydrostatic equilibrium, yielding then a measure of the soil water pressure. The use of tensiometers is limited to pressure heads ranging from 0 to 800 cm. For higher pressures, the use of psychrometers is recommended. A detailed description of the different types of tensiometers is given by Cassel and Klute (1986).

6.2.5.2.2 Psychrometer

In this method, the soil water potential is related to the relative humidity defined by the ratio of the water vapor pressure in equilibrium with the liquid phase (p) to the saturated vapor pressure (p_0) as:

$$h = \frac{R_g T_l}{M_{\text{mol}}} \ln \left(\frac{p}{p_0} \right) \quad (6.29)$$

where M_{mol} is the molecular weight of water, R_g is the universal gas constant, and T_l is the temperature (Kelvin) of the liquid phase. Details about the thermocouple psychrometer design and functioning are given by Rawlins and Campbell (1986).

6.2.5.2.3 Other Methods

Additional methods for measuring soil water potential include *electric resistance sensors*, which can be gypsum, nylon, or fiberglass. Once potential equilibrium is reached between the resistance sensor and the soil matrix, the electric conductivity is measured and then transformed to water potential through pre-established calibration curves. Additional methods such as *heat dissipation*, are described by Campbell and Gee (1986).

6.2.5.3 Hydraulic Conductivity

Hydraulic conductivity is a soil characteristic that cannot be measured directly. Unlike the water retention characteristic, which can be considered as a quasistatic soil property, the hydraulic conductivity function is always related to water movement into or through the soil. The transient and steady movement of water in the unsaturated zone of soils depends to a large extent upon the pore network resulting from the assemblage of soil particles and aggregates. This dependence of $K(\theta)$ on the pore-size distribution underlines the complicity that exists between the water retention and hydraulic conductivity functions. It implies at the same time that the optimization of soil water characteristic parameters over measured field data should be carried out simultaneously with a combined objective function. As only very little information is available in the literature on this problem (e.g., Yates et al., 1992), it seems most likely that combined optimization of water retention and hydraulic conductivity parameters is unfortunately seldom used in practice.

In the following, three methods developed for *in situ* determination of hydraulic conductivity properties are presented. The *instantaneous profile method* must be considered as a fixed ground based experiment, while the two other methods, *tension disk infiltrometer* and *pressure ring infiltrometer*, can be looked upon as mobile experiments. The two latter methods are based on inverse techniques. *Inverse methods* consist of procedures that use solutions for a flow process inversely against observations of that process. The hydraulic parameters are then estimated either via reorganization of the solution into an explicit expression, or through numerical optimization (e.g., Simunek et al., 1998). Numerical solutions usually have high computation overheads. A more attractive approach is to use analytical solutions that can yield better appreciation of the role of the different soil parameters interfering in the flow processes, and also require less computation. For a possible successful application of inverse methods, it is crucial to describe the flow process as precisely as possible and to control perfectly well the imposed initial and boundary conditions.

6.2.5.3.1 Instantaneous Profile Method

In field studies, the instantaneous profile method is a transient method used to observe the natural water movement into the soil. During the time interval $\Delta t = t_2 - t_1$, the change per unit surface in the total water storage of the vadose zone (ΔS), from the soil surface to the reference depth z_m (Figure 6.10), is calculated as:

$$\Delta S(z) = \int_0^{z_m} [\theta(z, t_2) - \theta(z, t_1)] dz \quad (6.30)$$

Without any water supply to the soil profile during the period $[t_1, t_2]$, the storage variation corresponds to the water volume drained across the z_m plane or evaporated (i.e., evapotranspiration) through the plane $z = 0$, or even to a combination of both processes simultaneously. The flow direction can be determined from the gradient of the measured profiles of hydraulic head $H(z, t)$. A negative gradient, $dH/dz < 0$, indicates a positive, or downward-oriented water flux in Darcy's law (see also Section 6.3, Equation 6.49). This flux is associated with percolation or drainage. A positive gradient, $dH/dz > 0$, corresponds to a negative or upward-oriented water flux (Figure 6.10), associated with evaporation. A *zero flux plane* z_0 is defined when the hydraulic gradient $dH/dz = 0$. During a redistribution, the zero flux plane moves downward.

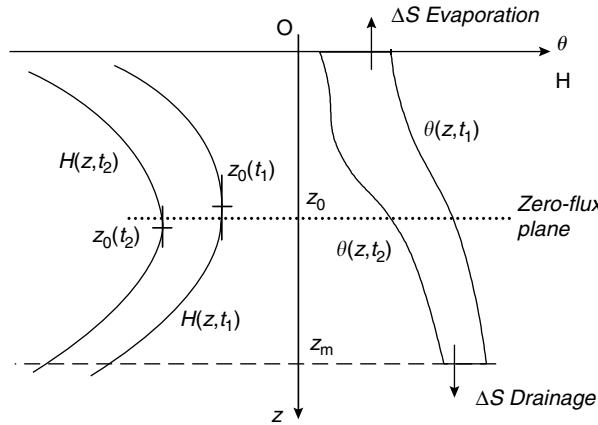

FIGURE 6.10 Instantaneous profile method to estimate unsaturated hydraulic conductivity.

To determine the mean water flux per surface unit, at any soil depth, $q(z)$, it is possible to integrate the mass conservation equation from the zero flux plane z_0 to the chosen depth z as:

$$q(z) = \frac{\Delta S(z_0, z)}{t_2 - t_1} \quad (6.31)$$

where z_0 is the position of the zero flux plane averaged over the period $[t_1, t_2]$. The application of the Darcy's law (Equation 6.49) gives the hydraulic conductivity directly:

$$K(\theta) = -\frac{q(z)}{dH/dz} \quad (6.32)$$

The hydraulic gradient dH/dz in Equation 6.32 is the averaged value for the period Δt calculated at the depth z .

6.2.5.3.2 Tension Disk Infiltrometer

A representation of three tension disk infiltrometers with 250, 80, and 48 mm diameter bases (after the design of Perroux and White, 1988) are shown in Figure 6.11. A graduated reservoir tower provides the water supply; the bubble tower with a moveable air-entry tube (C_1) permits to impose different boundary condition pressure head values at the cloth base (with a mesh of $20 \mu\text{m}$). A thin layer of fine sand is placed over the soil surface to ensure a good hydraulic contact between the disk and the soil. *Cumulative infiltration*, $I(t)$, is recorded by measuring the water level drop in the reservoir tower (for the proper definition of cumulative infiltration see Section 6.3). The transient infiltration flux is then given by the derivative: $q(t) = dI/dt$. By the use of an inverse procedure, these flux data allow the calculation of the spot values of hydraulic conductivity and *sorptivity* valid for the initial and boundary conditions chosen (for the proper definition of sorptivity, see Section 6.4). Under field conditions, the contact layer of sand may be important. When this is the case, the water volume stored during the early stages of infiltration can be significant. Noting I_{sa} as the water volume necessary to fill the sand layer over the time period t_{sa} , the infiltration measurements have to be corrected by the coordinate transformation: $(I - I_{sa})$ and $(t - t_{sa})$.

In most cases, slightly negative supply pressures are applied (Perroux and White, 1988), which allow the determination of hydraulic conductivity values close to saturation representative for the fine soil matrix without being biased by the possible influence of macroporosity. The fact that the initial and boundary conditions are well-controlled makes the disk infiltrometer experiments particularly appropriate for data analysis through inverse procedures. The standard analysis uses Wooding's (1968) solution for

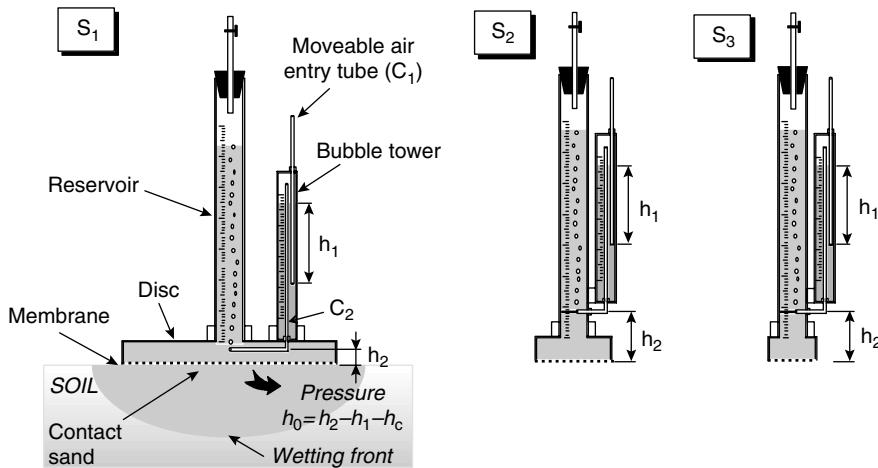

FIGURE 6.11 Tension disk infiltrometer. (Adapted from the design of Perroux, K. M. and White, I. 1988. *Soil Sci. Soc. Am. J.*, 52: 1205–1215. With permission.)

three-dimensional (3D) steady state infiltration valid for infinite time and uniform initial conditions. Unfortunately, these conditions are seldom met in the field. To overcome these limitations, a 3D analytical solution of infiltration has been derived (Haverkamp et al., 1994; Smettem et al., 1994), which allows the description of transient 3D infiltration behavior.

6.2.5.3.3 Pressure Ring Infiltrometer

The pressure ring infiltrometer is formed by a metallic ring that is driven into the soil to a given depth and connected to a reservoir system where the cumulative infiltrated volume could be measured for constant or falling hydraulic head. The reservoir system has to be adapted to the permeability characteristics of each soil. For soils with high permeability, water is supplied to the soil surface at a constant head (H_1) through the sealed top lid from a Mariotte bottle, with a moveable air tube allowing a wide range of different head values H_1 to be applied. For soils with low permeability, water must be supplied from a small capillary tube also acting as a measuring burette. This tube can be positioned either horizontally for water to infiltrate at a constant head, or vertically for water to infiltrate at a continually falling head. The cumulative infiltration, $I(t)$, is obtained from readings of the water supply tube. The saturated hydraulic conductivity is then deduced from the cumulative infiltration measurements by the use of analytical infiltration solutions developed for 1D positive head infiltration subject to uniform initial conditions (Elrick et al., 1995). As these conditions are rarely met under field conditions, the results should be interpreted with caution. The initial condition is determined from undisturbed soil water content samples taken near the single ring.

6.2.5.3.4 Other Methods

Over the last decade the *multistep outflow* method has gained interest in the literature (e.g., Kool et al., 1987; Kool and Parker, 1988; Echings and Hopmans, 1993; van Dam et al., 1994). It concerns a laboratory-based method that allows the estimation of the soil characteristics by inverse modeling of a series of outflow experiments. For a successful application of the inverse optimization procedure it is crucial to ensure the uniqueness of the solution; consequently, various laboratory outflow experiments subject to different initial and boundary conditions are generally required. The multistep outflow method becomes more and more time-consuming as the number of unknown parameters to be determined increases. As for most laboratory methods, the representativity of the results for field conditions is questionable.

6.2.5.4 Combined Water Retention and Hydraulic Conductivity

Recently, a portable field method has been reported in the literature that allows for the simultaneous characterization of both hydraulic soil characteristics, $h(\theta)$ and $K(\theta)$. The method termed as the *Beerkan*

method, was initially pioneered by Haverkamp et al. (1996). It uses the van Genuchten water retention function (Equation 6.21) and the Brooks and Corey hydraulic conductivity function (Equation 6.25) to describe the hydraulic characteristic curves, and estimates their texture-dependent shape parameters (m , n , and η) from simple particle analysis, and their structure-dependent scale parameters (θ_s , h_g , and K_s) from field infiltration experiments at null pressure head. This method earlier described by Haverkamp et al. (1998a) was applied to many field studies (Galle et al., 2001; Braud et al., 2003) and has recently been improved and assessed with simulated data (Braud et al., 2005; Lassabatère et al., 2005).

6.2.5.4.1 Beerkan Method

As for the pressure ring infiltrometer, the Beerkan method uses a simple annular ring. The surface vegetation is removed while the roots remain *in situ*. A soil sample is collected for particle-size analysis and to determine its initial gravimetric water content. Another sample of known volume is extracted to determine its bulk density (ρ_d). Then, the cylinder is positioned at the soil surface and inserted to a depth of about 1 cm to avoid lateral loss of the ponded water at the surface. A fixed volume of water is poured into the cylinder at time zero, and the time elapsed during the infiltration of the known volume of water is measured. When the first volume has completely infiltrated, a second known volume of water is added to the cylinder and the time needed for it to infiltrate is measured (cumulative time). The procedure is repeated for several times until a quasi steady state infiltration flux is observed. At the end of the experiment, the saturated soil is sampled to determine the saturated gravimetric water content (w_s) and thus the saturated volumetric water content (θ_s) from the bulk density (ρ_d) considering the specific density of water (ρ_w) equals 1 g/cm³ (Equation 6.9).

Fitting infiltration experiment data on either numerical or analytical expressions provides estimations of scale parameters and combinations of them, such as sorptivity (described in more detail in Section 6.4 and Section 6.5). Considering an infiltration experiment with zero water pressure on a circular surface above a uniform soil with a uniform initial water content (θ_0), the 3D cumulative infiltration, $I(t)$, and the infiltration rate, $q(t)$, can be approached by the very accurate explicit transient two-term and steady-state expansions given by Haverkamp et al. (1994, 1998a, 1998b). Considering that the conductivity shape parameter (η) and the initial and saturated water content (θ_0 and θ_s) were determined beforehand, the fit of experimental data provides estimations of saturated hydraulic conductivity (K_s) and sorptivity. The latter parameter is then expressed as a function of the soil characteristic scale parameters (θ_s , h_g and K_s) using expressions given by Haverkamp et al. (1998b). It allows for the determination of the pressure scale parameter h_g .

The originality of the *Beerkan method* lies in its inverse procedure which uses a specific identification algorithm based on soil physical constraints. The algorithm noted as BEST (Beerkan Estimation of Soil Transfer parameters) is described in detail by Lassabatère et al. (2005). The identification technique used for the estimation of the water retention and conductivity shape parameters (m , n , and η) from the measured cumulative particle-size distribution (Equation 6.18) is embedded in the BEST algorithm.

6.2.6 Estimation Techniques of Soil Characteristics

As shown in the previous section, direct measurements, either *in situ* or in laboratory, may be very time-consuming and expensive, in particular for large hydrological studies. Furthermore, it is extremely useful to have efficient methods for estimating soil transfer characteristics in areas where the amount of available information is limited. This explains that many attempts have been made in the literature at estimating soil characteristics from readily available data, such as textural soil properties (i.e., particle-size distribution) and porosity, which are the most common measured soil data across the world. These relationships previously referred to (Section 6.2.4.) as PTFs, are particularly enticing as they can either be applied at the local scale using point textural properties or at the watershed scale where textural information has been aggregated (soil maps). However, the PTFs should be used with caution, as they often rely on statistical regression equations which make them site (data) specific.

6.2.6.1 Water Retention Relation

Basically, three different approaches have been developed to predict soil water characteristics from the particle-size distribution: (1) discrete matric potential regression methods, (2) functional regression methods, and (3) semi-physical approaches.

6.2.6.1.1 Discrete Matric Potential Regression Methods

In this approach, a multiple linear regression analysis is conducted to relate specific potential to particle-size distribution, porosity (ε), organic carbon content (CO) and bulk density (ρ_d). These methods make no assumptions concerning the form of the soil water retention curve. Gupta and Larson (1979) developed regression equations between specific matric potential, particle-size distribution, and organic matter content. Rawls and Brakensiek (1982) developed three regression models. The first model uses particle-size distribution, organic matter content, and bulk density as fitting variables. To improve their estimates, Rawls and Brakensiek (1982) introduced soil water content values at -1 , 500 kPa and -33 kPa, respectively, in the second and third model. Tietje and Tapkenhinrichs (1993) as well as Vereecken et al. (1992), who tested the point matric potential approach extensively, concluded that the discrete methods often give poor results as the regression equations are usually based on measurements conducted on disturbed soil samples, limiting their representativeness and applicability.

6.2.6.1.2 Functional Regression Methods

In this approach, a preliminary shape of the soil water retention curve is assumed (e.g., the Brooks and Corey function), and its parameters are derived through fitting (e.g., Clapp and Hornberger, 1978; Bloemen, 1980; Vereecken et al., 1989; Wösten and van Genuchten, 1988). The method is more adapted for unsaturated flow modeling since it gives a continuous functional description of the water retention curve. McCuen et al. (1981) found that the mean and standard deviation of the Brooks and Corey parameters (i.e., λ and h_{bc} of Equation 6.20) vary across soil textural classes. Cosby et al. (1984) extended this work and concluded that the textural soil properties can explain most of the variations of these parameters. This led to the development of regression equations between the mean and standard deviation of the soil hydraulic parameters and soil textural classes (Table 6.1). Rawls and Brakensiek (1985) developed a set of regression equations to estimate the water retention curve from particle-size distribution and porosity (Table 6.2).

All foregoing functional regression models have been developed using extensive databases for soils of temperate regions and, hence, apply to mono-modal water retention functions. As explained before (Section 6.2.4), the tropical and sub-tropical regions often show data outside the range of textural validity of the “temperate soil” PTFs tested. For example, the PTF of Rawls and Brakensiek (1985), illustrated in Table 6.2, is valid for soils with a clay content of 5–60% and a sand content of 5–70%, but some kaolinite tropical soils, particularly *Ferralsols*, can have a clay content of 70–90% (cf. Hodnett and Tomasella, 2002). This might suggest, from a temperate soils viewpoint, that they are heavy clays with a low permeability

TABLE 6.1 Regression Coefficients for the Brooks and Corey Parameters

Coefficients	Mean (μ) $\mu = c_1 + c_2Cl + c_3Sa + c_4Si$				Standard Deviation (σ) $\sigma = c_1 + c_2Cl + c_3Sa + c_4Si$			
	$\log(h_{bc})$	$1/\lambda$	θ_s	$\log(K_s)$	$\log(h_{bc})$	$1/\lambda$	θ_s	$\log(K_s)$
c_1	1.54	3.10	50.5	-0.6000	0.72	0.92	8.23	0.43
c_2	0	0.157	-0.037	-0.0064	0.0012	0.0492	-0.0805	0.0011
c_3	-0.0095	-0.003	-0.142	0.0126	0	0	0	0
c_4	0.0063	0	0	0	-0.0026	0.0144	-0.0070	0.0032

Note: h_{bc} is expressed in cm and K_s in inch/h; Cl, Si, and Sa represent the clay, silt, and sand fractions (%), respectively.

Div., ASCE*, Denver, Colorado, and from Rawls, W. J. and Brakensiek, D. L. 1989. Estimating soil hydraulic properties. In *Unsaturated Flow in Hydrologic Modeling*, Morel-Seytoux, H. J. (Ed.), Kluwer Academic Publishers, published in cooperation with NATO Scientific Affairs Division, Boston. With permission.

and a moderate to high available water capacity. However, most of these soils have a low bulk density (ρ_d) in the order of 0.9–1.2 g/cm³ which is reflected in the much higher values of porosity (ε) and, hence, θ_s (Equation 6.3). If the pores are large, they will drain readily leading to small values of h_g . Indeed, Hodnett and Tomasella (2002) observed that most of the more clayey tropical soil show smaller mean values of h_g than for the temperate soils. Combined with the high porosity, this results in high values of K_s . Taking once again the example of the *Ferralsols*, it was found (Chauvel et al., 1991) that these soils show a range of large pores leading to small values of h_g , but also have a large proportion of their total porosity in very fine pores. These pores remain water filled at negative pressure values as high as $h = -4000$ kPa suggesting either a high residual water content value in the order of $\theta_r = 0.30 \text{ cm}^3/\text{cm}^3$ (Hodnett and Tomasella, 2002) or a bimodal behavior such as seems clearly imposed by the bimodal shape of the cumulative particle-size distribution function.

For the reasons mentioned above, we have preferred to include an example of a PTF derived exclusively using data for tropical soils. Basically, three tropical PTFs have been reported in the literature, that is, those of Tomasella and Hodnett (1998); Tomasella et al. (2000); and Hodnett and Tomasella (2002). The first study gives multiple regression equations to estimate the Brooks and Corey water retention parameters from texture data, based on a dataset of 614 samples for Amazonian soils. When reported on the USDA soil texture triangle of Figure 6.3 (Tomasella and Hodnett, 1998), they cover mainly the left area where bimodal behavior is expected. The regression coefficients as a function of the different soil textural classes are given in Table 6.3. While the second and third study use perhaps more comprehensive regression analyses, they also include supplementary explicative parameters such as the basic information on coarse and fine sand, organic carbon content (OC), dry bulk density (ρ_d), and pH values.

TABLE 6.3 Regression Coefficients for the Brooks and Corey Parameters According to Equation 6.20

Regression Coefficient	Function Type ^a

Notwithstanding that most of foregoing regression models clearly show correlation trends between water retention and textural or structural soil data, the application validity is often restricted to the soils tested for each study, hence, limiting the transportability of the methods. The models certainly present the advantage of easiness of use, but when applied for predictions, they give sometimes hazardous results with important errors on water content, especially in the wet range of $h(\theta)$, which is mostly due to the fact that the models fail to predict correctly the soil structure related water content and pressure scale parameters (θ_s and h_{bc} or h_g) from soil textural information alone.

6.2.6.1.3 Semophysical Methods

In spite of the problem of transportability, the foregoing group of functional regression models has put in evidence the correlation trend between the shape parameters of the water retention and cumulative particle-size distribution functions. This *shape similarity* formed the main hypothesis for the few semophysical models proposed in the literature (e.g., Arya and Paris, 1981; Haverkamp and Parlange, 1986). The shape-similarity hypothesis (different from shape identity) was recently confirmed by an analysis of the soil database GRIZZLY presented by Haverkamp and Reggiani (2002). Similar to the definition of the water retention shape index P_{wr} (Equation 6.23), the shape of the cumulative particle-size distribution functions can be expressed by the particle-size shape index P_{pa} :

$$P_{pa} = \frac{MN(k_M + MN)}{k_M + 2MN} \quad (6.33)$$

where M , N , and k_M are given by Equation 6.18 and Equation 6.19. The positive correlation between P_{wr} and P_{pa} is clearly shown in Figure 6.12a. This result confirms the fact that for a large number of soils the water retention shape parameter depends mainly on texture. A similar analysis for the particle-size scale parameter (D_{pg}) of Equation 6.18 and the pressure scale parameter (h_g) of Equation 6.21 shows no correlation (Figure 6.12b). This observation highlights the danger of predicting the soil structure dependent scale parameters from soil textural information alone.

The two semophysical methods considered here, which are both texture-based, take into account of the soil structural effect through the dry bulk density (ρ_d) embedded in the *tortuosity* parameter (α) for the Arya–Paris model (1981) or through the proportionality factor between pore-size and associated particle diameter for the Haverkamp–Parlange model (1986). An extensive review of both semophysical models is given in the *Soil Science Society Book on “Methods of Soil Analysis”* (Haverkamp and Reggiani, 2002).

6.2.6.1.3.1 *The Arya–Paris Model (1981)* which is the most common used, involves dividing the cumulative particle-size distribution function into a number of fractions, assigning a pore volume and a

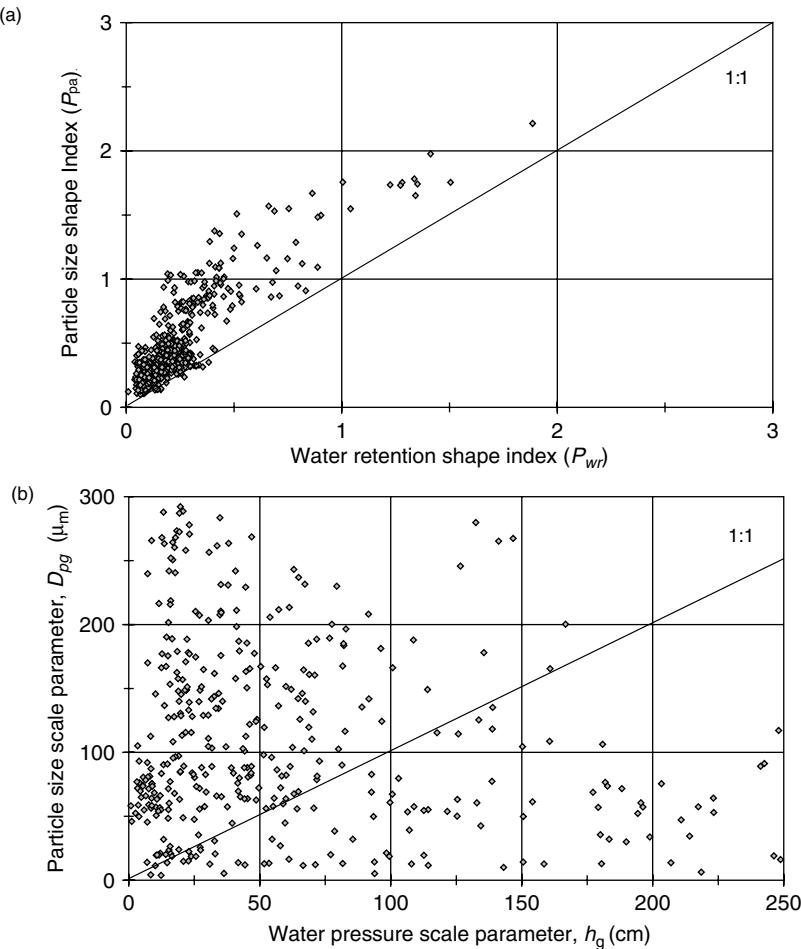

FIGURE 6.12 (a) The particle-size shape index P_{pa} as a function of the water retention shape index P_{wr} calculated for the 660 soils of the GRIZZLY soil database. (b) Pressure scale parameter h_g as a function of the particle-size scale parameter D_{pg} calculated for the 660 soils of the GRIZZLY soil database. (Adapted from Haverkamp, R. and Reggiani, P. 2002. Physical-based water retention prediction models. In *Methods of Soil Analysis, Part 4, Physical Methods*, Dane, J. H., and Clarke, G. C. [Eds.], Soil Science Society of America Book Series, *Soil Sci. Soc. Am. Inc.*, Madison, WI, pp. 762–777.)

volumetric water content to each fraction, and then computing a representative mean pore radius (R_i) and a corresponding water pressure head (h_i) value. They proposed the following nonlinear relationship to relate the pore radius (R_i) to the mean particle radius (D_{pi}):

$$R_i = D_{pi} \left[\frac{2e(nb_i)^{1-\alpha}}{3} \right]^{0.5} \quad (6.34)$$

where e is the void ratio; and nb_i is the number of particles in each size class calculated from:

$$nb_i = \frac{6W_i}{\pi\rho_s(D_{pi})^3} \quad (6.35)$$

W_i is the solid mass per unit sample mass corresponding with D_{pi} chosen in such a way that the sum of W_i is unity; ρ_s is the particle density taken equal to 2.65 g/cm^3 ; and α is an empirical factor referred to

as the *tortuosity factor* fixed at a constant value $\alpha = 1.38$. Subsequently, the pore volume dVp_i associated with each size fraction is defined by:

$$dVp_i = \frac{\pi}{6} e(nb_i)(Dp_i)^3 \quad (6.36)$$

Finally, the volumetric water content values are calculated from the pore volumes dVp_i by:

$$\theta_i = \rho_d \sum_{j=1}^{nb_i} dVp_j \quad (6.37)$$

In doing so, it is assumed that the pore volumes generated by each size fraction are progressively accumulated, from smallest to largest size fraction, and filled with water. The largest cumulative pore-size corresponds to porosity ε . Even though the Arya–Paris model is extremely easy to use, it has some slight drawbacks.

1. The first problem lies in the fact that it considers the porosity ε as the upper limit of the pore space to be filled with water which is rarely the case for field soils. Hence, it does not account for trapped air and systematically overestimates the water content scale parameter. This obviously induces errors in the predicted water content values which are most visible at the wet end of the water retention curve. As indicated by Arya and Paris (1982), this effect could be accounted for in the model at cost of additional soil information. In a later study, Arya et al. (1999) introduced a correction factor θ_s/ε in front of the sum term in Equation 6.37. However, the presence of trapped air translates in a disguised way the problem of tortuosity and, consequently, not only affects the water content scale parameter but also the pressure scale parameter of the water retention curve.
2. The second difficulty lies in the definition of the parameter α , which relates the particle-size to the pore radius. Arya and Paris proposed a constant average α -value ($\alpha = 1.38$) calculated over a limited number of soils. However, several researchers (e.g., Mishra et al., 1989; Gupta and Ewing, 1992) have suggested that predictions of the water retention curve could be improved if α is allowed to vary over the range of particle-sizes. Haverkamp et al. (1998b) have tested the validity of a constant α for more than 1000 soils taken from the UNSODA database (Leij et al., 1996). For the reported soils, both the water retention and particle-size distribution curves are available and the value of α can easily be calculated. Defining the normalized water content as $\theta_i^* = \theta_i/\theta_s$, a series of θ_i^* values was chosen at various intervals between zero and unity. Subsequently, for each soil a value of α was calculated for each θ_i^* . The results shown in Figure 6.13, challenge the validity of a constant α . The values vary not only as a function of soil type, but also as a function of water content. Neither at the wet nor at the dry end of the water retention curve is the constant average value of $\alpha = 1.38$ satisfied. Prompted by the different studies on a non-constant α value, Arya et al. (1999) has proposed an empirical method that allows the estimation of the tortuosity parameter α_i as a function of the number of soil particles (nb_i) and, hence, as a function of water content (θ_i). The method was developed by the use of “real” soil data taken from the UNSODA database (Leij et al., 1996). For five different soil textural classes of the USDA soil texture triangle, namely, sand, sandy loam, loam, silt loam, and clay (see Figure 6.3), about five soils were selected for which the linear relationship between $\log(W_i/Dp_i^3)$ and $\log(Nb_i)$ have been explored (where Nb_i is the number of “real” soil particles calculated from the UNSODA water retention data). Arya et al. (1999) established the following regression equation:

$$c_i = 1 + \left[\frac{c_1 + c_2 \log(W_i/(Dp_i)^3)}{\log(Nb_i)} \right] \quad (6.38)$$

where the parameters c_1 and c_2 are empirical regression parameters with different values for different textural classes (Table 6.4). Haverkamp et al. (2002) have tested the validity of the new formulation

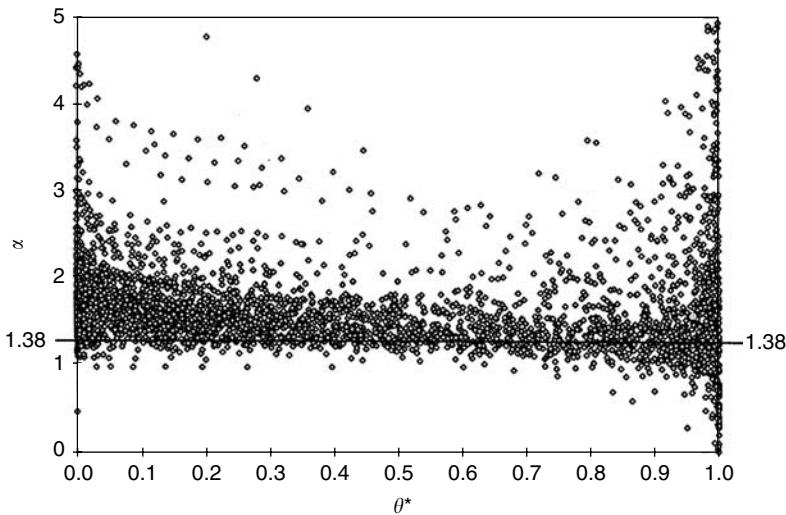

FIGURE 6.13 Evolution of the tortuosity factor α of the Arya and Paris (1981) model as function of θ_i^* calculated for more than 1000 different soils of the UNSODA and GRIZZLY soil databases.

TABLE 6.4 Regression Coefficients According to Equation 6.38

Textural Class	Regression Coefficients	
	c_1	c_2
Sand	-1.415	0.489
Sandy loam	-2.353	0.773
Loam	-0.644	0.395
Silt loam	-1.425	0.353
Clay	-1.559	0.305

Source: From Arya, L. M., Leij, F. J., van Genuchten, M. Th., and Shouse, P. J. 1999. *Soil Sci. Soc. Am. J.*, 63: 510–519. With permission.

of α on the same population of soils as used before. The authors showed that the new formulation of α systematically overestimated the best-fit α -values with roughly 25 to 50%, which is not a serious improvement with respect to the initial definition with a constant α . However, for each particular soil textural class the scatter between the predicted and calculated α -values was considerably reduced putting in evidence that the principles used for the new formulation of α are basically sound but that the regression analysis calculated over a small soil population of roughly five soils is not representative for the soil taken from UNSODA database.

3. The third and last difficulty of the Arya–Paris model (1981) concerns the problem of hysteresis. As the cumulative particle-size distribution is unique for a given soil, only one associated water retention curve can be predicted, either the main wetting curve or the main drying curve. To pass from one main curve to the other and/or along scanning curves, the water retention prediction model should theoretically be coupled with a hysteresis model that does not require any supplementary information. Although the discrete equations used by the Arya–Paris model were not formulated to facilitate such coupling, it is feasible to do so.

In conclusion, the Arya–Paris model is definitely very user-friendly which explains the fact that the model is the most widely used.

6.2.6.1.3.2 The Haverkamp–Parlange Model (1986). The second semi-physical model proposed by Haverkamp and Parlange (1986) is certainly much more complicated and has not the easiness of use of the Arya–Paris model. Their method allows the direct estimation of the parameters of Equation 6.20 for sandy soils without organic matter. The predicted $h(\theta)$ curve was then associated to the boundary wetting curve (BWC). Coupled with the hysteresis model proposed by Parlange (1976) the full family of wetting curves can be predicted. For the sake of simplicity, the authors assumed a linear relationship between the mean pore radius (R) and the corresponding particle radius (D_p):

$$R = \gamma D_p \quad (6.39)$$

where γ is an empirical packing factor to be determined through fitting from textural data.

This method presents the advantage of interpreting the cumulative particle-size distribution function in its continuous form, but it uses the extremely simple relationship between R and D_p (Equation 6.39) which is perhaps valid for structureless soils such as pure sand soils, but which is questionable for non-sandy soils. Moreover, the use of the hysteresis concept obliged the authors to choose different type-equations for $F_p(D_p)$ (Equation 6.18) and $h(\theta)$ (Equation 6.20). This complicated the model description and, hence, made the model more difficult to follow and less user-friendly as compared to the Arya–Paris model addressed before.

6.2.6.1.3.3 Other Methods In the first edition of the *Handbook of Groundwater Engineering*, Chapter 5, Haverkamp et al. (1998b) introduced a method for predicting the van Genuchten water retention shape parameter m (Equation 6.18) as a function of the particle-size shape parameter M (Equation 6.21). Extending this method to the concept of shape indices as given by Equation 6.23 and Equation 6.33, we have:

$$P_{pa} = P_{wr}[1 + \gamma s] \quad (6.40)$$

where γs is a tortuosity factor defined as a function of the fractal dimension s introduced by (Fuentes et al., 1998):

$$\gamma s = \frac{2s - 1}{2s[1 - s]} \quad (6.41)$$

and calculated as the root of the equation:

$$[1 - \varepsilon]^s + \varepsilon^{2s} = 1 \quad (6.42)$$

Parameter ε is the soil porosity defined by Equation 6.3. Application of this method in the algorithm BEST (Lassabatère et al., 2005) gives promising results.

6.2.6.2 Hydraulic Conductivity Relation

Methods used to estimate the hydraulic conductivity curve rely on capillary model hypotheses. Most models proposed in the literature (e.g., Millington and Quirk, 1961; Mualem, 1976) are based on the Burdine's equation (1953) and make use of the water retention equation $h(\theta)$:

$$K^* = [\theta^*]^{p\beta} \left[\frac{\int_0^{\theta^*} 1/(h(\bar{\theta}^*)^2) d\bar{\theta}^*}{\int_0^1 1/(h(\theta^*)^2) d\theta^*} \right] \quad (6.43)$$

where θ^* and K^* are the dimensionless water content and hydraulic conductivity, respectively, given by Equation 6.27; and $p\beta$ is a parameter generally associated with the effect of tortuosity. The differences between the various models arise from the hypotheses introduced to describe the pore structure (i.e., tortuosity) and its interaction with the relative permeability (Equation 6.17). Solving Equation 6.43 allows deriving an expression that relates the hydraulic conductivity shape parameter (i.e., η of Equation 6.25) as function of the water retention shape parameters (i.e., λ or m of Equation 6.20 or Equation 6.21 respectively) and the tortuosity factor:

$$\eta = \frac{2}{\lambda} + 2 + p\beta \quad (6.44)$$

Different values of $p\beta$ can be derived dependent on the capillary model chosen, that is, Childs and Collis George (1950) used $p\beta = 0$; Mualem (1976) $p\beta = 1/2$; Burdine (1953) $p\beta = 1$; and Millington and Quirk (1961) $p\beta = 4/3$. Although these $p\beta$ -values have to be interpreted with considerable caution (as they were mostly based on pure intuition of the different authors combined with some subjective statistical analyses), they definitely have the benefit of indicating the existence of some complicity between the shape parameters of the water retention and hydraulic conductivity functions. The ideal case would be if the $p\beta$ -value could be individualized for each soil.

The scale parameter K_s is strongly related to soil structure. Among the different soil hydraulic characteristic parameters, the saturated hydraulic conductivity is the parameter which is the most influenced by effects such as macropores, stones, fissures, cracks, and other irregularities formed for various biological and mechanical reasons. Hence, it is the parameter which is the most difficult to predict. The models proposed in the literature either give estimations of the capillary conductivity value or are based on site- and soil-specific databases. The results should therefore be considered with caution when applied for field studies.

Mishra and Parker (1990) used the Mualem model (1976) with the van Genuchten water retention function (Equation 6.21) to obtain a closed-form expression of the saturated hydraulic conductivity:

$$K_s = c_1 \frac{[\theta_s - \theta_r]^{2.5}}{h_g^2} \quad (6.45)$$

where c_1 is a constant including the effects of fluid characteristics and the porous media geometric factor; it has a value of $108 \text{ cm}^3/\text{sec}$ when K_s is expressed in cm/sec ; h_g is the van Genuchten (1980) pressure scale parameter. The authors derived a similar predictive equation by the use of the Brooks and Corey (1964) water retention equation (Equation 6.20):

$$K_s = c_1 \frac{[\theta_s - \theta_r]^{2.5}}{h_{bc}^2} \left[\frac{\lambda}{1 + \lambda} \right]^2 \quad (6.46)$$

where λ and h_{bc} are the Brooks and Corey (1964) shape and scale parameters respectively. Ahuja et al. (1985) used the general Kozeny–Carman approach to determine the saturated hydraulic conductivity from the effective porosity ($\varepsilon - \theta_r$):

$$K_s = c_2 [\varepsilon - \theta_r]^{c_3} \quad (6.47)$$

where c_2 is equal to 1058 cm/h when K_s is expressed in cm/h ; and c_3 takes a value of 4 or 5.

Cosby et al. (1984) derived a statistical regression between the saturated hydraulic conductivity and the clay, silt, and sand fractions of soil (Table 6.1). In a similar way Rawls and Brakensiek (1989) presented a statistical model using particle-size distribution and porosity (Table 6.2).

6.2.7 Spatial Variability of Soil Water Properties

The difficulty of parametrization of soil moisture dynamics lies in the characterization and understanding of the different processes involved and the scale at which they take place: microscale, macroscale, and megascale. As underlined by Kabat et al. (1997), water transfer in the vadose zone is characterized by laminar flow with small mixing ratios, whereas atmospheric fluxes occur in the turbulent domain causing large mixing ratios, resulting in different characteristic spatial scales. There is an urgent need to characterize and incorporate the spatial variability into current modeling approaches. The use of distributed models can only represent explicitly heterogeneities of processes with a characteristic length scale larger than the model grid size. This type of approach still uses some lumping at the grid level, and there remains the problem of characterizing the variability at the subgrid level.

Water movement in the unsaturated zone is affected by intrinsic parameters such as soil characteristics and by external factors such as rainfall and management practices. The movement is thus characterized by a high spatial variability. It is important, concerning the concept of spatial variability, to separate the concept of modeling of the unsaturated flow process and the parametrization of the soil hydraulic characteristics. In addition to the obvious lack of theoretical knowledge of the behavior of the flow equation in the unsaturated zone across temporal and spatial scales, the nonlinearity of the flow equations adds also to the complexity of representing spatial variability. The validity of extrapolating concepts developed at the local scale to larger scale may be questioned. A second major problems arises for the model parametrization. Is there a physical meaning for a characteristic curve representing 1 km² grid cell?

As mentioned earlier (Section 6.2.4, Equations 6.20 to 6.26), characterizing soil properties require the determination of five unknown parameters: two shape parameters (i.e., m and η , or λ and η) and three scale parameters (θ_s , K_s and h_g or h_{bc}). The shape parameters as shown by Haverkamp and Reggiani (2002) are strongly linked to soil texture, while the scale parameters depend mainly on the soil structural properties. Textural properties are characterized by a smaller underlying variability than structural properties. This is mainly due to the fact that anthropogenic factors, such as management practices, have a much larger impact on structural properties than on textural properties. Thus, it would be expected to be able to capture and determine the shape parameters λ , m , and η (*static characteristics*) across different scales by the use of pedotransfer functions. However, the scale parameters θ_s and K_s (*dynamic characteristics*) will unlikely be determined from textural information, especially for K_s , which is a driving parameter for modeling surface and subsurface flow. It is furthermore indispensable to note that soil characteristics have a meaning for capillary flow and that this concept will not hold in field conditions where macropore and preferential flow may be present and prevail over capillary flow. Thus the use of pedotransfer functions for estimating the dynamic parameters are doomed to fail. Haverkamp et al. (1998a) proposed an alternate method to determine the scale parameters by coupling the soil characteristics with the unsaturated flow equation. This methodology which will be presented in more detail in a later section of this chapter consists in the upscaling of the transfer equation and the derivation of scale-invariant soil parameters.

Another approach for incorporating spatial variability is the determination of effective parameters which are supposed to be valid over a representative elementary volume (e.g., Woods et al., 1995). However, because of the non linearity between soil water fluxes and the soil properties, and the extrapolation of theories developed at the local scale to large scale, the validity of the concept of effective parameters can be questioned.

6.3 Conceptual Aspects of Unsaturated Soil Water Flow

For the following analysis, soil water movement is supposed to be isothermal and one-dimensional, whereas the influence of swelling and shrinking of the soil porous material is not taken into consideration. For a more detailed description of water movement in swelling soils we refer to work published by Smiles and Rosenthal (1968); Philip (1969a); Smiles (1974, 1995); Groenevelt and Parlange (1974); Sposito (1973, 1975a, 1975b, 1975c); and Gérard-Marchant et al. (1997). Moreover, the case of two-phase flow will not be addressed in this study. Under general field conditions, the effects due to air displacement can be

considered negligible because of the large differences in dynamic viscosity. Only in particular situations (such as flooding, storm rains, or stratified soil profiles) may air not be free to escape, resulting in an increased air pressure ahead of the wetting front and, hence, in a reduced infiltration rate (see also Peck, 1965a, 1965b; Brustkern and Morel-Seytoux, 1970; Phuc and Morel-Seytoux, 1972; Vachaud et al., 1973, 1974; Starr et al., 1978; Touma et al., 1984).

6.3.1 General Flow Equations

For 1D vertical flow the continuity equation takes the form:

$$\frac{\partial \theta}{\partial t} = -\frac{\partial q}{\partial z} \quad (6.48)$$

where θ is volumetric soil water content; q is soil water flux; z is depth taken positive downward; and t is time. Combined with the generalized Darcy's law (1856):

$$q = -K(\theta) \frac{\partial H}{\partial z} \quad (6.49)$$

the soil water transfer equation can be written as:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left[K(\theta) \left(\frac{\partial h}{\partial z} - 1 \right) \right] \quad (6.50)$$

where h is soil water pressure head relative to atmospheric pressure ($h \leq 0$); K is hydraulic conductivity as function of θ ; and H is hydraulic head defined as:

$$H = h(\theta) - z \quad (6.51)$$

For non-swelling soils, the hydraulic head (H) represents the energy of soil water per unit of weight at a given depth (z); the possible osmotic component which arises from the presence of solutes in the soil water is neglected (see also Section 6.2.3). Equation 6.50 can be expressed as a θ -dependent equation by introducing the concept of soil water diffusivity (Childs and Collis-George, 1950):

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left[D(\theta) \frac{\partial \theta}{\partial z} - K(\theta) \right] \quad (6.52)$$

where $D(\theta)$ is diffusivity defined by

$$D(\theta) = K(\theta) \frac{dh}{d\theta} \quad (6.53)$$

Equation 6.52 is generally known as the Fokker–Planck equation.

Similarly Equation 6.50 can be expressed as function of only soil water pressure head (h) by introducing the concept of specific capacity:

$$C(\theta) \frac{\partial h}{\partial t} = \frac{\partial}{\partial z} \left[K(\theta) \left(\frac{\partial h}{\partial z} - 1 \right) \right] \quad (6.54)$$

where C is specific capacity given by $C(\theta) = d\theta/dh$. Equation 6.54 referred to as the Richards (1931) equation, is the 1D, isothermal, unsaturated soil water transfer equation generally used in vadose zone hydrology, especially when coupled saturated and unsaturated flow problems are considered. The use of Equation 6.52 with volumetric water content (θ) as independent variable, without doubt

causes computational difficulties when applied for numerical simulation of water movement in regions close to saturation.

The solution of Equation 6.52 and Equation 6.54 subject to given initial and boundary conditions describes the evolution of the water content profiles $\theta(z, t)$ as a function of depth and time. The initial condition imposed on $\theta(z, t)$ is given by:

$$\theta(z, 0) = \theta_0(z) \quad (6.55)$$

where θ_0 is the initial water content value. The upper boundary condition on $\theta(z, t)$ is either the *Dirichlet* concentration condition:

$$h(0, t) = h_1(t) \quad \text{and/or} \quad \theta(0, t) = \theta_1(t) \quad (6.56)$$

or the *Neumann* flux condition:

$$\left[K - K \frac{\partial h}{\partial z} \right]_{z=0} = q_1(t) \quad (6.57)$$

where h_1 is the surface soil water pressure, θ_1 is the corresponding volumetric soil water content and q_1 is the flux at the soil surface. Both values of h_1 and q_1 may be positive, zero, or negative.

6.3.2 Infiltration

Infiltration concerns the physical process of water entry into the soil through the surface. It is governed by either the concentration type boundary condition (e.g., water ponding at the soil surface) or the flux type surface boundary condition (e.g., rainfall). For a nonuniform initial water content profile, $\theta_0(z)$, the 1D cumulative infiltration (I) expressed in volume per unit surface is defined by the integral of the flux at the soil surface:

$$I(t) = \int_0^t q_1(\bar{t}) d\bar{t} \quad (6.58)$$

For the particular case of infiltration under uniform initial conditions:

$$\theta(z, 0) = \theta_0, \quad t = 0 \text{ for } z \geq 0 \quad (6.59)$$

and constant surface boundary conditions:

$$\begin{aligned} \theta(0, t) &= \theta_1, \quad z = 0 \text{ for } t \geq 0 \\ h(0, t) &= h_1, \quad z = 0 \text{ for } t \geq 0 \end{aligned} \quad (6.60)$$

the cumulative infiltration Equation 6.58 takes the form:

$$I(t) = K_0 t + \int_0^{z_f} [\theta(z, t) - \theta_0] dz \quad (6.61)$$

where $z_f(t)$ is depth of the infiltration wetting front; and K_0 is the hydraulic conductivity at initial water content (θ_0). The constant water pressure value h_1 can be negative or positive equal to the ponded water depth (h_{surf}) imposed at the soil surface ($h_1 = h_{\text{surf}} \geq 0$).

Generally speaking, the time limits of cumulative infiltration are well defined:

$$\lim_{t \rightarrow 0} I(t) = 0 \quad \text{and} \quad \lim_{t \rightarrow \infty} I(t) = \infty \quad (6.62)$$

The infiltration rate, q_1 at the soil surface is defined as $q_1 = dI/dt$ with the time limits:

$$\lim_{t \rightarrow 0} q_1(t) = \infty \quad \text{and} \quad \lim_{t \rightarrow \infty} q_1(t) = K_1 \quad (6.63)$$

where K_1 is the hydraulic conductivity corresponding to the surface boundary condition $\theta = \theta_1$ and/or $h = h_1$; obviously, K_1 becomes equal to $K_1 = K_s$ for $\theta_1 = \theta_s$ and/or $h_1 \geq 0$.

More details on the empirical infiltration equations are given in Chapter 7.

6.4 Analytical Solutions of the Unsaturated Flow Equation

Although the solution of the Richards (and/or Fokker–Planck) equation under general initial and boundary conditions can only be obtained through numerical simulation, exact analytical solutions under idealized conditions exist. As most of the numerical codes are now available from reliable commercialised software packages (e.g., HYDRUS-2D) we rather prefer to explore in this section some aspects of the analytical solutions. Good summaries of most of the numerical problems involved in solving Equation 6.54 can be found in literature. Many different techniques are explored, for example, finite difference, finite element, and/or flux volume methods.

The mathematical difficulties associated with the analytical solutions for $\theta(z, t)$ and/or infiltration, can be best discussed through the initial and boundary conditions given by Equation 6.59 and Equation 6.60. The constant pressure head (h_1) can be chosen negative, zero, or positive. In this section we only consider the problem of constant pressure head infiltration. The flux condition is fully discussed in Chapter 7. The concept of *sorptivity* is addressed in some detail because it represents an important integral variable which links water retention and hydraulic conductivity characteristics. We then give a short discussion of two positive constant head infiltration equations required for the last section dealing with the spatial variability of water flow.

6.4.1 Constant Negative (or Zero) Pressure Head Condition at the Soil Surface

Different analytical solutions have been proposed in the literature (e.g., Philip, 1955, 1957a; Parlange, 1971b, 1975; Philip and Knight, 1974; Babu, 1976; Parlange et al., 1982; Broadbridge, 1990). A good summary can be found in Parlange et al. (1999).

6.4.1.1 Without Gravity Effects

In our discussion we first consider the case where gravity effects can be ignored (such as would be the case for horizontal infiltration). The water movement equation (Equation 6.52) is then reduced to:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z} \left[D(\theta) \frac{\partial \theta}{\partial z} \right] \quad (6.64)$$

subject to the conditions:

$$\begin{aligned} \theta(z, 0) &= \theta_0, & t = 0 \text{ for } z \geq 0 \\ \theta(0, t) &= \theta_1, & z = 0 \text{ for } t \geq 0 \end{aligned} \quad (6.65)$$

The partial differential equation (Equation 6.64) along with corresponding initial and boundary conditions can be reduced to an ordinary integral-differential equation by introducing the Boltzmann (1894) similarity variable χ_1 defined by $\chi_1(\theta) = z/t^{1/2}$:

$$\int_{\theta_0}^{\theta} \chi_1(\bar{\theta}) d\bar{\theta} = -2D(\theta) \frac{d\theta}{d\chi_1(\theta)} \quad (6.66)$$

subject to the condition:

$$\theta = \theta_1 \quad \text{for } \chi_1(\theta_1) = 0 \quad (6.67)$$

Equation 6.66 and Equation 6.67 are generally known as the similarity equation of Bruce and Klute (1956). It shows that there exists a fundamental dynamic similarity between z and t associated with the solution of the diffusivity equation (Equation 6.66); it reveals that the advance of the normalized wetting front is proportional to $t^{1/2}$.

Integrating the Boltzmann transform from θ_1 to θ_0 , yields the cumulative infiltration equation:

$$I(t) = S_1(\theta_1, \theta_0) \sqrt{t} \quad (6.68)$$

where $S_1(\theta_1, \theta_0)$ is the sorptivity defined by:

$$S_1(\theta_1, \theta_0) = \int_{\theta_0}^{\theta_1} \chi_1(\theta) d\theta \quad (6.69)$$

The sorptivity S_1 , which is clearly specific for the initial (θ_0) and boundary (θ_1) conditions encountered during each infiltration event, characterizes the ability of the soil to absorb water in the absence of gravity. It was initially presented by Green and Ampt (1911) and later coined by Philip (1957b).

Many solutions of Equation 6.66 have been proposed over time. One of the first reported in the literature is that of Crank and Henry (1949). However, their iterative method suffered from slow convergence and was often found slightly erroneous in the region close to initial water content θ_0 . To overcome this problem Philip (1955) proposed a modified iterative procedure with the value of χ_1 close to θ_0 truncated at a fixed value calculated from an analytical inverse “erfc”-function. Even though the procedure of Philip improved the solution of Crank and Henry (1949) with respect to the convergence criterion, it still remained rather imprecise close to θ_0 , and today this method is considered somewhat tedious and rather imprecise for the calculation of sorptivity.

A different solution of Equation 6.66 was proposed by Parlange (1971a) who started with a slightly modified version of Equation 6.64:

$$\frac{\partial z}{\partial t} + \frac{\partial}{\partial \theta} \left[D(\theta) \frac{\partial \theta}{\partial z} \right] = 0 \quad (6.70)$$

Integration of Equation 6.70 is carried out iteratively in two steps yielding the relation for $\chi_1(\theta)$ and hence $z(\theta, t)$ of the form:

$$\chi_1(\theta) = \frac{z(\theta, t)}{\sqrt{t}} = \int_{\theta}^{\theta_1} \frac{D(\bar{\theta})}{F_{PA}(\bar{\theta})} d\bar{\theta} \quad (6.71)$$

where $F_{PA}(\theta)$ is given by:

$$F_{PA}(\bar{\theta}) = \frac{\int_{\theta_0}^{\bar{\theta}} \left[\int_{\hat{\theta}}^{\theta_1} D(\tilde{\theta}) d\tilde{\theta} \right] d\hat{\theta}}{\left[2 \int_{\theta_0}^{\theta_1} [\theta - \theta_0] D(\theta) d\theta \right]^{1/2}} \quad (6.72)$$

Parameters $\bar{\theta}$, $\hat{\theta}$, and $\tilde{\theta}$ are simply the integral variables. Equation 6.71 gives the moisture content profile $\chi_1(\theta)$ directly for any soil once $D(\theta)$ is known. Obviously, the approach can easily be extended to the case where gravity is not negligible (Parlange, 1971b).

In a later article Philip (1973) used this iterative concept by reformulating the F -function as:

$$F(\theta) = \frac{q(z, t)}{q_1(t)} = \frac{\int_{\theta_0}^{\theta} \chi_1(\bar{\theta}) d\bar{\theta}}{\int_{\theta_0}^{\theta_1} \chi_1(\theta) d\theta} \quad (6.73)$$

where $F(\theta)$ was referred to as the *flux-concentration* relation. Integration of Equation 6.70 after substitution of Equation 6.73 yields the well-known equation of $\chi_1(\theta)$:

$$\chi_1(\theta) = \frac{2}{S_1(\theta_1, \theta_0)} \int_{\theta}^{\theta_1} \frac{D(\bar{\theta})}{F(\bar{\theta})} d\bar{\theta} \quad (6.74)$$

The substitution of Equation 6.74 into Equation 6.69 allows us to redefine the sorptivity expression as:

$$S_1^2(\theta_1, \theta_0) = 2 \int_{\theta_0}^{\theta_1} \frac{[\theta - \theta_0] D(\theta)}{F(\theta)} d\theta \quad (6.75)$$

Probably the best understanding of the structure of any solution of Equation 6.66 can be based on the analytical expansion technique of Heaslet-Alksne (1961) which was applied by Parlange et al. (1992). A good compromise for the F -function which balances accuracy with simplicity (Elrick and Robin, 1981) was given by Parlange (1975):

$$F(\theta) = \frac{2[\theta - \theta_0]}{[\theta_1 + \theta - 2\theta_0]} \quad (6.76)$$

resulting in the sorptivity equation used for many studies (e.g., Ross et al., 1996):

$$S_1^2(\theta_1, \theta_0) = \int_{\theta_0}^{\theta_1} [\theta_1 + \theta - 2\theta_0] D(\theta) d\theta \quad (6.77)$$

6.4.1.2 With Gravity Effects

For the case where the gravity effects cannot be neglected the analytical solutions are mostly expressed through the Fokker–Planck equation (Equation 6.52). The infiltration solution of Philip (1957a, 1957b)

which originally was developed for the surface boundary condition $h_1 = 0$ and $\theta_1 = \theta_s$, is written in terms of a series expansion in powers of $t^{1/2}$ as:

$$z(\theta, t) = \chi_1(\theta)t^{1/2} + \chi_2(\theta)t + \chi_3(\theta)t^{3/2} + \dots \quad (6.78)$$

where the first term, $\chi_1(\theta)$ embodies the influence of the capillary forces on the flow process, and the following terms, for example, $\chi_2(\theta)$ and $\chi_3(\theta)$, reflect the gravity effect on infiltration. Integration of Equation 6.78 gives the cumulative infiltration equation, $I(t)$:

$$I(t) = S_1(\theta_1, \theta_0)t^{1/2} + [K_0 + S_2(\theta_1, \theta_0)]t + O(t^{3/2}) + \dots \quad (6.79)$$

where the definition of $S_1(\theta_1, \theta_0)$ is given above by Equation 6.69 and:

$$S_2(\theta_1, \theta_0) = \int_{\theta_0}^{\theta_1} \chi_2(\theta)d\theta \quad (6.80)$$

Like the sorptivity ($S_1(\theta_1, \theta_0)$) the second term ($S_2(\theta_1, \theta_0)$) is specific for the initial and boundary conditions encountered during each particular infiltration event. The third and higher terms of Equation 6.79 can easily be calculated by transforming the time series expansion into a recurrence series as a function of the first and second term (Haverkamp et al., 1990).

In theory, the Philip infiltration equation is physically based which makes it suitable for the simulation (*a posteriori*) of infiltration events once the soil characteristics are fully known. However, in practice, when the solution is used for prediction purposes (*a priori*) some ambiguity exists over the correct interpretation of Equation 6.79:

1. Though an accurate and simple estimation of sorptivity has been developed by Parlange (1975) in the form of Equation 6.77, no simple approximation exists for the second integral term. Generally, the value of $S_2(\theta_1, \theta_0)$ is associated to a constant A_2 calculated from curve fitting with:

$$I(t) = A_1\sqrt{t} + [K_0 + A_2]t \quad (6.81)$$

over experimental cumulative infiltration data where A_2 is confined over the interval (Youngs, 1968; Philip, 1969b; Talsma and Parlange, 1972):

$$\frac{K_1 - K_0}{3} \leq A_2 \leq 2\frac{K_1 - K_0}{3} \quad (6.82)$$

As Equation 6.81 neglects deliberately all higher order terms ($O(t^{3/2})$) of the original time series expansion (Equation 6.79), it is evident that the optimized values of A_1 and A_2 reflect to some extent this truncation effect. Consequently, A_1 and A_2 are just specific ad hoc constants which become rather delicate to compare with the physically defined integral parameters $S_1(\theta_1, \theta_0)$ and $S_2(\theta_1, \theta_0)$ (Haverkamp et al., 1988).

2. Then, the definitions of $S_1(\theta_1, \theta_0)$ and $S_2(\theta_1, \theta_0)$ were originally developed for the case of infiltration with negative or zero head surface boundary condition ($h_1 \leq 0$ and $\theta_1 \leq \theta_s$). For the case of positive head infiltration ($h_1 \geq 0$ and $\theta_1 = \theta_s$) the integrals S_1 and S_2 have to be reformulated. This can easily be done for the sorptivity definition of S_1 :

$$S_1^2(h_{\text{surf}}, h_0) = S_1^2(\theta_s, \theta_0) + 2K_s h_{\text{surf}}[\theta_s - \theta_0] \quad (6.83)$$

where h_0 stands for the initial soil water pressure $h(\theta_0)$ and h_{surf} is the ponded water depth imposed at the soil surface. However, for the second integral term (S_2) it is far more difficult to adjust Equation 6.80.

3. Finally, the main problem for the application of the Philip (1957a) solution lies in the fact that the time series of Equation 6.78 becomes divergent for large times no matter how many terms are developed. Thus, the solution is only valid for a limited time range. The time limit is mostly set at t_{grav} :

$$t_{\text{grav}} = \left[\frac{S_1(\theta_s, \theta_0)}{K_s - K_0} \right]^2 \quad (6.84)$$

a time for which the gravity forces are supposed to become predominant over the capillary forces during the infiltration process (Philip, 1969b).

To overcome this time limit problem Parlange et al. (1982) developed a quasi-exact infiltration solution of the Fokker–Planck equation (Equation 6.52) valid over the entire time range $t \in [0, \infty]$. This work made use of a special double integration procedure of the water transfer equation. In later studies by Parlange et al. (1985a) and Haverkamp et al. (1990), this infiltration solution which originally was developed for a zero or negative surface head condition, was extended to a positive head boundary condition ($h_1 \geq 0$). For the sake of brevity, we will report more details on this solution in Section 6.4.2 dealing with positive head infiltration. To transform the positive head solution to a negative head solution the value of h_{surf} has simply to be set equal to zero and θ_s has to be replaced by θ_1 when necessary.

6.4.2 Constant Positive Pressure Head Condition at the Soil Surface

Before discussing the quasi-exact positive head solution of Parlange et al. (1985a), it is preferred to address the somewhat simpler infiltration equation of Green and Ampt (1911); the latter solution which is widely used for hydrologic studies will be used in Section 6.5 to illustrate the scaling principles.

The hypotheses underlying the Green and Ampt approach for positive head infiltration assume a nominal wetting front in the form of a step function with a one-point hydraulic conductivity function ($K(\theta) = K_s$) behind the wetting front and a constant driving pressure ($h_{\text{surf}} - h_f$) pulling the wetting front downward through the unsaturated zone; h_f is a constant equivalent water pressure head at the wetting front. The corresponding water retention curve takes the form of a step function with $\theta = \theta_0$ for $h \leq h_f$ and $\theta = \theta_s$ for $h_f \leq h \leq 0$. In the original infiltration equation of Green and Ampt (1911), the initial value of hydraulic conductivity (K_0) was considered equal to zero. However, for hydrologic model studies this condition is quite often not verified. Hence, we choose to present here the generalized Green and Ampt infiltration equation with $K_0 \neq 0$ (e.g., Swartzendruber, 1987; Ross et al., 1996):

$$I(t) = K_s t + \frac{[\theta_s - \theta_0][h_{\text{surf}} - h_f(\theta_s, \theta_0)]K_s}{[K_s - K_0]} \ln \left\{ 1 + \frac{[I(t) - K_0 t][K_s - K_0]}{[\theta_s - \theta_0][h_{\text{surf}} - h_f(\theta_s, \theta_0)]K_s} \right\} \quad (6.85)$$

The corresponding infiltration flux (q_1) at the soil surface can be solved by:

$$t = \frac{[\theta_s - \theta_0][h_{\text{surf}} - h_f(\theta_s, \theta_0)]K_s}{[K_s - K_0]^2} \left\{ \frac{K_s - K_0}{q_1 - K_s} - \ln \left[1 + \frac{K_s - K_0}{q_1 - K_s} \right] \right\} \quad (6.86)$$

Note that Equation 6.85 and Equation 6.86 take the form of the classical Green and Ampt equations given in Chapter 7 (Equation 7.10) when K_0 is set equal to zero. When nonpositive constant head infiltration is involved ($h_1 \leq 0$), Equation 6.85 and Equation 6.86 can be applied equally well simply by replacing the values of θ_s and K_s by θ_1 and K_1 and setting h_{surf} equal to zero. Further details on the derivation of the Green and Ampt equation can be found in Chapter 7.

Although Equation 6.85 and Equation 6.86 are exact solutions of the Richards equation (Equation 6.54) for soils that correspond to the Green and Ampt configuration (hereafter referred to as “Green and Ampt”

soils), these conditions are seldom met under field conditions. For that reason, emphasis is given in the literature to relating the value of h_f in some theoretical way to more realistic soil hydraulic properties (e.g., Bouwer, 1964; Mein and Larson, 1973; Neuman, 1976). Even though the value of h_f changes slightly with time during infiltration (Haverkamp et al., 1988), a good estimation of h_f can be obtained from its short time limit (Neuman, 1976) derived from the second-order sorptivity definition as given by Parlange (1975):

$$h_f(\theta_1, \theta_0) = \frac{1}{2} \int_{h(\theta_1)}^{h(\theta_0)} \left[\frac{\theta_1 + \theta(h) - 2\theta_0}{\theta_1 - \theta_0} \right] \frac{K(h)}{K_1} dh \quad (6.87)$$

Parameter $h_f(\theta_s, 0)$ must be seen as the pressure scale parameter of the Green and Ampt water retention curve. Equation 6.87 clearly shows the dependence of $h_f(\theta_1, \theta_0)$ on initial conditions (θ_0) and boundary conditions (θ_1) encountered during infiltration; hence, all estimations that relate $h_f(\theta_1, \theta_0)$ in a statistical way to purely textural soil data (such as used by most PTFs [e.g., Rawls and Brakensiek, 1983]), lead necessarily to erroneous results.

As the integral parameter $h_f(\theta_1, \theta_0)$ is properly defined only for Green and Ampt soils, it is preferable to use the sorptivity concept instead (Equation 6.77 and Equation 6.83) when dealing with general field soils. For a negative head surface boundary condition ($h_1 \leq 0$) the relation between h_f and sorptivity is given by:

$$S_1^2(\theta_1, \theta_0) = 2K_s[\theta_1 - \theta_0]h_f(\theta_1, \theta_0) \quad (6.88)$$

and for the positive head surface boundary condition ($h_{\text{surf}} = h_1 > 0$) by:

$$S_1^2(h_{\text{surf}}, \theta_0) = 2K_s[h_{\text{surf}} - h_f(\theta_s, \theta_0)][\theta_s - \theta_0] \quad (6.89)$$

Substitution of Equation 6.88 and Equation 6.89 into Equation 6.85 and Equation 6.86 allows the Green and Ampt infiltration equation to be expressed in terms of sorptivity.

Parlange et al. (1982) developed a quasi-exact infiltration solution of the Fokker–Planck equation (Equation 6.52) valid over the entire time range $t \in [0, \infty]$. This work was concerned with a zero or negative surface head condition ($h_1 \leq 0$). In later studies by Parlange et al. (1985a) and Haverkamp et al. (1990), this infiltration solution was extended to a positive head boundary condition ($h_1 = h_{\text{surf}} \geq 0$). Without going in to too much detail we will report here a concise description of the approach.

Considering the case of infiltration into a soil at a uniform initial soil water pressure, $h_0 = h(\theta_0)$ (Equation 6.59) from a surface boundary source at either a constant negative head ($h_1 \leq 0$) or a constant positive head ($h_1 = h_{\text{surf}} \geq 0$), double integration of Equation 6.54 allows the expression of the water content profiles, $z(\theta, t)$, in the rigorous form:

$$z(\theta, t) = z_s(t) + \int_{\theta}^{\theta_s} \frac{D(\bar{\theta})}{F(\bar{\theta}, t)[q_1(t) - K_0] - [K(\bar{\theta}) - K_0]} d\bar{\theta} \quad (6.90)$$

where $\bar{\theta}$ is the integration variable; z_s is the depth of soil considered to be saturated when $h_1 \geq 0$; and $F(\theta, t)$ is the flux concentration relation defined for diffusivity and gravity driven infiltration (see also Equation 6.73). Obviously, $z_s = 0$ and $\theta_s = \theta_1$ when $h_1 \leq 0$. Integrating z by parts from θ_0 to θ_s yields then:

$$[I(t) - K_0 t] = h_{\text{surf}} \frac{[\theta_s - \theta_0]K_s}{q_1(t) - K_s} + \int_{\theta_0}^{\theta_s} \frac{[\theta - \theta_0]D(\theta)}{F(\theta, t)[q_1(t) - K_0] - [K(\theta) - K_0]} d\theta \quad (6.91)$$

For the integration of Equation 6.91, Parlange et al., (1982) introduce an integral soil parameter β expressed as a function of conductivity and diffusivity. The relation was later slightly generalized by Haverkamp et al., (1990) to:

$$\frac{[K(\theta) - K_0]}{[K_s - K_0]} = f(\theta) \left[1 - \frac{2\beta(\theta_s, \theta_0)}{S_1^2(\theta_s, \theta_0)} \int_{\theta}^{\theta_s} \frac{[\bar{\theta} - \theta_0]}{f(\bar{\theta})} D(\bar{\theta}) d\bar{\theta} \right] \quad (6.92)$$

where $f(\theta)$ is the purely diffusivity-driven flux-concentration relation, $F(\theta, 0)$, given by Equation 6.76. Obviously β is defined over the interval $0 \leq \beta \leq 1$ and is function of the soil type and governing initial and boundary conditions. The lower limit $\beta = 0$ corresponds to the Green and Ampt type of soil in which $dK/d\theta$ increases much less rapidly with θ than the diffusivity, whereas the upper limit $\beta = 1$ corresponds to soils in which $dK/d\theta$ and the diffusivity behave similarly. Following Equation 6.92, parameter β is defined as function of volumetric water content ($\theta_0 \leq \theta \leq \theta_s$); as a result, β is only influenced by the surface boundary condition when $\theta_1 \leq \theta_s$ or $h_1 \leq 0$. Ross et al. (1996) showed that β is slightly affected by changes in the surface boundary condition θ_1 , especially when θ_1 stays close to θ_s ($\theta_1 \geq 0.75\theta_s$). The effect of the changing initial condition θ_0 is even more straightforward: obviously, β equals 1 for $\theta_0 = 0$ (Equation 6.92); it remains close to 1 for $\theta_0 \leq 0.25\theta_s$ and decreases then substantially at the initial water content $\theta_0 = 0.25\theta_s$ (Ross et al., 1996).

The use of Equation 6.92 allows the solution of the integral term of Equation 6.91 resulting in the following cumulative infiltration equation (Haverkamp et al., 1990):

$$I(q_1, t) = K_0 t + h_{\text{surf}} [\theta_s - \theta_0] \frac{K_s}{q_1 - K_s} + \frac{S_1^2(\theta_s, \theta_0)}{2[K_s - K_0]} \ln \left[1 + \frac{K_s - K_0}{q_1 - K_s} \right] \quad (6.93)$$

However, the cumulative infiltration (I) can only be calculated from Equation 6.93 once the corresponding surface infiltration flux (q_1) is known. The derivation in time of Equation 6.93 yields the necessary flux/time equation, $q_1(t)$:

$$2[K_s - K_0]t = \frac{2h_{\text{surf}} K_s [\theta_s - \theta_0]}{q_1 - K_s} + \frac{S_1^2(\theta_s, \theta_0)}{\beta[1 - \beta][K_s - K_0]} \ln \left[1 + \beta \frac{K_s - K_0}{q_1 - K_s} \right] - \frac{S_1^2(\theta_s, \theta_0) + 2[1 - \beta]h_{\text{surf}} K_s [\theta_s - \theta_0]}{[1 - \beta][K_s - K_0]} \ln \left[1 + \frac{K_s - K_0}{q_1 - K_s} \right] \quad (6.94)$$

The infiltration solution given by the combined use of Equation 6.93 and Equation 6.94 is valid over the entire time range $t \in [0, \infty]$ and is applicable for both positive and negative head surface boundary conditions. Although this solution is proven to be extremely precise, it is also admittedly cumbersome to apply. For that reason Barry et al. (1995) presented an extension of foregoing infiltration solution that improved the applicability of the approach by transforming the implicit combination of Equation 6.93 and Equation 6.94 into an explicit infiltration equation without affecting the precision.

6.5 Scaling Principles

In addition to the obvious lack of theoretical knowledge of the behavior of the flow equation in the unsaturated zone across temporal and spatial scales, the nonlinearity of the flow equations adds also to the complexity of representing spatial variability. There exists an acute disparity between the current theoretical knowledge, characterization, and measurement of water movement in the vadose zone and the characteristic spatial scales for which surface flux models such as SVATs and GCMs are trying to make predictions.

Hence, there is an urgent need to assess the adequacy and usefulness of scale matching between the different flow phenomena involved in the interactions between atmosphere, land surface, vadose zone, and aquifer. The correct specification of soil hydrological processes at small or large scales is directly conditioned by the possibility of parameterizing soil water fluxes for the scales compatible with the grid size of field scales involved. The efficiency of soil characteristic parameterization at different scales depends on the clear definition of the functional relationships and parameters to be measured. The use of actual technologies to characterize surface fluxes gives only local information and provides only an indication of the underlying spatial variability of the different processes. For these multiple reasons, the input parameters used in different modeling approaches bear little resemblance to those measured. Spatial variability can be incorporated by the determination of effective parameters which are supposed to be valid over an REV (e.g., Woods et al., 1995). Some of these methods are based on the use of PTFs that employ textural soil properties as principal input data. As mentioned earlier (Section 6.2.7), textural properties are characterized by a smaller underlying variability than the structural properties. The soil characteristic shape parameters (such as the water retention shape parameter m and the hydraulic conductivity shape parameter η , Equation 6.21 and Equation 6.25), which are strongly related to soil textural properties, could be determined from PTFs. However, the description of water flow in the unsaturated zone requires not just the knowledge of the shape parameters; the information about the soil hydraulic scale parameters (such as the water content scale parameter θ_s , the water pressure scale parameter h_g , and the hydraulic conductivity scale parameter K_s , is even more important. The scale parameters that imbed the dynamical properties of soils cannot be determined just from soil textural properties. Any attempt to determine the soil scale parameters at different spatial grid scales has to incorporate, in one way or another, the flow behavior of the soil at the chosen grid scale. The nonlinearity between soil water fluxes and soil properties, and the extrapolation of theories developed at the local scale to large scales introduce inherent limitations. Hence, methods that simply try to upscale the soil hydraulic characteristic scale parameters and then describe the flow behavior with those aggregated soil characteristics do not take into account these nonlinearities and will generally fail to predict the unsaturated flow behavior in a correct way. As the knowledge of the unsaturated flow behavior of a soil is of major importance for vadose zone hydrology, rather than the knowledge of the hydraulic soil characteristics (which are nothing else than intermediate mathematical functional relationships used to calculate the flow behavior), it would be more obvious to upscale the transfer equation itself.

Basically, two categories of scaling techniques can be distinguished: physically based techniques such as *dimensional* and *inspectional* analyses, and empirically based techniques such as the *functional normalization* technique. A complete discussion of the different methods is given by Langhaar (1951) and Kline (1965). As stated by Tillotson and Nielsen (1984), the former category allows one “to convert a set of physically interrelated dimensional quantities into a set of nondimensional quantities which conserve the original interrelationship for a system that manifests geometric, kinematic or dynamic similarity.” The scaling factors obtained through such dimensional analysis have definite physical meaning in terms of the system being studied. On the other hand, the second category (i.e., functional normalization analyses) derives scaling factors relating properties of the two systems in some empirical way. Most of these methods (e.g., Miller and Miller 1955a, 1955b, 1956; Reichardt et al., 1972; Warrick et al., 1977; Simmons et al., 1979; Warrick and Nielsen, 1980; Nielsen et al., 1983) attempt to combine sets of soil water characteristic curves into one single reference curve on the base of simple geometric similarity and, hence, fail *a priori* to scale the vadose zone flow behavior in a general way. For the sake of generality, it is evident that the first category of dimensional and inspectional analyses is the most desirable and appropriate for tackling the problem of scaling.

6.5.1 Scaling Infiltration

Dynamical analysis rests on the fundamental postulate that the *invariance* of a physical law under a series of scale transformations implies the invariance of all consequences of the law under the same transformations (Birkhoff, 1960). As the solution of the cumulative infiltration problem is simply a consequence of the

flow equation for a particular set of initial and boundary conditions, this postulate guarantees that the scaling factors obtained for the cumulative infiltration law apply equally for the flow equation.

The following set of scale transformations is chosen:

$$\begin{aligned} z &= \alpha_z z^*, \quad t = \alpha_t t^*, \quad \theta = \alpha_\theta \theta^* \\ h &= \alpha_h h^*, \quad K = \alpha_K K^*, \quad C = \alpha_C C^* \end{aligned} \quad (6.95)$$

where α_z , α_t , α_θ , α_h , α_K , and $\alpha_C = \alpha_\theta/\alpha_h$ are constant parameters which define, respectively, the non-dimensional variables z^* , t^* , θ^* , h^* , K^* , and C^* . Substitution of these scaling factors into Equations 6.54 to 6.57 allows us to express the flow equation (e.g., Richards' equation) as a non-dimensional boundary-value problem. The particular values of the scaling factors α should reflect the effect of the initial and boundary conditions on the values of the independent variable.

The first step of inspectional analysis is to select a quasi-exact solution of the infiltration problem. The generalized positive head infiltration solution (Equation 6.93 and Equation 6.94) of Parlange et al. (1985a) is a quasi-exact 1D analytical solution that is valid for any soil type and over the complete time range: $t \in [0, \infty]$. The obvious choice would be to apply the scaling analysis to this infiltration solution (see Haverkamp et al., 1998a). However, for the sake of brevity we choose here to illustrate the principles of the dynamical scaling analysis on the Green and Ampt (1911) solution (Equation 6.85 and Equation 6.86) subject to initial and boundary conditions given by Equation 6.59 and Equation 6.60 with $h_1 = h_{\text{surf}} > 0$. Even though it is perhaps the least realistic infiltration equation among the many different analytical solutions of 1D infiltration presented in the literature, it is still an exact solution of the flow equation for the particular case where soils are considered to behave like Green and Ampt soils. The scaling factors which will be derived for the Green and Ampt equations (Equation 6.85 and Equation 6.86) apply equally well for the generalized infiltration solution of Parlange et al. (1985a) (Haverkamp et al., 1998a).

The second step of inspectional analysis (Sposito and Jury, 1985) consists of trying to define the scaling factors α of Equation 6.95. To do so, the infiltration solution represented by Equation 6.85 and Equation 6.86 is expressed in a dimensionless form through the use of the following dimensionless variables:

$$[I - K_0 t] = \frac{S_1^2(h_{\text{surf}}, \theta_0)}{c_p [K_s - K_0]} \Delta I^* \quad (6.96)$$

and

$$t = \frac{S_1^2(h_{\text{surf}}, \theta_0)}{c_p [K_s - K_0]^2} t^* \quad (6.97)$$

where ΔI^* is the dimensionless net cumulative infiltration; and c_p represents a proportionality constant that depends on the functional relationships chosen to describe the soil hydraulic characteristics. For the case of the Green and Ampt configuration where the soil characteristics are simply defined as functions of the soil structure-dependent scale parameters θ_s , h_f , and K_s , the value of c_p is equal to 2. From Equation 6.96 and Equation 6.97, the dimensionless infiltration flux at the soil surface is defined as:

$$\Delta q_1^* = \frac{d\Delta I^*}{dt^*} = \frac{q_1 - K_0}{K_s - K_0} \quad (6.98)$$

Substitution of Equations 6.96 to 6.98 into Equation 6.85 and Equation 6.86 allows us to express the Green and Ampt infiltration solution in the following dimensionless form:

$$\Delta I^* = t^* + \frac{c_p}{2} \ln \left[1 + \frac{2}{c_p} \Delta I^* \right] \quad (6.99)$$

and

$$\frac{2}{c_p} t^* = \frac{1}{\Delta q_1^* - 1} - \ln \left[1 + \frac{1}{\Delta q_1^* - 1} \right] \quad (6.100)$$

The simultaneous use of Equation 6.99 and Equation 6.100 reduces the infiltration problem to a dimensionless boundary-value problem valid for all soil types (obviously, still in the context of the Green and Ampt concept), initial and boundary conditions. This dimensionless solution allows the straightforward determination of the specific scaling factors for cumulative infiltration (α_I) and infiltration rate (α_q). Choosing the scaling factors α_I and α_q in a similar way to the general scale transformations defined previously for Equation 6.95:

$$[I - K_0 t] = \alpha_I \Delta I^* \quad \text{and} \quad [q_1 - K_0] = \alpha_q \Delta q_1^* \quad (6.101)$$

the scaling factors α_I and α_t can directly be calculated from Equation 6.96 and Equation 6.97:

$$\alpha_I = \frac{S_1^2(h_{\text{surf}}, \theta_0)}{c_p [K_s - K_0]} \quad (6.102)$$

and

$$\alpha_t = \frac{S_1^2(h_{\text{surf}}, \theta_0)}{c_p [K_s - K_0]^2} \quad (6.103)$$

The infiltration rate scaling factor α_q can then be determined from Equation 6.98:

$$\alpha_q = \frac{\alpha_I}{\alpha_t} = [K_s - K_0] \quad (6.104)$$

The key point illustrated by foregoing analysis is that for any Green and Ampt soil the infiltration behavior (cumulative and infiltration flux) is fully determined by only two scaling factors: α_I (or α_q) and α_t . Both parameters embody the effect of soil type, initial and boundary conditions. The dimensionless invariant cumulative infiltration curve ($\Delta I^*(t^*)$) fixes the only *dynamical similarity class* for which the physical system can be said to be macroscopically similar.

So far, the scaling factors α_I and α_q still exhibit the specific character related to the type of flow problem analyzed (cumulative constant head infiltration). To bypass this specificity it is necessary to go down one step in the hierarchy of the water movement problematic by establishing the set of basic scaling factors that reduce the Richards' equation ($\theta(z, t)$) rather than those reduce the cumulative infiltration equation $I(t)$. This can be pursued by decomposing the specific infiltration scaling factors α_I and α_q into the set of scaling factors α_θ , α_h , α_K , and α_z . The determination of the conductivity scaling factor α_K is straightforward:

$$\alpha_K = \alpha_q = [K_s - K_0] \quad (6.105)$$

The introduction of the scaling factors α_t and α_K into the Richards' equation (Equation 6.54) gives the identities:

$$\alpha_h = \alpha_z \quad \text{and} \quad \alpha_I = \alpha_\theta \alpha_h \quad (6.106)$$

By choosing the definition for the scaling factor α_θ as:

$$\alpha_\theta = [\theta_s - \theta_0] \quad (6.107)$$

the pressure scaling factor (α_h) and thus the space scaling factor (α_z) are defined by:

$$\alpha_h = \alpha_z = \frac{S_1^2(h_{\text{surf}}, \theta_0)}{c_p[\theta_s - \theta_0][K_s - K_0]} \quad (6.108)$$

As the time and space scaling factors (i.e., α_t and α_z) are fully determined by the soil scaling factors α_θ , α_h , and α_K , the soil water transfer equation can be transformed simply into a non-dimensional form by the use of only three scaling factors; these factors take into account the effect of soil type, initial and boundary conditions giving the dimensionless form of the Richards' equation (Equation 6.54) the flexibility to encompass the water flow behavior of diverse physical systems through the adjustment of experimentally controllable parameters.

To make this inspectional analysis of the water transfer and infiltration equation useful for practical application, the soil scale factors should be expressed in terms of the classically used soil characteristic parameters contained in the expressions of $h(\theta)$ and $K(\theta)$ such as Equation 6.21 and Equation 6.25. To do so, the scaling factors α_θ , α_h , and α_K have to be stripped of initial and boundary condition effects. Letting λ stand for the fraction of α , which is purely related to the soil characteristic, the different soil scaling factors can be redefined as functions of the governing surface boundary condition ($h_1 = h_{\text{surf}}$):

$$\alpha_\theta = \lambda_\theta \left\{ \frac{\theta_s - \theta_0}{\theta_s} \right\} \quad \text{with } \lambda_\theta = \theta_s \quad (6.109)$$

$$\alpha_K = \lambda_K \left\{ \frac{K_s - K_0}{K_s} \right\} \quad \text{with } \lambda_K = K_s \quad (6.110)$$

and

$$\alpha_h = \lambda_h \left\{ \frac{S_1^2(h_{\text{surf}}, 0)}{S_1^2(\theta_s, 0)} \right\} \left\{ \frac{\theta_s}{\theta_s - \theta_0} \frac{K_s}{K_s - K_0} \frac{S_1^2(h_{\text{surf}}, \theta_0)}{S_1^2(h_{\text{surf}}, 0)} \right\} \quad (6.111)$$

where

$$\lambda_h = \frac{S_1^2(\theta_s, 0)}{c_p \theta_s K_s} \quad (6.112)$$

For the definitions given above, the residual water content θ_r is chosen equal to zero (Kool et al., 1987). For the case of positive head infiltration, the effect of the surface boundary condition enters only through the definition of the pressure scaling factor α_h . The second and third factors on the right-hand side of Equation 6.111 represent, respectively, the correction for the surface boundary condition effects and the initial condition effects.

Although the different sorptivity ratios which enter in the scaling factor α_h (Equation 6.111) are well-defined by Equation 6.77 and Equation 6.83, it is preferable to simplify the definitions of α_h to a maximum by expressing the sorptivity ratios in terms of the scaling factors α_K and α_θ . A precise estimation of the sorptivity ratio $S_1^2(\theta_s, \theta_0)/S_1^2(\theta_s, 0)$ is given by:

$$\frac{S_1^2(\theta_s, \theta_0)}{S_1^2(\theta_s, 0)} \cong \frac{\theta_s - \theta_0}{\theta_s} \frac{K_s - K_0}{K_s} \quad (6.113)$$

Using Equation 6.83 and Equation 6.113, the expression for the positive head pressure scale parameter (α_h) can be simplified considerably:

$$\alpha_h \cong \lambda_h + \frac{2}{c_p} \frac{\lambda_K}{\alpha_K} h_{\text{surf}} \quad (6.114)$$

The foregoing equations (Equation 6.109 to Equation 6.114) are valid not only for the Green and Ampt (1911) infiltration solution (Equation 6.85 and Equation 6.86), but for the generalized analytical infiltration solution of Parlange et al. (1985a), (Equation 6.93 and Equation 6.94) as well. For the particular case of Green and Ampt soils, the scaling factors α_h and λ_h take the form:

$$\alpha_h = \lambda_h + \frac{K_s}{K_s - K_0} h_{\text{surf}} \quad \text{with } \lambda_h = -h_f \quad (6.115)$$

where h_f is taken as a negative pressure head value.

The essence of this example on the Green and Ampt infiltration equation is that there exists a unique dynamical similarity in the behavior of unsaturated soil water movement in Green and Ampt soils when governed by the Richards' equation. The infiltration behavior is defined by an invariant curve. However, when the scaling analysis is applied on the generalized constant head infiltration solution (Equation 6.93 and Equation 6.94) there exists, theoretically, no unique dynamical similarity in the soil water behavior (Haverkamp et al., 1998a). Instead there is a multitude of dynamical similarity classes depending on the combination of soil type, initial and boundary conditions. In its most general form, the positive or negative head infiltration behavior is defined by three infiltration scaling factors embodying the effect of soil type, initial and boundary conditions. However, the non-uniqueness of the different similarity classes was found to be very small implying that for practical purposes the hypothesis of unique dynamical similarity can be applied once the Green and Ampt equation is adapted to more general field conditions.

The purely soil-related scaling factors λ_θ , λ_h , and λ_K represent the soil characteristic scale parameters used by the soil hydraulic characteristic curves such as Equations 6.20, 6.21, 6.25, and 6.26. Considering the water retention curve of Brooks and Corey (1964) substitution of λ_θ and λ_h into Equation 6.20 gives:

$$\begin{cases} \frac{\theta}{\lambda_\theta} = \left[\frac{h}{\lambda_h} \right]^{-\lambda} & \text{for } h \leq \lambda_h \\ \theta = \lambda_\theta & \text{for } \lambda_h \leq h \leq 0 \end{cases} \quad (6.116)$$

and for the van Genuchten (1980) water retention curve:

$$\frac{\theta}{\lambda_\theta} = \left[1 + \left(\frac{h}{\lambda_h} \right)^n \right]^{-m} \quad (6.117)$$

Substitution of λ_θ and λ_K in the hydraulic conductivity equation (Equation 6.25) of Brooks and Corey (1964) yields:

$$\frac{K}{\lambda_K} = \left[\frac{\theta}{\lambda_\theta} \right]^\eta \quad (6.118)$$

When describing unsaturated water flow subject to a given set of initial and boundary conditions, the water flow behavior of the soil should be independent of the choice of the soil hydraulic functional relationships. This can be guaranteed by applying the sorptivity criterion that imposes the sorptivity, $S_1(\theta_s, 0)$ (Equation 6.77) calculated by the use of the redefined water retention and hydraulic conductivity equations such as given by Equation 6.116 to Equation 6.118, and the sorptivity, $S_1(\theta_s, 0)$, expressed as function of λ_h (Equation 6.112) to be equal. Establishing this equality yields the correct c_p value which is specific for the functional relationship of $h(\theta)$ chosen and guarantees the sorptivity criterion.

The values of c_p calculated for the Brooks and Corey (1964) and van Genuchten (1980) water retention equations are respectively:

$$c_p = \frac{2\lambda\eta[\lambda\eta - 1] + \lambda[2\lambda\eta - 1]}{[\lambda\eta - 1][\lambda\eta - 1 + \lambda]} \quad (6.119)$$

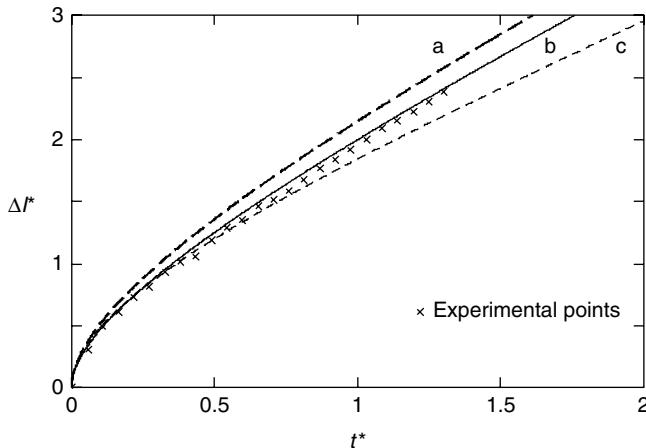

FIGURE 6.14 Experimental points (Touma et al., 1984) and predicted dimensionless cumulative infiltration curves: (a) the classical Green and Ampt (1911) equation, (b) the modified Green and Ampt equation, and (c) the Talsma and Parlange (1972) equation.

and

$$c_p = \Gamma \left(1 + \frac{1}{n} \right) \left\{ \frac{\Gamma(m\eta - 1/n)}{\Gamma(m\eta)} + \frac{\Gamma(m\eta + m - 1/n)}{\Gamma(m\eta + m)} \right\} \quad (6.120)$$

where Γ stands for the usual gamma function. Obviously, for Green and Ampt soils with the sorptivity given by Equation 6.88, the particular value of c_p is equal to 2. When dealing with general field soils, c_p is purely defined by textural soil parameters (Equation 6.119 and Equation 6.120). The values of m and η or λ and η can be determined by the use of PTFs (see Section 6.2.6) allowing the values of c_p to be easily calculated.

The use of c_p together with the Green and Ampt equation (Equation 6.99) has the advantage of being an invariant dimensionless infiltration curve valid for general field soils without being limited by the hypothesis of the Green and Ampt configuration. The fact that the proportionality constant c_p is pinned down on the sorptivity expression that is valid for realistic soil hydraulic characteristics relations (such as the van Genuchten and Brooks and Corey curves), guarantees a realistic description of the infiltration flow behavior as textural soil properties are taken into account. This result is illustrated by the dimensionless cumulative infiltration curves ($\Delta I^*(t^*)$) shown in Figure 6.14. The envelope of possible similarity classes bounded by the two invariant solutions of the classical Green and Ampt equation ($c_p = 2$) and the Talsma and Parlange (1972) equation (valid for the Gardner [1958] soil) are presented, together with the experimental constant head infiltration data given by Touma et al. (1984). The Green and Ampt equation (Equation 6.99) with c_p calculated from Equation 6.120 gives a good agreement with the measured infiltration data.

The experimental cumulative infiltration data together with the surface boundary condition (h_{surf}) are the only data supposed to be known from field measurements. The identification procedure aims to determine the scaling factors α_I and α_t from these input data. Generally speaking, the optimization of two parameters on a monotone increasing function (such as the cumulative infiltration curve), guarantees *a priori* the uniqueness of the solution. Once the values of α_I and α_t are determined, the purely soil-related scaling parameters λ_θ , λ_h , and λ_K can be calculated (details of the identification procedure are given by Haverkamp et al., 1998a). Some of the results are shown in Figure 6.15. In the context of the European international project on Climate and Hydrological Interactions between the Vegetation, the Atmosphere, and the Land surface (ECHIVAL) an infiltration field experiment was carried out in the desertification-threatened area of La Mancha (Spain). One hundred cumulative infiltration curves were measured over

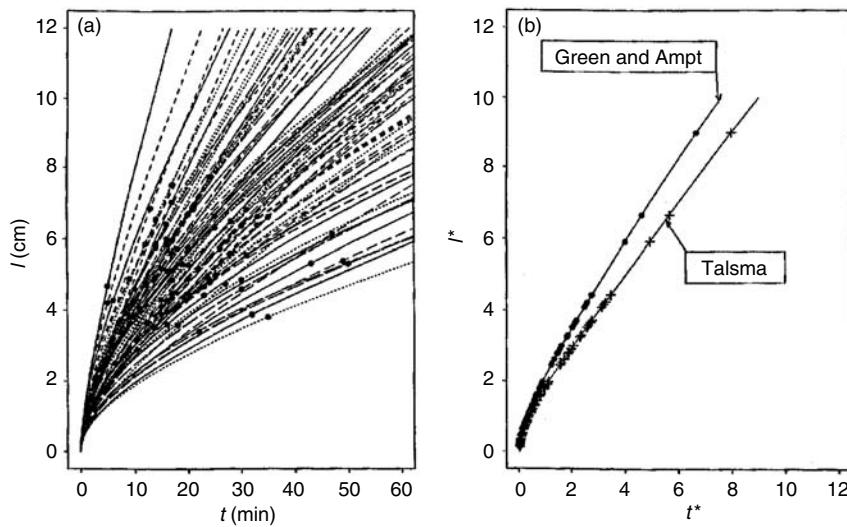

FIGURE 6.15 Fan of 100 different cumulative infiltration curves measured over an area of 100 km² before scaling (a) and after scaling (b). (Adapted from Haverkamp, R., Parlange, J.-Y., Cuenca, R., Ross, P. J., and Steenhuis, T. S. 1998a. Scaling of the Richards' equation and its application to watershed modeling. In *Scale Invariance and Scale Dependence in Hydrology*, Sposito, G. [Ed.], Cambridge University Press, New York, pp. 190–223. With permission.)

an area of 100 km² with a grid mesh of 1 × 1 km. The results are given in Figure 6.15a. For each of the 100 curves the parameters α_1 and α_t were determined by the use of the Green and Ampt equation (Equation 6.99) with $c_p = 2$ and the Talsma and Parlange (1972) solution. The scaled results, $I^*(t^*)$ are given in Figure 6.15b showing the unique similarity which exists for both infiltration curves. All the 100 points fit each of the two infiltration curves perfectly well. It showed that with a minimum of measurement points for $I(t)$ precise information could be obtained on local soil hydraulic characteristics and their possible variations (upper and lower limits). Large areas were surveyed in short times. For example, the entire cumulative infiltration measurement campaign over the area of 100 km² did not take more than three weeks.

The foregoing scaling concept is valid for any spatial grid scale provided that suitable scaling factors can be measured and the soil is considered equivalent homogeneous for the grid scale involved. The concept can be used for any flow equation. Although the details of the approach were discussed through the infiltration law as flow equation, there are inherent limitations for using the infiltration phenomenon. The characteristic grid size of infiltration is still rather small (in the order of 1 m²). When dealing with hydrologic model studies the ideal choice would be to use the evaporation flux as flow phenomenon as its characteristic grid size is much larger (in the order of 1 km²).

6.5.2 Scaling Evaporation

An identical approach to that developed previously can be applied for evaporation using Salvucci's (1997) approximate exfiltration equation based on moisture profile similarity:

$$[K(\theta_0)]^2 t = \frac{S_d(\theta_1, \theta_0)}{2} \left[\frac{K(\theta_0)}{f_e} - \ln \left(1 + \frac{K(\theta_0)}{f_e} \right) \right] \quad (6.121)$$

subject to initial and boundary conditions:

$$\begin{aligned} \theta &= \theta_0 & \text{at } t = 0 & \text{and } z \geq 0 \\ \theta &= \theta_1 & \text{at } z = 0 & \text{and } t > 0 \end{aligned} \quad (6.122)$$

where f_e is the exfiltration rate; and the *desorptivity* $S_d(\theta_1, \theta_0)$ is estimated by analogy with sorptivity (Parlange et al., 1985b) from:

$$S_d(\theta_1, \theta_0) = \frac{8}{3} \int_{h_0}^{h_1} [\theta - \theta_0] K dh \quad (6.123)$$

Note that for evaporation $\theta_1 < \theta_0$. Even though Equation 6.121 does not assume a sharp water content front in the drying soil, it is similar to the Green and Ampt infiltration (1911) equation. Considering, for the sake of brevity, $K_0 = 0$ and $c_p = 2$, the following dimensionless variables can be defined:

$$f_e^* = \frac{K(\theta_0)}{f_e^*} \quad \text{and} \quad t = \frac{S_d^2(\theta_1, \theta_0)}{2[K(\theta_0)]^2} t^* \quad (6.124)$$

Equation 6.121 can then be written in the dimensionless form:

$$f_e^* = t^* + \ln[1 + f_e^*] \quad (6.125)$$

As Equation 6.125 is identical to the Green and Ampt equation (Equation 6.99) with $c_p = 2$, the scaling analysis explained previously can be applied to determine the invariant exfiltration curve. This approach is extremely interesting as there are actually methods, such as remote sensing, that provide areal averages of evaporation. It would then be possible from cumulative exfiltration (by analogy with cumulative infiltration) to evaluate the exfiltration scaling factors. Once the desorptivity is converted to sorptivity, the areal soil hydraulic scale parameters consistent with the flow process can be determined.

As new technologies such as Geographic Information Systems (GIS) and remote sensing are increasingly becoming standard tools for evaluating flow processes at various scales, this scaling methodology proposes compatibility rules for combining different parameters and data sets, which is an aspect that is often neglected in GIS operations (Band and Moore, 1995).

6.6 Conclusions and Perspectives on Future Research

This chapter is mainly concerned with the water transfer in the unsaturated or vadose zone. The conceptual aspects of unsaturated soil water flow related to soil physical properties and soil water characteristics have been presented. Different functional relationships to represent soil hydraulic characteristics and different measurement and estimation techniques have been addressed. An overview of the most significant analytical solutions and the most important physical infiltration laws are given. It has been shown that the textural soil properties could give information regarding the shape parameters of the soil hydraulic characteristics, and the scale parameters that imbed the dynamic characteristics of the soil could only be determined if a flow equation is somehow considered. In this perspective, a scaling approach of the water transfer equation in the unsaturated zone has been given.

This new theory is based on the scaling of the unsaturated flow equation rather than on the scaling of the soil hydraulic characteristics. Following the postulate of invariance of a physical law and its consequences under a series of transformations, it is shown that in general there exists no unique dynamical similarity in the behavior of unsaturated soil water movement. A unique dynamical similarity is only found for two particular soil descriptions: the Green and Ampt (1911) soil and the Gardner (1958) soil. Both limit the envelope of possible similarity classes that exist for general field soils. However, when modifying the Green and Ampt configuration by taking into account the effects of soil texture, an invariant infiltration law can be determined that is realistic for general field soils.

This approach offers a real alternative to classic estimation techniques of soil hydraulic characteristics, which are virtually impossible to perform over a great number of grid locations over a catchment, with a

realistic use of resources in terms of time and costs. It is possible through quick infiltration experiments to determine the dynamic characteristics of soils that are far more representative and accurate than any estimate given from textural information such as PTFs. Furthermore, the effects of preferential flow can be taken into account. The second major advantage of the scaling approach is that it is compatible with the scale of measurement. As this methodology can be applied to any flow equation such as evaporation, it is possible through the use of remote sensing, which provide realistic aggregated values of water fluxes, to tackle the mismatch that exists between the scale on which current knowledge of vadose zone water transfer processes is based and the scale for which the water budget models are making predictions.

Glossary and Parameter Notation

a	stone weight fraction
b	porous rock weight fraction
A_1	first term of Philip's truncated infiltration equation ($\text{m/sec}^{1/2}$)
A_2	second term of Philip's truncated infiltration equation (m/sec)
$c_{1,\dots,n}$	regression coefficients
c	light velocity (m/sec)
c_p	proportionality constant
C	specific capacity ($1/\text{m}$)
C_e	dielectric constant
Cl	clay fraction (%)
dVp_i	pore volume associated with each size class ' i ' of the Arya and Paris (1981) model (m^3)
D	diffusivity (m^2/sec)
Dpg	particle-size scale parameter (m)
Dp	effective diameter of soil particle (m)
Dp_i	particle radius of size class ' i ' of the Arya and Paris (1981) model (m)
e	void ratio (m^3/m^3)
f_p	particle-size distribution frequency expressed as a percentage of particle weight per unit sample mass
f_e	exfiltration rate (m/sec)
f_e^*	dimensionless exfiltration rate
F	flux-concentration relation
F_{PA}	flux-concentration relation defined by Parlange (1971a)
F_p	cumulative distribution of particle weight
g	gravitational acceleration, 9.82 m/sec^2
h	soil water pressure head (m)
h_0	soil water pressure head at initial water content (m)
h_1	surface soil water pressure head (m)
h_{bc}	Brooks and Corey (1964) soil water retention scale parameter (m)
h_g	van Genuchten (1980) soil water retention scale parameter (m)
h_f	Green and Ampt wetting front pressure head value (m)
h_{surf}	ponded water depth at soil surface (m)
h^*	dimensionless soil water pressure head
H	hydraulic head (m)
I	one-dimensional cumulative infiltration (m^3/m^2)
k	intrinsic permeability (m^2)
k_m	parameter relating van Genuchten (1980) shape parameters m and n
k_M	parameter relating particle-size shape parameters M and N
k_{rw}	relative water permeability
K	hydraulic conductivity (m/sec)
K_s	hydraulic conductivity at natural saturation (m/sec)

K_0	hydraulic conductivity at initial water content θ_0 (m/sec)
K_1	hydraulic conductivity at water content θ_1 (m/sec)
K^*	dimensionless hydraulic conductivity
l	rod length of TDR probe (m)
m	van Genuchten (1980) water retention shape parameter
M	particle-size shape parameter
M_g	mass of gas phase of REV (kg)
M_l	mass of liquid phase of REV (kg)
M_{mol}	molecular weight
M_s	mass of solid phase of REV (kg)
M_t	total mass of REV (kg)
n	van Genuchten (1980) water retention shape parameter
N	particle-size shape parameter
nb_i	number of particles in size class ' i ' of the Arya and Paris (1981) model
OC	percentage of organic carbon content
p	water vapor pressure
p_0	saturated vapor pressure
$p\beta$	tortuosity factor
pF	logarithmic mode of pressure head
P_{wr}	water retention shape index
P_{pa}	particle-size shape index
PTF	pedo-transfer function
q	soil water flux (m/sec)
q_1	one-dimensional infiltration flux at the soil surface (m/sec)
r	radius pore opening (m)
R	radius of the main pore (m)
R_i	pore radius of size class ' i ' of the Arya and Paris (1981) model (m)
R_g	universal gas constant
REV	representative elementary soil volume (m^3)
s	fractal dimension
S	degree of saturation (m^3/m^3)
Sa	sand fraction (%)
S_d	desorptivity ($\text{m/sec}^{1/2}$)
Si	silt fraction (%)
S_l	sorptivity ($\text{m/sec}^{1/2}$)
S_2	second integral term of Philip's analytical infiltration equation
t	time (sec)
t_{tr}	travel time of electromagnetic TDR wave (sec)
t^*	dimensionless time
T_l	temperature liquid phase (K)
V_g	volume gas phase of REV (m^3)
V_l	volume liquid phase of REV (m^3)
V_s	volume solid phase of REV (m^3)
V_t	total volume of REV (m^3)
w	gravimetric soil water content (kg/kg)
W_g	weight of gas phase of REV (kg)
W_l	weight of liquid phase of REV (kg)
W_s	weight of solid phase of REV (kg)
W_t	total weight of REV (kg)
x	horizontal space coordinate (m)
z	depth, positive downward (m)

z_m	reference depth of instantaneous profile method (m)
z_0	zero flux plan (m)
z^*	dimensionless depth
z_f	depth of infiltration wetting front (m)
α	tortuosity factor ($\alpha = 1.38$) of the Arya and Paris (1981) model
α_C	specific capacity scaling factor (1/m)
α_h	pressure head scaling factor (m)
α_I	cumulative infiltration scaling factor (m)
α_K	hydraulic conductivity scaling factor (m/sec)
α_q	flux scaling factor (m/sec)
α_t	time scaling factor (sec)
α_z	depth scaling factor (m)
α_θ	water content scaling factor (m^3/m^3)
β	Parlange et al. (1982) conductivity shape parameter
γ	packing coefficient of the Haverkamp and Parlange (1986) model
γ_s	tortuosity factor defined by the water retention shape index
ΔS	change in water storage (m)
Δt	time step (sec)
ΔI^*	dimensionless net cumulative infiltration
Δq_I^*	dimensionless net infiltration flux
ε	soil porosity (m^3/m^3)
ε_{ap}	whole soil porosity (m^3/m^3)
ε_c	porosity of porous coarse fragments (m^3/m^3)
λ	Brooks and Corey (1964) shape parameter
λ_h	purely soil-related pressure head scaling factor (m)
λ_K	purely soil-related hydraulic conductivity scaling factor (m/sec)
λ_θ	purely soil-related water content scaling factor (m^3/m^3)
η	Brooks and Corey (1964) hydraulic conductivity shape parameter
θ	volumetric soil water content (m^3/m^3)
θ_r	residual volumetric soil water content (m^3/m^3)
θ_s	volumetric soil water content at natural saturation (m^3/m^3)
θ_0	initial volumetric soil water content (m^3/m^3)
θ_1	surface volumetric soil water content (m^3/m^3)
θ^*	dimensionless volumetric soil water content: θ/θ_s
μ_w	water viscosity (kg/m/sec)
ρ_{ap}	whole soil dry bulk density (kg/m ³)
ρ_c	specific weight of porous coarse fragments (kg/m ³)
ρ_d	dry bulk density (kg/m ³)
ρ_s	specific weight of soil particles: 2.65 (g/cm ³)
ρ_w	soil water specific weight (kg/m ³)
σ_{LV}	liquid-vapor surface tension of water (kg/m/sec ²)
ϕ_a	air potential (joule/m ³)
ϕ_c	capillary potential (joule/m ³)
ϕ_e	envelope potential (joule/m ³)
ϕ_g	gravitational potential (joule/m ³)
ϕ_o	osmotic potential (joule/m ³)
Φ	total soil water potential (joule/m ³)
χ_1	Boltzmann similarity variable (m/sec ^{1/2})
χ_2	second term of Philip's time series solution (m/sec)
χ_3	third term of Philip's time series solution (m/sec ^{3/2})
ω	contact angle between liquid and solid phase (rad)

7.1 Introduction

Water entry into the soil by infiltration is among the most important of soil hydrological processes, as it controls the partitioning between runoff and soil water storage. Runoff water determines the surface water's quantity and quality, whereas infiltrated water determines the plant's available water, evapotranspiration, groundwater recharge, and groundwater quality. Also through exinfiltration, infiltrated water can affect the surface water's characteristics as in riparian zones. Yet, despite its relevance and our solid physical understanding of infiltration, we have generally great difficulty in predicting the infiltration in the field at larger spatial scales. Mostly, this is so because the infiltration rate is a time-varying quantity that is highly dependent on soil properties that are generally highly variable in space, both in the vertical and horizontal directions of the hydrologic basin. Moreover, infiltration rate and runoff are affected by vegetation cover, as it protects the soil's surface from the energy impacts of falling rain drops or intercepting rainfall, serving as a temporary water storage. The kinetic energy of rainfall causes soil degradation, leading to soil surface sealing and decreasing infiltration.

Historically, solutions to infiltration problems have been presented through analytical or empirical means. Analytical solutions provide values of infiltration rate or cumulative infiltration as a function of time, making simplified assumptions of soil depth variations of water content, before and during the infiltration. In contrast, powerful computers nowadays use numerical simulations of unsaturated water flow to solve for water content and water fluxes throughout the unsaturated soil domain in a single vertical direction or in multiple spatial dimensions, allowing complex initial and boundary conditions. However, although the multi-dimensional unsaturated water flow modeling is extremely useful for many vadose zone applications, it does not necessarily improve the soil surfaces infiltration rate prediction, in light of

the large uncertainty of the soil's physical properties and the initial and boundary conditions that control the infiltration. In contrast, empirical infiltration models serve primarily to fit model parameters to the measured infiltration, but have limited power as a predictive tool.

In this chapter, we will first review the basic processes of infiltration and introduce the relevant soil and infiltration parameters that control infiltration (Section 7.2). In doing so, we will use the notation introduced by Haverkamp et al. (this volume), and start with the so-called Green and Ampt equation for ponded infiltration. In Section 7.3 we introduce the most frequently used physically-based and empirical infiltration equations. We will present methods of measuring infiltration (Section 7.4), and demonstrate that specific field tests can be used to characterize the soil's physical properties in an inverse way. In Section 7.5, we review the spatial considerations of infiltration and highlight infiltration studies at the basin scale, whereas Section 7.6 presents the effects of the soil surface sealing on infiltration and the implications in terms of runoff estimates at the watershed scale. We will conclude with a summary in Section 7.7.

7.2 Soil Properties and Processes of Infiltration

The soil is a complex three-phase porous medium of mostly connected solid, liquid, and gaseous phases, with the spatial distribution and geometrical arrangement of each phase, and the partitioning of solutes between phases, controlled by physical, chemical, and biological processes. The vadose zone is bounded by the soil surface and merges with the groundwater in the capillary fringe. Water in the unsaturated soil matrix is attracted by capillary and adsorptive forces. Soils are subjected to fluctuations in water and chemical content by infiltration and leaching from rainfall or irrigation, water uptake by plant roots (transpiration), and evaporation from the soil surface.

As introduced by Haverkamp (this issue), we represent the soil's dry bulk density by ρ_b , and define the porosity ($\varepsilon L^3 L^{-3}$) by:

$$\varepsilon = 1 - \frac{\rho_b}{\rho_s} \quad (7.1)$$

with ρ_s being the soil's particle density. *Soil porosity* decreases as *bulk soil density* increases. The volumetric water content θ expresses the volume of water present per unit bulk soil as

$$\theta = \frac{w \rho_b}{\rho_w} \quad (7.2)$$

where w is defined as the mass water content and we take $\rho_w = 1000 \text{ kg m}^{-3}$. Alternatively, the soil water content can be described by the degree of saturation $S(-)$, or the equivalent depth of stored water $D_e(L)$,

$$S = \frac{\theta}{\varepsilon} \quad \text{and} \quad D_e = \theta D_{\text{soil}} \quad (7.3)$$

so that θ can also be defined by the equivalent depth of water per unit depth of bulk soil, D_{soil} . (L). The volumetric water content ranges between 0.0 (dry soil) to the saturated water content θ_s , which is equal to the porosity if the soil were completely saturated. The degree of saturation varies between 0.0 (completely dry) and 1.0 (all pores completely water-filled). When considering water flow, the porosity term is replaced by the saturated water content θ_s , and both terms in Equation 7.3 are corrected by subtracting the so-called residual water content θ_r , so that the effective saturation S_e , is defined as

$$S_e = \frac{\theta - \theta_r}{\theta_s} \quad (7.4)$$

The soil-water retention function determines the relation between the volume of water retained by the soil, expressed by θ , and the governing soil matric, or suction forces. These suction forces are typically expressed

by the soil water matric head (L, strictly negative) or soil suction (strictly positive). Also known as the soil-water release or soil-water characteristic function, this soil hydraulic property describes the increase of θ and the size of the water-filled pores with a decrease in matric potential, as occurs by infiltration. As the matric forces are controlled by pore size distribution, specific surface area, and type of physico-chemical interactions at the solid–liquid interfaces, the soil water retention curve is very soil-specific and very nonlinear. It provides an estimate of the soil's capacity to hold water after irrigation and free drainage (field capacity), minimum soil water content available to the plant (wilting point), and therefore water availability in the rootzone for plants. The soil water retention curves shows hysteresis, that is, the θ value is different for wetting (infiltration) and drying (drainage).

The relation between the soil's unsaturated hydraulic conductivity, K , and volumetric water content, θ , is the second essential fundamental soil hydraulic property needed to describe water movement in soils. It is also a function of the water and soil matrix properties, and determines water infiltration and drainage rates, and is strongly affected by water content and possibly by hysteresis. It is defined by the Darcy–Buckingham equation, which relates the soil-water flux density to the total driving force for flow, with K being the proportionality factor. Except for special circumstances, the total driving force for water flow in soils is determined by the sum of the matric and gravitational forces, expressed by the total water potential head gradient, $\Delta H/L$ (L L⁻¹), where ΔH denotes the change in total water potential head over the distance L , and $H = (h + z)$. For vertical flow, the application of Darcy's law yields the magnitude of water flux from the steady-state flow equation:

$$q = -K(\theta) \left(\frac{dh}{dz} + 1 \right) \quad (7.5)$$

where q is the Darcy water flux density (L³L⁻² T⁻¹), z is vertical position ($z > 0$, upwards, L). A soil system is usually defined by the bulk soil, without consideration of the size and geometry of the individual flow channels or pores. Therefore, the hydraulic conductivity (K) describes the ability of the bulk soil to transmit water, and is expressed by the volume of water flowing per unit area of bulk soil per unit time. Functional models for unsaturated hydraulic conductivity can be based on pore size distribution, pore geometry, and connectivity, and require the integration of soil water retention functions to obtain analytical expressions for the unsaturated hydraulic conductivity. The resulting expressions relate the relative hydraulic conductivity, K_r , defined as the ratio of the unsaturated hydraulic conductivity, K , and the saturated hydraulic conductivity, K_s , to the effective saturation, S_e , or matric potential head h , as in Equation 7.20b. We note that θ_s in the vadose zone is typically about 85% of the porosity, so that a saturated soil (e.g., as the result of ponded infiltration) is really a “saturated” soil due to entrapped air, with a saturated hydraulic conductivity that is significantly smaller than the true K_s .

For transient vertical water flow, with no root water uptake, the Darcy–Buckingham equation for unsaturated flow is combined with the mass balance equation to yield:

$$\frac{\partial \theta}{\partial t} = -\frac{\partial q}{\partial z} \quad (7.6)$$

which is defined as the Richards' equation after substitution of Equation 7.5 and written with h being the single dependent variable (Haverkamp, et al., this volume). Numerous studies have been published addressing different issues in the numerical modeling of unsaturated water flow in multiple spatial dimensions, using the Richards' equation. For the purpose of deriving analytical infiltration models, a linearized version of Equation 7.6 is often used. Specifically, for one-dimensional infiltration, the infiltration rate (L T⁻¹), $i(t)$, can be defined by Equation 7.5 at the soil surface (subscript $surf$), or

$$i(t) = -K(\theta) \left(\frac{\partial h}{\partial z} + 1 \right)_{surf} \quad (7.7a)$$

Cumulative infiltration $I(t)$, expressed as volume of water per unit soil surface area (L), is defined by

$$I(t) = \int_0^t i(t) dt \quad (7.7b)$$

Analytical solutions of infiltration generally assume that the wetted soil profile is homogeneous in texture with uniform initial water content. They also make distinction between ponded (positive h) and non-ponded soil surface (negative h) infiltration. The infiltration capacity of the soil is defined by $i_c(t)$, defined by the maximum rate at which a soil can absorb water for ponded soil-surface conditions. Its maximal value is at time zero, and decreases with time to its minimum value approaching the soil's saturated hydraulic conductivity, K_s , as the total water potential gradient decreases, and tends to unity, with the downward moving wetting front. As defined by Equation 7.7b, the soil's cumulative infiltration capacity, $I_c(t)$ is defined by the area under the capacity curve. It represents the maximum amount of water that the soil can absorb at any time. Typically at the onset of infiltration ($t = 0$), the rainfall rate $r(t)$, will be lower than $i_c(t)$, so that the infiltration rate is equal to the rainfall rate (i.e., $r(t) < i_c(t)$ for $h_{surf} < 0$). If at any point in time, the rainfall rate becomes larger than the infiltration capacity, ponding will occur ($h_{surf} > 0$), resulting in runoff. The time at which ponding occurs is defined as t_p . Thus, the actual infiltration rate will depend on the rainfall rate and its temporal changes. This makes prediction of infiltration and runoff much more difficult for realistic time-variable rainfall patterns.

Therefore infiltration rate prediction is often described as a function of the cumulative infiltration, I , or $i(I)$, independent of the time domain, and with $i(I)$ curves that are independent of rainfall rate (Skaggs, 1982). An example of such a time-invariant approach is the IDA or infiltrability-depth approximation (Smith et al., 2002). The main IDA assumption is that time periods between small rainfall events are sufficiently small so that soil water redistribution and evaporation between events does not affect the infiltration rate. IDA implies that the infiltration capacity at any given time depends only on the cumulative infiltration volume, regardless of the previous rainfall history. Following this approach, t_p is defined as the time during a storm event when I becomes equal to $I_c(t_p)$, or $R = \int_{t=0}^{t_p} r(t) dt = I_c(t_p)$, whereas $i(t) = r(t)$ for $t < t_p$. The time invariance of $i(I)$ holds true also when a layered/sealed soil profile is considered (Mualem and Assouline, 1989). However, it may not remain valid during the dynamic stage of seal formation (Assouline and Mualem, 2001).

For illustration purposes, we present an hypothetical storm event with time-varying $r(t)$ in Figure 7.1, in combination with an assumed soil-specific infiltration capacity curve, $i_c(t)$. At what time will ponding occur? It will not be at $t = 7$, when $r(t)$ exceeds i_c for the first time. To approximate t_p , we plot both I_c and R for the storm in Figure 7.2a, as a function of time and determine t_p as the time at which both curves intersect ($t_p = 13$, for $R = I_c = 110$), since at that time, the cumulative infiltration of the storm is identical to the soil's infiltration capacity. The final corresponding $i(I)$ for this soil and storm event is presented in Figure 7.2b, showing that the soil infiltration rate is equal to $r(t)$ until $I = R(t) = I_c(t_p) = 110$, after which the infiltration rate is soil-controlled and determined by $I_c(t)$. More accurate approximations to the time-invariant approach can be found in Sivapalan and Milly (1989) and Brutsaert (2005), using the time compression or time condensation approximation that more accurately estimate infiltration prior to surface ponding.

In addition to whether the soil is ponded or not, solutions of infiltration also distinguish between cases with and without gravity effects, as different analytical solutions apply. As Equation 7.7a shows, infiltration rate $i(t)$ is determined by both the soil water matric potential gradient, dh/dz , and gravity. However, at the early stage of infiltration into a relatively dry soil, infiltration rate is dominated by the matric potential gradient so that the gravity effects on infiltration can be ignored. Gravity becomes important in the later stages of infiltration, when the wetting front has moved down. For gravity-free drainage, a simple analytical solution can be found, after transforming Equation 7.6 into a diffusion type of equation by defining the diffusivity $D(\theta) = K(\theta)(dh/d\theta)$, and writing Equations 7.6 and Equation 7.7 in the θ -based

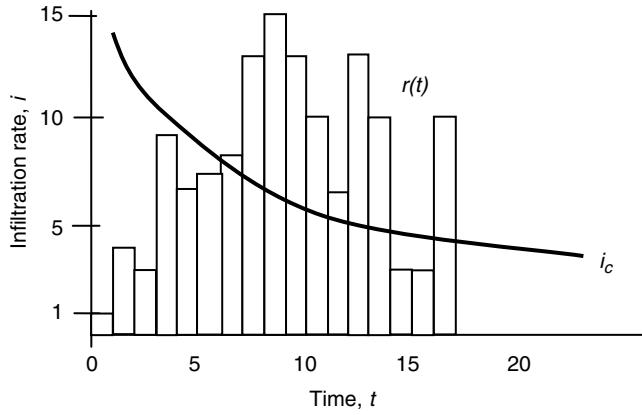

FIGURE 7.1 Hypothetical rainfall event, $r(t)$, and soil infiltration capacity, $i_c(t)$. The rainfall event starts at $t = 0$.

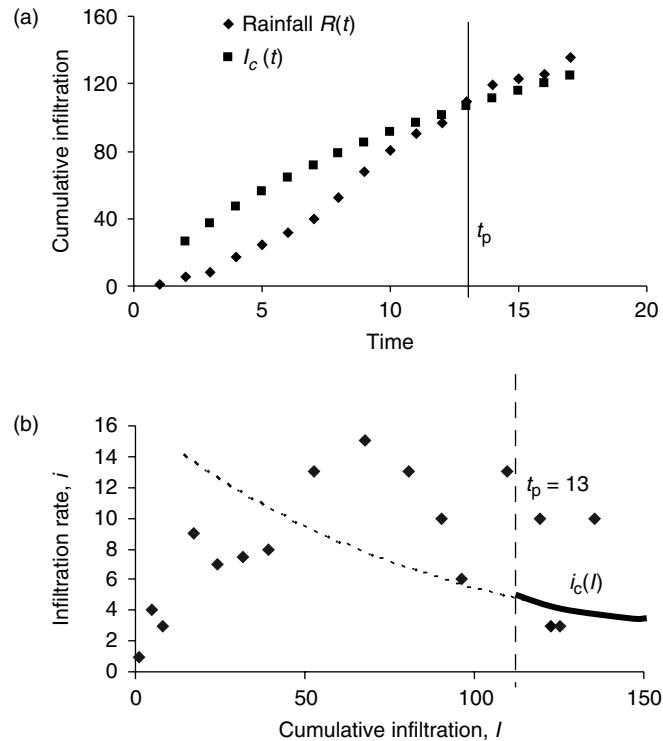

FIGURE 7.2 (a) Cumulative infiltration corresponding with infiltration capacity, $I_c(t)$, and cumulative rainfall, $R(t)$ and (b) actual infiltration rate vs I . Ponding starts only after $t_p = 13$, or $I = 110$.

form, so that:

$$i(t) = -D(\theta) \left(\frac{\partial \theta}{\partial z} \right)_{\text{surf}} \quad (7.8)$$

Using the Boltzmann transformation for a constant head boundary condition (Bruce and Klute, 1956), and defining the scaling variable $\varphi = z/t^{1/2}$, a combination of Equation 7.6 and Equation 7.8 results

in a unique solution of θ as a function of ϕ , from which the wetting profile can be computed for any time t (Kirkham and Powers, 1972). Using the terminology of Haverkamp et al. (this volume), θ_1 and θ_o define the surface water content during infiltration and uniform initial profile water content, respectively. Moreover, defining I as the volume of infiltrated water within the wetting soil profile, or

$$I = \int_{\theta_0}^{\theta_1} z d\theta = t^{1/2} \int_{\theta_0}^{\theta_1} \varphi d\theta \quad (7.9a)$$

results in the simple infiltration equation $I = St^{1/2}$ where the sorptivity $S(LT^{-1/2})$ is defined as:

$$S(\theta_1) = \int_{\theta_0}^{\theta_1} \varphi d\theta \quad (7.9b)$$

Equation 7.9a states that for “gravity-free” infiltration during the early times of vertical infiltration, and at all times for horizontal infiltration, I is a linear function of $t^{1/2}$, with S being defined as the slope of this line. Hence, for saturated soil conditions where $\theta_1 = \theta_s$, the infiltration capacity is computed from $i_c(t) = 1/2St^{-1/2}$. By the way, this also leads to $I_c = S^2/2i_c$.

A relatively simple analytical solution without and with gravity effects was suggested by Green and Ampt (GA, 1911) for a ponded soil surface, with $\theta_{surf} = \theta_1$. The assumptions are that the wetting front can be approximated as a step function (Figure 7.3) with a constant effective water potential, h_f , at the wetting front, a wetting zone hydraulic conductivity of $K(\theta_1) = K_1 = K_s$, and a constant soil water profile of $\Delta\theta = \theta_1 - \theta_o$. Using this so-called delta-function assumption of a $D(\theta)$ with a Dirac-delta function form, both solutions for horizontal and vertical infiltration can be relatively easily obtained (Jury et al., 1991; Haverkamp et al., this volume). Assuming that K_o at the initial water content, θ_0 , is negligible, the GA solution of vertical infiltration for ponded conditions is ($h = h_{surf} > 0$):

$$I = I_c = K_1 t + (h_{surf} - h_f) \Delta\theta \ln \left(1 + \frac{I}{(h_{surf} - h_f) \Delta\theta} \right) \quad (7.10)$$

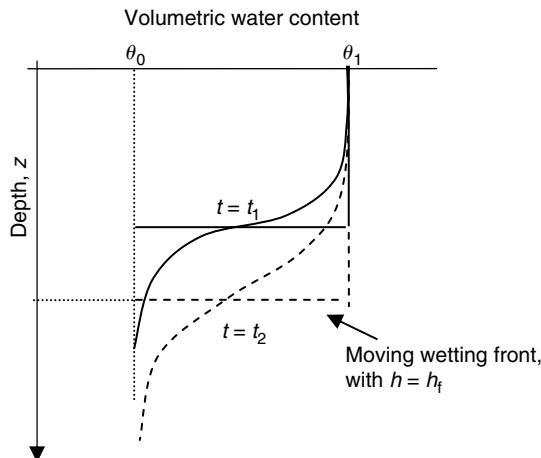

FIGURE 7.3 Water content distributions for an infiltrating soil profile under ponding at two times with $t_2 > t_1$. Step function represents Green and Ampt delta function infiltration model.

which can be solved iteratively for I . This simple, yet physically-based solution appears to work best for dry coarse-textured soils. A theoretical expression for the wetting front potential head, h_f , was defined by Mein and Farrel (1974), to yield that $h_f = \int_0^{h_o} K_r(h)dh$, where the relatively conductivity $K_r = K(h)/K_s$. The so-called S-form of the GA equation can be obtained by comparing the gravity-free solution of GA with the Boltzmann solution, to yield ($S_0^2 = -2K_1 h_f \Delta\theta$):

$$S_1^2(\theta_1) = 2K_1 \Delta\theta(h_{\text{surf}} - h_f) = S_0^2 + 2K_1 h_{\text{surf}} \Delta\theta \quad (7.11a)$$

so that

$$I = K_1 t + h_{\text{surf}} \Delta\theta + \frac{S_0^2}{2K_1} \ln \left(1 + \frac{I}{h_{\text{surf}} \Delta\theta + S_0^2 / 2K_1} \right) \quad (7.11b)$$

In reality, the wetting front is not a step function, but will consist of a time-dependent transition zone where water content changes from θ_1 to θ_0 (Figure 7.3). The shape of this transition zone will be a function of time and is controlled by soil type. The step function assumption is better for uniform coarse-textured soils that have a Dirac-like $D(\theta)$, for which there is a sharp decline in K with a decrease in water content near saturation. The wetting front is generally much more diffuse for finer-textured soils that have a wide pore-size distribution.

By now it must be clear that infiltration and its temporal changes are a function of many different soil's factors. In addition to rainfall intensity and duration and the soil physical factors such as soil water retention and hydraulic conductivity, infiltration is controlled by the initial water content, surface sealing and crusting, soil layering and the ionic composition of the infiltrated water (Kutilek and Nielsen, 1994; Assouline, 2004). For example, Vandervaere et al. (1998) applied the GA model to sealed soil profiles, by assuming that the wetting front potential decreases suddenly as it leaves the seal and enters the soil. This results in a discontinuous drop in the infiltration rate. Many relatively simple infiltration equations have been proposed and are successfully used in to characterize infiltration. This has been achieved despite the fact that these equations can be applied for homogeneous soils only, in theory.

7.3 Infiltration Equations

In addition to the solutions in Section 7.2, other physically-based analytical solutions have been presented. These can be potentially be used to predict infiltration from known soil hydraulic properties of homogeneous soils. However, in practice this is difficult as soil's physical characteristics near the soil surface are highly time-dependent because of the soil's structural changes, and because they are highly variable spatially. Alternatively, various empirical infiltration models have been proposed that are very useful for describing the measured infiltration data. A parameter sensitivity analysis of many of the presented infiltration models, analyzing the effects of measurement error, was given by Clausnitzer et al. (1998). This section presents the most frequently-used infiltration models in both categories.

7.3.1 Philip Infiltration Equation (PH)

Philip (1957a) presented an analytical infinite-series solution to the water-content based form of Richards' equation for the case of vertical infiltration. The so-called Fokker–Planck equation, or

$$\frac{\partial\theta}{\partial t} = \frac{\partial}{\partial z} \left(D \frac{\partial\theta}{\partial z} + K(\theta) \right) \quad (7.12)$$

for $h_{\text{surf}} = 0$ and $\theta_1 = \theta_s$ converges to the true solution for small and intermediate times, but fails for large times. In this case an alternative solution was presented (Philip, 1957b). With additional assumptions regarding the physical nature of soil water properties, Philip (1987) proposed joining solutions that are

applicable for all times. Philip (1957c) introduced a truncation of the small-time series solution that is a simple two-parameter model equation (PH model)

$$I_c = At + St^{1/2} \quad (7.13a)$$

“which should be accurate for all but very large t ”, and “suitable for applied hydrological studies.” The sorptivity S depends on several soil-physical properties, including initial water content θ_0 , and the hydraulic conductivity and soil-water retention functions. S is equal to the expression defined in Equation (7.9b). Because the coefficient A is not equal to K_1 , physical interpretation of Equation 7.13 fails for $t \rightarrow \infty$. Philip (1969) showed that A may take values between $0.38K_s$ and $0.66K_s$. However, for long times when gravity is dominant, A must be equal to K_s .

Differentiation of Equation 7.13 yields the infiltration rate, or

$$i_c = 1/2St^{-0.5} + A \quad (7.13b)$$

Using (Equation 7.13b) to express t as a function of i_c and substituting in Equation 7.13a yields $I(i)$, or

$$I = \frac{S^2(i - A/2)}{2(i - A)^2} \quad (7.13c)$$

For positive pressure heads, the correction of Equation (7.11a) to S can be applied. In many cases, values of S and A are obtained from curve fitting. We note that for gravity-free flow, the PH solution without the gravity term corresponds with the Boltzmann solution for horizontal flow in Equation 7.9.

7.3.2 Parlange et al. (PA) Model

Parlange et al. (1982) proposed the following universal model:

$$t = \frac{S^2}{2K_1^2(1-\delta)} \left[\frac{2K_1}{S^2} I - \ln \frac{\exp\left(\frac{2\delta K_1 I}{S^2}\right) + \delta - 1}{\delta} \right] \quad (7.14a)$$

assuming that K_0 is negligible small so that the ΔK in Parlange et al. (1982) is equal to K_1 . The value of the parameter δ can be chosen to approach various closed-form solutions. For example, Equation 7.14 reduces to the GA solution for δ equal to zero. Its value is a function of $K(\theta)$, and is defined by (Parlange et al., 1985) as

$$\delta = \frac{1}{\theta_s - \theta_0} \int_{\theta_0}^{\theta_s} \frac{K_s - K(\theta)}{K_s} d\theta \quad (7.14b)$$

An approximate value of $\delta = 0.85$ was suggested by Parlange et al. (1982) for a range of soil types. After taking the time derivative of I , the following $i(I)$ -relationship can be derived (Espinoza, 1999):

$$i = K_1 + \delta K_1 \left(1 - \exp\left(\frac{2I\delta K_1}{S^2}\right) \right)^{-1} \quad (7.14c)$$

Because this is based on integration of the water-content based form of Richards' equation, the theoretical scope of Equation 7.14 is limited to non-ponded conditions. A generalization of Equation 7.14 to include ponded conditions without affecting the value of S was introduced by Parlange et al. (1985). Haverkamp et al. (1990) presented a modification of their model to include upward water flow by capillary rise. The

resulting infiltration model contained six physical parameters, in addition to the interpolation parameter δ (Haverkamp et al., 1990). Both the PA and the Haverkamp model require an iterative procedure to predict $I(t)$. Barry et al. (1995) presented an explicit approximation to the Haverkamp et al. (1990) model, retaining all six physical parameters (BA model):

$$I = K_1 t + \frac{S^2 + 2K_1 h_{\text{surf}} \Delta\theta}{2\Delta K} \left[t^* + 1 - \gamma - \exp\left(\frac{-6(2t^*)^{0.5}}{6 + (2t^*)^{0.5}} - \frac{2t^*}{3}\right) \right. \\ \left. + \frac{\gamma}{1+t^*} \left\{ \exp\left(-\frac{2t^*}{3}\right) [1 - (1-\gamma)^8 t^{*2.5}] + (2\gamma + t^*) \ln\left(1 + \frac{t^*}{\gamma}\right) \right\} \right] \quad (7.15a)$$

where

$$t^* = \frac{2t(\Delta K)^2}{S^2 + 2K_1 h_{\text{surf}} \Delta\theta}, \quad \gamma = \frac{2K_1(h_{\text{surf}} + h_a)\Delta\theta}{S^2 + 2K_1 h_{\text{surf}} \Delta\theta} \quad (7.15b)$$

and h_a denotes the absolute value of the soil-water pressure head at which the air phase becomes discontinuous upon wetting. By defining

$$B_1 = (h_{\text{surf}} + h_a)\Delta\theta \quad \text{and} \quad B_2 = \frac{2}{S^2 + 2K_1 h_{\text{surf}} \Delta\theta} \quad (7.15c)$$

Equation 7.15a can be expressed by only four fitting parameters K_0 , K_1 , B_1 , and B_2 . The Clausnitzer et al. (1998) study concluded that both the PA and BA models described infiltration equally well, however, the BA model, while most advanced, was not as well suited to serve as a fitting model due to non-uniqueness problems caused by the larger number of fitting parameters.

7.3.3 Swartzendruber (SW) Model

Swartzendruber (1987) proposed an alternative series solution that is applicable and exact for all infiltration times, and also allows for surface ponding. Its starting point is similar to the GA approach, however, its derivation does not require a step function for the wetted soil profile. Its simplified form is a three-parameter infiltration equation (SW model)

$$I = K_1 t + \frac{S}{A_0} (1 - \exp(-A_0 t^{1/2})) \quad (7.16)$$

where A_0 is a fitting parameter of which its value depends on the surface water content, θ_1 . As $A_0 \rightarrow 0$, it reduces to a form of the Philip (1957b) model with K_1 as the coefficient of the linear term, and for which dI/dt approaches K_1 as $t \rightarrow \infty$. As for the GA model, the S-term can be corrected using Equation (7.11a) to account for ponded conditions.

7.3.4 Empirical Infiltration Equations

For most of these types of infiltration equations the fitting parameters do not have a physical meaning and are evaluated by fitting to experimental data only. However, in many cases, the specific form of the infiltration equation is physically intuitive. For example, the empirical infiltration equation by Horton (1940) is one of the most widely-used empirical infiltration equations. It considers infiltration as a natural “exhaustion process,” during which infiltration rate decreases exponentially with time from a finite initial value, $i_c|_{t=0} = (\alpha_1 + \alpha_2)$, to a final value, $\alpha_1 = K_1$. Accordingly, cumulative infiltration I (L) is predicted as a function of time t (HO model):

$$I = \alpha_1 t + \frac{\alpha_2}{\alpha_3} [1 - \exp(-\alpha_3 t)] \quad (7.17)$$

with the soil parameter $\alpha_3 > 0$, representing the decay of infiltration rate with time. In Equation 7.17, α_1 can be associated with the hydraulic conductivity (LT^{-1}) of the wetted soil portion, K_1 , for $t \rightarrow \infty$.

Another simple empirical infiltration equation is the Kostiakov (1932) model (KO):

$$i = at^{-b} \quad (7.18)$$

Clearly, this equation will not fit infiltration data at long times, as it predicts zero infiltration rate as $t \rightarrow \infty$. The value of a should be equal to the infiltration rate at $t = 1$, and $0 < b < 1$.

Mezencev (1948) proposed another infiltration model, and modified the KO model by including a linear term with a coefficient β_1 , so that $\beta_1 \rightarrow K_1$ for $t \rightarrow \infty$, provided $0 < \beta_3 < 1$ and $\beta_2 > 0$ (ME model)

$$I = \beta_1 t + \frac{\beta}{1 - \beta} t^{(1-\beta_3)} \quad (7.19)$$

Other models include the Soil Conservation Service (SCS) method and the Holtan solution (Kutilek and Nielsen, 1994; Espinoza, 1999). The only parameter needed for the SCS method (SCS, 1972) is the curve number (CN), which is available for most soil types in the United States, from which a soil water storage estimate is determined. The cumulative infiltration, I , is subsequently estimated from the measured precipitation and estimated runoff.

7.4 Infiltration Measurement Methods

Infiltration measurements can serve various purposes. In addition to characterizing infiltration, for example, to compare infiltration between different soil types, or to quantify macropore flow, infiltration is often measured to estimate the relevant soil hydraulic parameters from the fitting of the infiltration data to a specific infiltration model. This is generally known as inverse modeling. Infiltration is generally measured using one of three different methods: a sprinkler method, a ring infiltration method, or a permeameter method. The sprinkler method is mostly applied to determine the time of ponding for different water application rates, whereas the ring infiltrometer method is used when the infiltration capacity is needed. The permeameter method provides a way to measure infiltration across a small range of h -values ≤ 0 . A general review of all three methods was recently presented by Smettem and Smith in Smith et al. (2002), whereas a comparison of different infiltration devices using seven criteria was presented by Clothier (2001).

Rainfall sprinklers or rainfall simulators are also sprinkler infiltrometers, but they are typically used to study runoff and soil erosion (e.g., Morin et al., 1967). They mimic the rainfall characteristics (e.g., kinetic energy) of natural storms, specifically the rainfall rate, rainfall droplet size distribution, and drop velocity. Most of these devices measure infiltration by subtracting runoff from applied water. Using a range of water application rates, infiltration measurements can be used to determine the $i(I)$ curve for a specific soil type, with specific soil hydraulic properties such as K_s or S . Various design parameters for many developed rainfall simulators, specifically nozzle systems, were presented by Peterson and Bubenzier (1986). A portable and inexpensive simulator for infiltration measurements along hillslopes was developed by Battany and Grismer (2000). This low-pressure system used a hypodermic syringe needle system to form uniform droplets at rainfall intensities ranging from 20 to 90 mm/h.

Ring infiltrometers have historically been used to characterize soil infiltration by determining the infiltration capacity, i_c . A ring is carefully inserted in the soil so that water can be ponded over a known area. As a constant head is required, a constant water level is maintained by either manually adding water with a measuring stick in the infiltration to measure the depth of ponded water, by using a Mariotte tube, or by a valve connected to a float that closes at a predetermined water level. Measurements are usually continued until the infiltration rate is essentially constant. Water seepage around the infiltrometer is prevented by compaction of the soil around and outside of the infiltrometer. Multi-dimensional water flow under the ring is minimized by pushing the ring deeper into the soil, or by including an outer buffer

ring. In the latter case, the soil between the two concentric rings is ponded at the same depth as the inner ring, to minimize lateral flow directed radially outwards. The deviation from the assumed one-dimensionality depends on ring insertion depth, ring diameter, measurement time, and soil properties such as its hydraulic conductivity and the presence of the restricting soil layers. A sensitivity analysis on the diverging flow of infiltrometers was presented by Bouwer (1986) and Wu et al. (1997).

Permeameters are generally smaller than infiltrometers and allow easy control of the soil water pressure head at the soil surface. Generally, multi-dimensionality of flow must be taken into account, using Wooding's (1968) equation for steady flow (Q_∞ , L^3/T) from a shallow, circular surface pond of free water, or

$$Q_\infty = K_s \left(\pi r_0^2 + \frac{4r_0}{\alpha} \right) \quad (7.20a)$$

The first and second terms in parentheses denote the gravitational and capillary components of infiltration and α denotes the parameter in Gardner's unsaturated hydraulic conductivity function (1958)

$$K(h) = K_s \exp(\alpha h) \quad (7.20b)$$

In this model of the so-called Gardner soil, the macroscopic capillary length, λ_c , is equivalent to $1/\alpha$. The basic analysis for most permeameter methods relies on Wooding's solution. An extensive review of the use of permeameters was presented by Clothier (2001), including the tension infiltrometers and disk permeameters, by which the soil water pressure at water-entry is controlled by a bubble tower. Their use is relatively simple, and is based on analytical solutions of steady-state water flow. The permeameter method is economical in water use and portable. The soil hydraulic properties (S and K), in an inverse way, can be inferred from measurements using (7.1) both short and long-time observations, (7.2) disks with various radii, or (3) using multiple water pressure heads. Transient solutions of infiltration may be preferable, as it allows analysis of shorter infiltration times, so that the method is faster and likely will better satisfy the homogeneous soil assumption. Differences between one- and three-dimensional solutions for transient infiltration were analyzed by Haverkamp et al. (1994), Vandervaere et al. (2000), and Smith et al. (2002) from multi-dimensional numerical modeling analysis. These effects were reported to be small if gravity effects were included. Nowadays, permeameters are most often applied to estimate the soil's hydraulic characteristics in an inverse way, by fitting infiltration data to analytical solutions. The so-called mini-disk infiltrometer is available for simple and fast characterization of soil surface infiltration (<http://www.decagon.com/instruments/infilt.html>).

7.5 Spatial Variability Considerations

Although measurement scale is variable, all of the methods presented in Section 7.4 are small-scale measurements in the range of 0.2–1.0 m. This is relevant for irrigation purposes, especially for micro-irrigation applications. Yet, infiltration information is often needed for much larger spatial scales, at the pedon scale, hillslope, and watershed scale. Very little work has been done relating the infiltration process to measurement or support scale. Exceptions are the studies by Sisson and Wierenga (1981) and Haws et al. (2004), who measured steady-state infiltration at three spatial scales, ranging from 5 to 127 cm diameter infiltrometer rings. Their results showed that much of the larger-scale infiltration occurs through smaller-scale regions, and that the spatial variability of infiltration decreased as the measurement scale increased. Thus, in general we find that the process of infiltration might vary with spatial scale, and that larger spatial scales are required to estimate representative infiltration characteristics across a typical landscape.

Many field studies have dealt with the significant areal heterogeneity of soil hydraulic properties, and particularly that of the saturated hydraulic conductivity, K_s (Nielsen et al., 1973). The heterogeneity in K_s is recognized to have a major effect on unsaturated flow, and leading to significant variation in local infiltration. In general, accounting for areal heterogeneity leads to shorter ponding times and to a

more gradual decrease of the infiltration flux with time (Smith and Hebbert, 1979; Sivapalan and Wood, 1996). To characterize spatial variable infiltration rates, Sharma et al. (1980) measured infiltration with a double-ring infiltrometer at 26 sites in a 9.6 ha watershed. The infiltration data were fitted to the PH infiltration Equation 7.13a, and fitting parameters S and A were scaled to express their spatial variability and to describe the ensemble-average or composite infiltration curve of the watershed. A simpler but similar scaling technique for infiltration data was presented by Hopmans (1989), who measured transient infiltration at 50 sites along a 100 m transect. Data were fitted to both the PH and a modified KO model that includes an additional constant c as a second term in Equation 7.19. This paper showed that spatial variability of infiltration can be easily described by the probability density function of a single scaling parameter, to be used for applications in Monte Carlo simulation of watershed hydrology, as suggested for the first time by Peck et al. (1977). For application at the field scale, the so-called one point method was presented by Shepard et al. (1993) to estimate furrow-average infiltration parameters of PH Equation 7.13a, across a furrow-irrigated agricultural field. They used the volume-balance principle from advance time to the field end, inflow rate, and flow area measurements.

For modeling surface hydrology, by subtracting the infiltration rate, $i(t)$, from the rainfall rate, $r(t)$, it is possible to estimate spatial and temporal distributions of rainfall excess or runoff. The influence of spatially heterogeneity in rainfall and soil variability on runoff production was studied by Sivapalan and Wood (1986), from an analytical solution of infiltration and by making use of the IDA approximation. Statistical characteristics of ponding time and infiltration rate were presented for two cases, one with a spatially variable soil with a lognormal K_s distribution and uniform rainfall, and the other for a homogeneous soil with spatially variable rainfall. Among the various results, this study concluded the ensemble infiltration approach is biased for spatially variable soils. Their results also showed that the cumulative distribution of ponding times or proportion of ponded area is an excellent way of analyzing mean areal infiltration. Moreover, the spatial correction of infiltration rate is time-dependent and varies depending on the correlation lengths of rainfall and soil K_s . This study neglected the effects of surface water run-on, as caused by accumulated water upstream, running on to neighboring areas thereby contributing locally to infiltration. A quantitative analysis of soil variability effects on watershed hydraulic response that included surface water interactions such as run-on, was presented by Smith and Hebbert (1979), through analysis of the effects of deterministic changes of infiltration properties in the direction of surface water flow, using a kinematic watershed model. In a subsequent study by Woolhiser et al. (1996), it was clearly demonstrated that runoff hydrographs along a hillslope are significantly affected by spatial trends in the soil's saturated hydraulic conductivity. We expect to collect important new information can be collected by linking this interactive modeling approach with remote sensing and GIS tools. In addition to the soil's infiltration characteristics and its variability, surface runoff is controlled by spatial and temporal patterns in rainfall (Milly and Eagleson, 1988; Woolhiser and Goodrich, 1988). A detailed analysis and review of the control of spatially variable hydrologic properties on overland flow is presented by Govenderaju et al. (this issue).

Yet another concern regarding non-ideal infiltration, causing spatially variable infiltration at small spatial scales comes from the presence of water-repellent or hydrophobic soils. Since the 1980s much new research and findings have been presented, improving the understanding of the underlying physical processes and its relevance to soil water flow and water infiltration (DeBano, 2000; Wang et al., 2000).

7.6 Infiltration into Sealed or Crusted Soils

Seal formation is a complex phenomenon dominated by a wide variety of factors involving soil properties, rainfall characteristics, and local water flow conditions. Sealing involves the formation of a thin, dense layer of very low hydraulic conductivity at the soil surface. Soil surface sealing can have severe agricultural, hydrological, and environmental effects. It decreases the infiltration rate, thereby reducing plant-available water to the plant in the root zone, diminishing the natural recharge of aquifers, and increasing runoff and soil erosion. Two types of rainfall-induced soil seals can be identified (i) structural seals that are

directly related to rainfall through the impact of raindrops and sudden wetting, and (ii) depositional or sedimentary seals that are indirectly related to rainfall as it results from the settling of fine particles carried in suspension by the runoff in soil depressions. A recent review on concepts and modeling of rainfall-induced soil surface sealing was presented by Assouline (2004). The problem of the calculation of infiltration rate in crusted soils was first addressed by Hillel and Gardner (1969, 1970). They presumed that a sealed soil can be modeled as a uniform soil profile capped with a saturated thin layer of low permeability and they prescribed constant physical properties such as the saturated hydraulic conductivity. Their simplified solution was based on the Green and Ampt (1911) approach, and assumed constant water content (or suction) at the interface between the seal and the soil beneath. Variations and extensions of this basic approach included the simulation of infiltration with time-dependent seal hydraulic conductivity functions (Vandervaere et al., 1998).

Other studies such as those by Baumhardt et al. (1990) and Assouline and Mualem (1997) include the dynamic modeling of seal formation by assigning time-dependent physical properties to the seal that depend on soil and rainfall characteristics. The performance of the dynamic model of Assouline and Mualem (1997) is shown in Figure 7.4, where the predicted infiltration curves during seal formation under three different rainfall intensities, 20, 40, and 90 mm/h, are depicted. For the 90 mm/h rainfall case, the predicted infiltration rates can be compared to the one measured by Baumhardt (1985). The direct effect of the presence of the impeding seal layer at the soil surface is to reduce ponding time and infiltration rate during rainfall (compare the infiltration curves for the unsealed and the seal formation cases at the 40 mm/h rainfall intensity). As rainfall intensity increases, ponding time decreases, the infiltration rate curve decreases more rapidly, whereas the final infiltration rate increases. The latter can be caused by soil surface seal destruction after prolonged raindrop impact (Seginer and Morin, 1970) or reduction of seal thickness by erosion (Baumhardt, 1985). Other possible causes are the protection of the surface seal by the accumulated water layer on the soil surface (Schultz et al., 1985) as well as the reduction of the thickness of the saturated zone within the seal layer as the rainfall intensity increases (Mualem et al., 1993; Assouline and Mualem, 2001).

Two different approaches were followed in applying such a solution to flow processes in sealed soils or during seal formation. In one approach there is a gradual change in the soil water retention and hydraulic conductivity functions according to a prescribed exponential distribution of the seal bulk density such as done by Mualem and Assouline (1989). The other approach is to replace the nonuniform seal by a uniform equivalent layer, thereby generating a flow domain consisting of two uniform flow layers. The

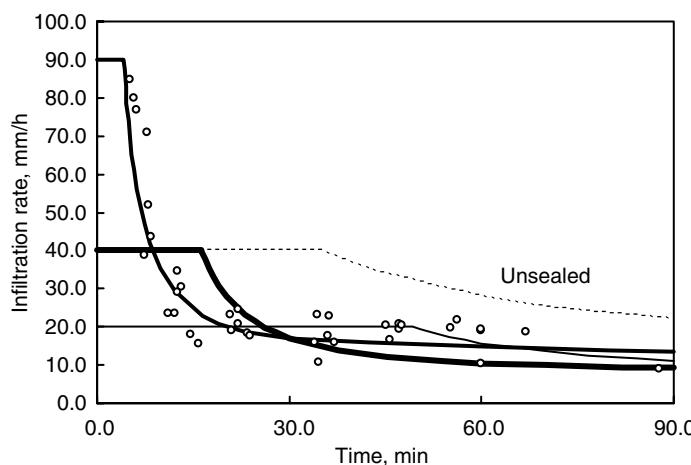

FIGURE 7.4 Infiltration curves predicted by the dynamic model of Assouline and Mualem (1997) for rainfall intensities of 20, 40 and 90 mm/h (solid lines), the corresponding infiltration curve for the unsealed soil case at 40 mm/h rainfall (dashed line); and the infiltration rates at 90 mm/h rainfall as measured by Baumhardt (1985).

effect of these two approaches was evaluated by Assouline and Mualem (2001). It appears that during seal formation, the approach adopted to represent the seal layer in the flow system has only a slight little effect on the infiltration curve. Still, a significant difference between the two approaches exists in terms of the soil water content distribution with depth, especially at the soil surface. However, in the case of a fully developed seal with constant properties, the approach adopted to represent the seal layer in the flow system has a much more significant effect on the infiltration curve. The use of an equivalent-uniform seal-layer causes a significant increase in the ponding time, assuming a uniform seal leads to overestimating the infiltration around ponding time. Therefore, approximating seals by equivalent uniform layers can induce errors in predicting the runoff hydrograph from bare fields or small bare watersheds where surface sealing predominates.

Under natural conditions, rainfall-infiltration relationships of bare soils at the field scale are mostly determined by the combined effect of soil seal formation and areal heterogeneity of soil hydraulic properties. The combined effect of these two factors on infiltration was presented by Assouline and Mualem (2002). Using the conceptual model of the non-uniform seal layer (Mualem and Assouline, 1989), this sensitivity study simulated the effect of areal variability of the initial soil properties on the seal properties. Subsequently, the dynamic model of seal formation (Assouline and Mualem, 1997) was applied to simulate the effect of the areal heterogeneity in the soil and the seal properties on the infiltration curve. The effect of areal heterogeneity on infiltration was estimated for a rainfall intensity of 40 mm/hr^{-1} and duration of 120 min. The infiltration curves for the unsealed case and during seal formation were simulated for a uniform field represented by mean values of the soil parameters and a heterogeneous one with all soil parameters being spatially distributed. The results are depicted in Figure 7.5, along with the corresponding measured infiltration rates in the packed soil columns (Baumhardt, 1985). For both the unsealed and the soil sealing case, the simulated infiltration curves corresponding to the uniform soil assumption fit the measured data, indicating that both the soil properties and the dynamic model represent the uniform conditions relatively well. For the unsealed field, areal heterogeneity of the soil properties has a considerable effect on infiltration. The ponding time is drastically reduced from 35 to 4 min, and the infiltration curve decreases more slowly. The maximal difference between the infiltration rates for the uniform and the heterogeneous fields is obtained at the time where ponding is estimated to occur for the uniform field case.

These trends are in agreement with the findings of Smith and Hebert (1979). In addition to the drastic reduction of the ponding time, areal heterogeneity in soil properties increases the steady infiltration rate reached after long rainfall. Similar trends are obtained when a seal develops at the soil surface, with some differences. The reduction of the ponding time when areal heterogeneity is accounted for is not as drastic as it is in the case of the unsealed soil. The interesting point here is that while the soil surface sealing significantly reduces the ponding time in the uniform field as expected, it does not affect the ponding time of the heterogeneous field. This is so as since part of the heterogeneous field has much lower hydraulic conductivity than that of the uniform field, and this generates the early runoff. This remains valid also when surface sealing is initiated.

Consequently, runoff will appear in the heterogeneous field about the same time, and is hardly affected by seal formation. Also, a higher quasi-steady infiltration rate is calculated in the case of the heterogeneous field during seal formation. Figure 7.5 shows that accounting for the areal heterogeneity in soil properties reduces the ponding time and increases the final steady infiltration rate, both for the unsealed case as well as under sealing conditions. Also, it seems that the relative effects of the areal heterogeneity on the ponding time and on the steady infiltration rate are both reduced when a seal develops at the soil surface. However, additional process occurring at the field scale, like run-on or depositional seal layers in surface depressions, can introduce some changes in these results.

7.7 Summary and Conclusions

Although important and seemingly simple, infiltration is a complicated process that is a function of many different soil properties and rainfall characteristics. In addition to rainfall intensity and duration and

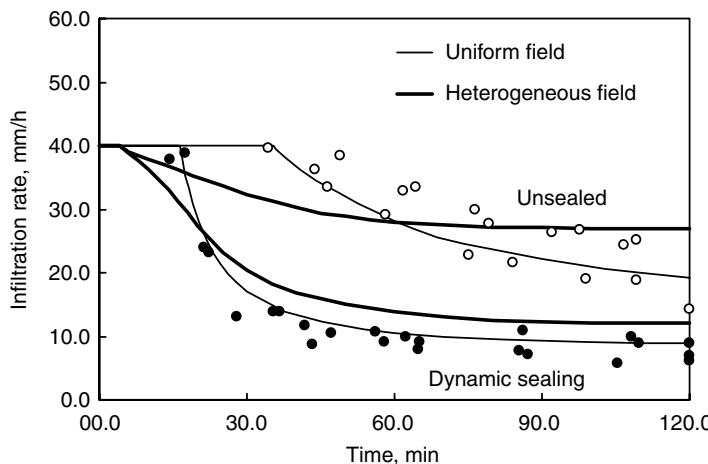

FIGURE 7.5 The infiltration curves simulated for a uniform (thin line) and a heterogeneous field (thick line) for the unsealed case and during seal formation, along with the corresponding measured infiltration rates in packed soil columns. From Baumhardt, R.L., 1985. The effect of rainstorm characteristics on soil sealing and filtration. Ph.D. Thesis, Mississippi State University, Mississippi State.

the soil physical factors such as soil water retention and hydraulic conductivity, infiltration is controlled by the initial water content, surface sealing and crusting, hydrophobicity, soil layering, and the ionic composition of the infiltrated water. Many relatively simple infiltration equations have been proposed and they are successfully used to characterize infiltration. Other physically-based analytical solutions have been presented that can potentially be used to predict infiltration. However, in practice this is difficult as the soils physical characteristics near the soil surface are time-dependent because of soil's structural changes and naturally high soil spatial variability. Alternatively, infiltration is often measured to estimate the relevant soil hydraulic parameters from the fitting of the infiltration data to a specific infiltration model by inverse modeling, such as by using permeameters.

Whereas most infiltration measurement techniques and infiltration models apply to relatively small spatial scales, infiltration information is often needed at the watershed and hill-slope scale. Yet, it has been shown that much of the larger scale infiltration occurs through smaller scale regions, for example because infiltration is largely controlled by spatial variations of the soil's saturated hydraulic conductivity. Infiltration and runoff predictions are even more complicated because of the surface soil's seal formation that is controlled by the impact of rain drops and type of vegetation cover. In general we find that the process of infiltration might vary with spatial scale, and that measurements at larger spatial scales are required to estimate representative infiltration characteristics across the hydrologic basin. We expect improved solutions to infiltration across scales from the field to the basin scale, using rapidly developing techniques such as remote sensing, GIS, and new measurement devices.

Further Information

Although this chapter deals specifically with infiltration, the basic physical concepts are treated in the following texts of unsaturated water flow:

- Hillel (2004) is a generally-applicable textbook on soil physics, and includes comprehensive chapters on water flow in field soils, including infiltration and redistribution.
- Jury et al. (1991) provides additional material related to infiltration, including a treatment of various infiltration equations.
- Kutilek and Nielsen (1994) present an in-depth and extensive review of the various infiltration models and associated assumptions.
- Soil Science Society of America (1996) is a Glossary of Soil Science Terms, defining soil parameters and properties used in this chapter.
- Stephens (1996) introduces the concept of vadose zone hydrology, blending soil physics with hydrogeology.
- Warrick (2002) addresses the most significant topics of contemporary soil physics, written by leading scientists in the respective topics.

8.1 Introduction

The processes governing water movement in natural fields are influenced by different factors such as rainfall intensity and duration, infiltration rates, catchment area, slope, and soil cover. Among these, a key role is played by infiltration, the process of water entering the soil (see Chapter 7). Hillslope hydrologic processes are strongly influenced by the patterns of infiltration rate through space and time (Freeze, 1980). The Hortonian mode of overland flow (Horton, 1933; Rubin and Steinhardt, 1963) is generated at a point on a hillslope when the rainfall intensity exceeds the infiltration rate, and surface ponding is initiated. A second mechanism, as described by Dunne (1978), requires surface saturation to occur from a rising water table over a shallow impeding layer; ponding and overland flow occur when no further soil moisture storage is available. The Horton mechanism is more common on upslope areas whereas the Dunne mechanism is generally observed in near-channel wetlands. While several other streamflow

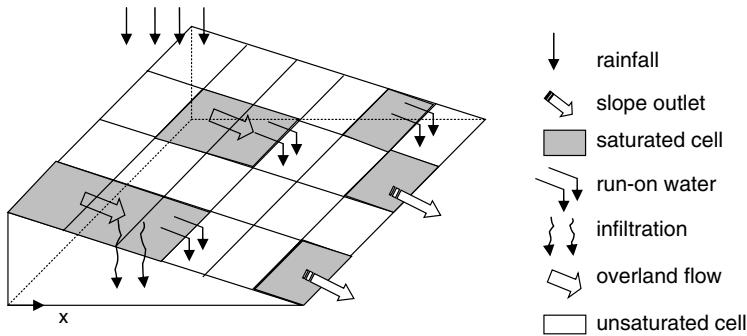

FIGURE 8.1 Schematic representation of the flow mechanisms that take place on a hillslope with the inclusion of run-on. (Adapted from Corradini et al., 1998, *J. Hydrol.*, 204:52–67.)

generation mechanisms exist (see Chow et al., 1988; Dingman, 2002), the focus of this chapter is on Hortonian runoff generation.

As mentioned in Chapter 6, natural watersheds exhibit spatial heterogeneity in topography, surface roughness, vegetation, and soil infiltration characteristics. Field measurements of soil hydraulic properties (Nielsen et al., 1973; Loague and Gander, 1990) and infiltration characteristics (Grah et al., 1983; Govindaraju et al., 1996) have shown that these properties exhibit a high degree of spatial variability, and several studies have demonstrated that this spatial variability has a significant effect on the generation of Hortonian runoff (Smith and Hebbert, 1979; Woolhiser and Goodrich, 1988; Corradini et al., 1998). Smith and Goodrich (2000) observed that ponding does not occur instantaneously over an entire field as conceptualized in many models because of spatial heterogeneity.

When ponded water is allowed to move in response to slope as overland flow, an important process called “run-on” manifests itself. The run-on process can be defined as the infiltration of surface water that, as it moves downslope, encounters areas where moisture deficit has not yet been satisfied. The infiltration rate here is larger than the runoff generated from upslope cells. In such cases, water available for infiltration includes rainfall and water supply from upslope areas. As seen in the schematic in Figure 8.1, run-on occurs when surface runoff from upstream cells infiltrates in pervious downstream cells. When the spatial variation of infiltration properties is taken into account, the run-on effect can be very significant in some cases. The goal of this chapter is to identify conditions when run-on is or is not significant, and to describe field-scale infiltration for both cases in a simple manner.

The importance of run-on has been documented in a few studies, but has largely been ignored in physically-based models. Run-on was first incorporated in an analysis of infiltration and Hortonian surface runoff by Smith and Hebbert (1979). They employed Monte Carlo simulations to analyze the effects of random distribution of soil infiltration properties on the hydrologic performance of catchments areas. The time for the initiation of hillslope hydrograph as well as runoff volume were strongly influenced by the inclusion of run-on even with deterministic variation in the soil saturated hydraulic conductivity, K_s . Saghafian and Julien (1995) carried out an extensive study of Hortonian overland flow with horizontal variability of saturated hydraulic conductivity K_s . They incorporated the run-on process utilizing two-dimensional finite-difference solutions of the diffusive wave approximation for surface flow with interactive infiltration described by the Green-Ampt equation. Again, hillslope hydrographs were markedly different when run-on effect was included from those when run-on was ignored. The relative placement of high hydraulic conductivity regions in the field was found to have a dramatic effect on hillslope hydrographs. Woolhiser et al. (1996) showed that runoff hydrographs are strongly affected by trends in hydraulic conductivity, particularly for small runoff events. They also demonstrated that run-on has major impacts on hydrograph peaks, runoff volumes, and time to peak. Corradini et al. (1998) observed the effects of run-on on Hortonian overland flow generated at the hillslope scale under conditions of horizontal heterogeneity of K_s . They concluded that the run-on process acted to reduce the sensitivity of the average overland flow hydrograph to the level of spatial correlation of K_s , which has found to be very

low, and that there exists a range of storm characteristics for which a deterministic formulation of effective K_s is acceptable. These conclusions were further confirmed by Nahar et al. (2004), where an extensive set of Monte Carlo simulations was used to examine infiltration and Hortonian runoff hydrographs both with and without run-on. They showed that the degree of spatial correlation in K_s also influenced the variance of field scale infiltration rate and overland flow, and this variance was higher for no run-on.

Even though several models describe infiltration into vertically-homogeneous soils “at a point” fairly accurately (see Chapter 7), upscaling of these models to the field scale has been complicated even in the absence of run-on. Most soils exhibit a high degree of spatial variability in their infiltration properties, particularly in the saturated hydraulic conductivity of the soil (Nielsen et al., 1973; Russo and Bresler, 1982; and others). The infiltration process, as described by these models, is highly nonlinear, so that “effective parameters” cannot be defined easily. The problem is aggravated further if macropore flow is present (Stillman et al., 2006). There appears to be a general consensus that the saturated hydraulic conductivity exhibits the maximum variability among the soil hydraulic properties that influence infiltration, and that this variability can be represented by a spatially-correlated lognormal random field for most practical purposes (Dagan and Bresler, 1983).

Researchers have followed a two-pronged approach to address the problem of describing field scale infiltration with or without run-on. The first approach has primarily relied on Monte-Carlo simulation techniques (Sharma and Seely, 1979; Smith and Hebbert, 1979; Maller and Sharma, 1981; Woolhiser and Goodrich, 1988), and are described in Chapter 14. Despite requiring significant computer effort, Monte-Carlo simulations are sometimes the only recourse when the governing equations are such as to render the mathematical analysis intractable as is the case when run-on is included. Such simulations can often be used to parameterize simple expressions for practical use (Smith and Goodrich, 2000; Corradini et al., 2002; Morbidelli et al., 2006).

Alternatively, many researchers have opted for providing simplified (analytical or semi-analytical) solutions. Maller and Sharma (1981, 1984) obtained distributions of time to surface ponding, infiltration rates, and cumulative infiltration volumes based on a known distribution of saturated hydraulic conductivity values. Hawkins and Cundy (1987) demonstrated a relationship between long term field scale infiltration and rainfall for spatially variable soils. Sivapalan and Wood (1986) used the two-term Philip equation to find the probabilistic distribution of ponding times, and subsequently presented approximate expressions for areal mean and variance of local infiltration rates. When macropore flow is important in determining infiltrated water, then simplified approaches may be utilized (Arabi et al., 2006; Stillman et al., 2006). Govindaraju et al. (2001) developed semi-analytical solutions to address the problem of field-scale infiltration under correlated hydraulic conductivity fields, and for time dependant rainfall. Corradini et al. (2002) presented an empirical analysis for field-scale infiltration and overland flow including the effect of run-on. Nahar et al. (2004) examined a wide range of cases of variability in K^* ($= K_s/r$, with r being rainfall intensity assumed uniform in space) and provided a framework for developing and solving averaged-equations for infiltration and overland flow when run-on can be neglected. Most of these studies utilized Monte-Carlo simulations to support their theoretical findings. However, none of these studies established definitive criteria as to when run-on could be neglected. In recent years, researchers (Morbidelli et al., 2006) have expressed interest in the problem of representing the effects of coupled spatial heterogeneity of both r and K_s on hydrological response.

8.2 Characterization of Spatial Variability

The generation of Horton runoff depends on both rainfall and soil infiltration properties, and the run-on process is influenced by spatial variation in these quantities. These are described briefly.

8.2.1 Spatial Variability of Saturated Conductivity

The saturated hydraulic conductivity, K_s , is treated as a spatial random field, while other soil parameters such as residual water content, θ_r , saturated water content, θ_s , and capillary head gradient, ψ (a parameter

in the Green-Ampt infiltration model), are assumed constant. The justification for this assumption is that K_s changes over several orders of magnitude for a single field, while the other parameters vary over a much narrower range (Dagan and Bresler, 1983). Previous statistical analysis (Russo and Bresler, 1982) indicated that the impact of the variability of other parameters is indeed limited compared to the influence of variability exhibited by K_s . The probability distribution of K_s has long been treated as a correlated log-normal random field based on several experimental studies (see e.g., Law, 1944; Bulnes, 1946; Warren and Price, 1961; Willardson and Hurst, 1965; McMillan, 1966; Rogowski, 1972; Nielsen et al., 1973; Baker and Bouma, 1976; Sharma et al., 1980, 1987; Burden and Selim, 1989; Govindaraju et al., 1996).

In line with previous studies, univariate probability density function of K_s is given by:

$$f_{K_s}(k) = \frac{1}{\sqrt{2\pi}\sigma_Y k} \exp\left[-\frac{(\ln k - \mu_Y)^2}{2\sigma_Y^2}\right] \quad (8.1)$$

where $Y = \ln(K_s)$ with mean μ_Y and variance σ_Y^2 . The isotropic autocovariance function of Y is assumed as

$$\Gamma_Y(\delta) = E[Y(x_1)Y(x_2)] = \sigma_Y^2 \exp\left(-\frac{\delta}{L_c}\right), \quad \delta = |x_1 - x_2| \quad (8.2)$$

where $E[\cdot]$ stands for the expectation operation, x_1 and x_2 denote vectorial spatial locations, δ denotes separation distance, and L_c determines the correlation length.

8.2.2 Spatial Variability of Rainfall

In addition to the heterogeneity of soil hydraulic properties, experimental studies show that rainfall also exhibits spatial variability at a larger scale than K_s (Goodrich et al., 1995; Krajewski et al., 2003). There is interaction between the effects of the variability of r and K_s on the areal-average infiltration and generation of surface runoff that needs to be accounted for in models. Studies which considered a coupled spatial variability of r and K_s were carried out by Wood et al. (1986), Castelli (1996), and Govindaraju et al. (2006). Govindaraju et al. (2006) and Morbidelli et al. (2006) argue that a uniform distribution of rainfall between the limits of r_{\min} and $r_{\min} + R$ allows for a reasonable representation of spatial variability of rainfall rate.

8.2.3 Generation of Random Fields

Several algorithms are available for generation of correlated random fields (see Chapter 14). Among these, the turning bands method (Mantoglou, 1987; Tompson et al., 1989) has been popular for the generation of random fields of saturated hydraulic conductivity for use in Monte-Carlo simulations. The turning bands method is a multidimensional random number generator designed to simulate spatially correlated random fields (Mejia and Rodriguez-Iturbe, 1974; Journel and Hujibregts, 1978; Delhomme, 1979; Smith and Freeze, 1979; Smith and Schwartz, 1981; Clifton and Neuman, 1982; Brooker, 1985; Miller and Borgman, 1985; Frankel and Clayton, 1986; Ababou et al., 1988). The method performs simulations along uni-dimensional lines instead of synthesizing the multidimensional field directly and the method is more efficient than, for instance, the LU decomposition algorithm (Gotway, 1994; Gotway and Rutherford, 1994). Tompson et al. (1989) provided new recommendations for accurate and efficient implementation of the three-dimensional algorithm.

Following Dagan and Bresler (1983), two-dimensional random fields over the soil surface (see Figure 8.1) of K_s and r may be also generated through the theory of similar media. Specific realizations of K_s are obtained by assuming a log-normal probability density function (pdf) and fixing the mean value $\langle K_s \rangle$ and the coefficient of variation $cv(K_s)$. Since previous studies (Corradini et al., 1998; Govindaraju et al., 2001) have shown that spatial correlation of K_s has a minor influence on average overland flow hydrograph and expected areal-average infiltration, K_s values may be assumed to be spatially independent

for studying the ensemble mean behavior. Because of the one-dimensional flow paths along the x -direction and in the absence of a spatial correlation structure for K_s and r along the y -direction, a one-dimensional generation would suffice in principle. However, a two-dimensional representation has been adopted in several studies (Govindaraju et al., 2006; Morbidelli et al., 2006) because it contributes to reduction in sampling statistical errors.

Similarly, by fixing the mean value of rainfall rate, $\langle r \rangle$, and the coefficient of variation, $cv(r)$, two-dimensional realizations of r corresponding to a uniform pdf may be carried out. Govindaraju et al. (2006) conducted a comparative analysis of the behavior of the expected areal-average infiltration $\langle I \rangle$ by adopting a uniform and a lognormal pdf for r and found that they produced substantially similar results, but the uniform pdf assumption leads to a simpler mathematical representation of $\langle I \rangle$.

8.3 Numerical Simulation Results

The role of run-on has been primarily evaluated numerically through simulations for lack of detailed experimentation. To clarify the role of run-on, a one-dimensional representation is often adopted. As shown in Figure 8.1, a typical field is represented by a plane of slope S_0 along the flow direction. For a rainfall event that generates Hortonian overland flow, the local infiltration is governed both by the rainfall and surface runoff generated from upstream areas. The soil is assumed to be vertically homogeneous, implying that subsurface horizontal flow components are neglected in comparison to vertical ones. This assumption is satisfied when the correlation scale in the horizontal plane is much larger than the vertical length scale associated with the head gradient (Dagan and Bresler, 1983; Chen et al., 1994a, 1994b).

8.3.1 Local Scale Model

The saturated hydraulic conductivity over the soil surface is represented by a stochastically homogeneous random field with a log-normal pdf characterized by the mean value $\langle K_s \rangle$ and the coefficient of variation $cv(K_s)$. Given a rainfall rate randomly varying in space with uniform pdf, with mean value $\langle r \rangle$ and coefficient of variation $cv(r)$, the local generation of surface runoff will be governed by infiltration of both rainfall and surface water from saturated areas running downslope over a pervious soil. For a given realization of K_s and r , local infiltration rate, q_0 , is formally expressed as:

$$q_0 = r + v_0 \quad \text{over unsaturated surface} \quad (8.3)$$

$$q_0 = f \quad \text{over saturated surface} \quad (8.4)$$

where v_0 is the discharge per unit surface generated upstream, with $v_0 = 0$ until the adjacent upstream area is unsaturated; f is the local infiltration capacity at time t computed by the Green–Ampt equation (see Chapter 7 for details):

$$f = K_s + \frac{K_s(\theta_s - \theta_i)\psi}{F}, \quad t > t_p \quad (8.5)$$

where F is the cumulative infiltration; θ_i and θ_s are the surface soil water content at $t = 0$ and saturation, respectively; t_p is the time to ponding, determined by the relation:

$$\int_0^{t_p} (r + v_0) dt = \frac{K_s(\theta_s - \theta_i)\psi}{r(t_p) - K_s} \quad (8.6)$$

where ψ is the capillary head gradient or suction head.

Surface runoff is routed over the plane by the kinematic wave approximation with flow resistance expressed by the Manning law (Singh, 1996):

$$\frac{\partial h}{\partial t} + \frac{S_0^{1/2}}{n} \frac{\partial h^m}{\partial x} = r - q_0 \quad (8.7)$$

with boundary and initial conditions given by:

$$h(0, t) = 0 \quad (8.8)$$

$$h(x, 0) = 0 \quad (8.9)$$

where x is the spatial coordinate increasing downslope, h is the flow depth, n is the Manning roughness coefficient and $m = 5/3$. Specifically, Equation 8.7 has to be combined with Equation 8.3 and Equation 8.4 in order to obtain, at each time, the values of h over saturated locations and v_0 over the unsaturated computational cells where Equation 8.7 becomes:

$$v_0 = - \frac{S_0^{1/2}}{n} \frac{\partial h^m}{\partial x} \quad (8.10)$$

which gives $v_0 > 0$ when $h > 0$ in the adjacent upstream cell.

8.3.2 Soil Properties and Selected Cases

The results in this chapter are mostly based on the work of Nahar et al. (2004), Govindaraju et al. (2006), and Morbidelli et al. (2006) who conducted an extensive set of numerical simulations over a wide range of cases by considering a 50 m long and 20 m wide plane with uniform slope $S_0 = 4\%$. Two soils representative of a clay loam soil, Soil B, and a sandy loam soil, Soil SL, were evaluated in detail by these authors (see Table 8.1). Conclusions are based on Monte-Carlo simulations of the coupled numerical solutions of the infiltration and the kinematic wave equations. These authors also carried out Monte-Carlo simulations for $v_0 = 0$ in order to quantify the relevance of the run-on process. These computations were performed using a Manning roughness coefficient $n = 0.15$ (metric units) and adopting a 0.5 m long and 2 m wide grid to meet stability requirements of the numerical procedure which are strictly governed by the representation of the run-on process.

It should be noted that the representation of the run-on process requires the coupled numerical solution of the infiltration and kinematic wave equations and incurs a significant computational burden.

TABLE 8.1 Hydraulic Data Used for the Study of Soils

Property	Soil B	Soil SL
Saturated water content, θ_s	0.3325	0.4120
Residual water content, θ_r	0.1225	0.0410
Initial water content, θ_i	0.1659	0.0613
Suction head, ψ [mm]	1116	360
Mean saturated hydraulic conductivity, $\langle K_s \rangle$ [mm h ⁻¹]	0.75	20.0
Coefficient of variation, $cv(K_s)$	0.3–1.0	0.3–1.0

8.3.3 Expected Spatial Average Infiltration Rates

With spatial variability in K_s and r , the areal-average infiltration rate, I , over the plane of area A is therefore partly controlled by the rainfall rate and run-on (unsaturated area A_1) and partly controlled by the soil (saturated area A_2):

$$I = \frac{1}{A} \iint_A q_0(x, y) dA = \frac{1}{A} \left[\iint_{A_1(t)} \left(r - \frac{S_0^{1/2}}{n} \frac{\partial h^m}{\partial x} \right) dA_1 + \iint_{A_2(t)} f dA_2 \right] \quad (8.11)$$

For each realization, the hillslope hydrograph $Q(t)$ is obtained through the spatial average of the product of velocity and flow depth at the hillslope outlet. Thus, using a variety of K_s and r realizations, the expected areal-average infiltration and hillslope response, $\langle Q(t) \rangle$, can be estimated by averaging I and Q over the ensemble of realizations.

8.3.4 Discussion of Numerical Results

Numerical simulations performed for the study soils revealed that the spatial variability of K_s and r greatly influence the ensemble-averaged infiltration rate and the production of surface runoff, the latter in terms of both the peak discharge and the water volume, especially for storms of short duration and low intensity. Figure 8.2 shows representative simulations of the these effects on outflow hydrographs, for a fixed value of $cv(K_s)$ combined with a wide range of $cv(r)$ values, applied to Soil B. As can be seen from this figure,

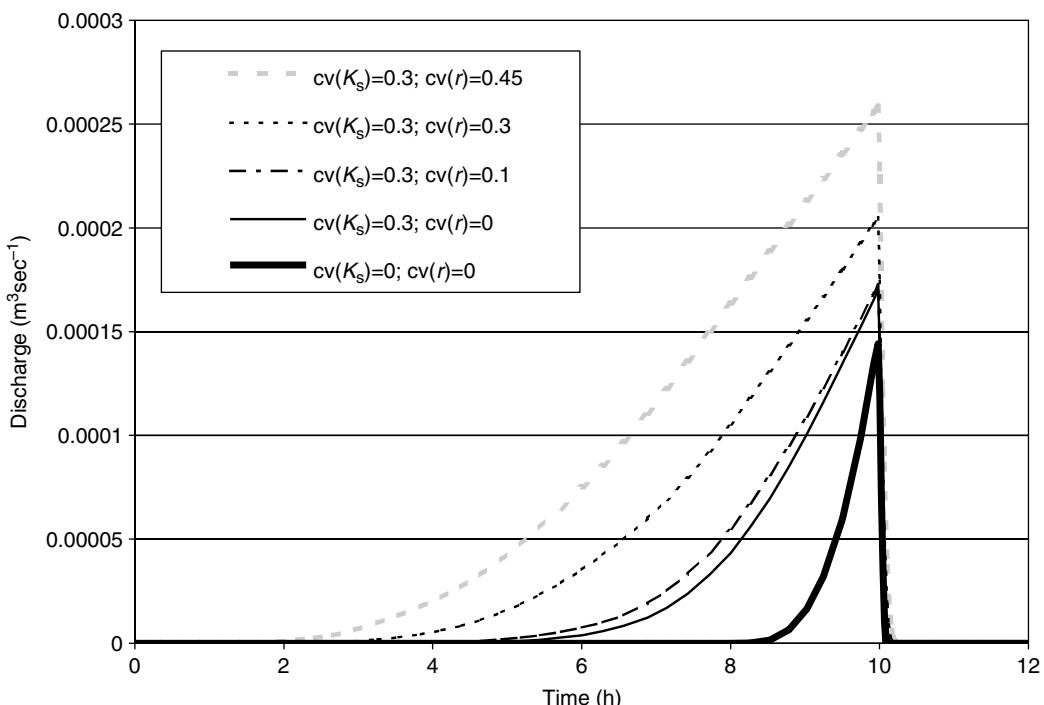

FIGURE 8.2 Surface outflow hydrograph for different combinations of the coefficients of variation of saturated hydraulic conductivity, $cv(K_s)$, and rainfall rate, $cv(r)$. Soil B with average value of rainfall rate $\langle r \rangle = 4.5 \text{ mm/h}$, and with rainfall duration 10 h. (Adapted from Morbidelli et al., 2006, *Hydrol. Proc.*, John Wiley & Sons. Reproduced with permission.)

the coefficient of variation of r plays a role very similar to that of K_s , and it is only when $\text{cv}(r) \ll \text{cv}(K_s)$ that the assumption of K_s as random variable and r as a uniform quantity appears reasonable.

Furthermore, when a larger rainfall rate with the same duration was used over each soil, the variation in $\langle Q \rangle$ with the level of heterogeneity in r and K_s was substantially reduced. However, when the rainfall duration decreased with increasing $\langle r \rangle$ the effects of spatial heterogeneity were found to be significant. Computations carried out over Soil B choosing appropriately the storm duration, t_d , revealed that the effects of spatial heterogeneity of r and K_s were in some way dependent on the rainfall rate. An overall analysis indicated that the role of spatial variability of r and K_s becomes less prominent for heavy storms and particularly when rainfall duration is much greater than the time to ponding t_{pa} obtained using $\langle K_s \rangle$ and $\langle r \rangle$. This implies that for small and moderate flood events in real watersheds the spatial variability of r and K_s need to be explicitly accounted for in models in order to avoid misleading results.

8.3.5 When Is Run-On Important?

To quantify the importance of run-on under various degrees of spatial variability, the Nash and Sutcliffe (1970) efficiency criterion can be used. The efficiency criterion E_f is expressed in this context as follows

$$E_f = \left[\sum_{i=1}^n (I_i - \bar{I})^2 - \sum_{i=1}^n (\hat{I}_i - I_i)^2 \right] \cdot \left[\sum_{i=1}^n (I_i - \bar{I})^2 \right]^{-1} \quad (8.12)$$

where I_i is the expected field-scale infiltration rate, \bar{I} is the mean value of field-scale quantity over n time steps considering run-on, and \hat{I}_i is the expected field-scale infiltration rate without run-on. According to this criterion, if the field-scale infiltration remains unchanged with or without run-on, then E_f attains its maximum value 1.0. As suggested by James and Burges (1982), an E_f value greater than 0.97 would imply that run-on may be ignored without incurring serious errors.

Figure 8.3 shows a contour map of E_f values over a range $0 \leq \mu_k^*, \sigma_k^* < 2$, to cover a wide range of field conditions. Here μ_k^* and σ_k^* are the mean and standard deviation, respectively, of $K^* = K_s/r$. Based

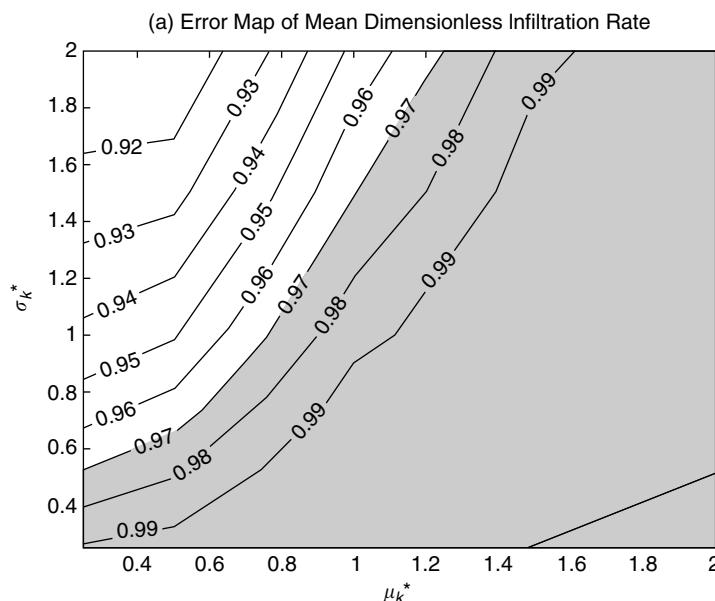

FIGURE 8.3 Error map of expected areal-average infiltration rate for various combinations of mean, μ_k^* , and standard deviation, σ_k^* , of the ratio between saturated hydraulic conductivity and rainfall rate.

on the threshold value of $E_f > 0.97$, the shaded regions in this figure shows when run-on process may be ignored. It is clear that if $\mu_k^* \gg \sigma_k^*$, then the nature of spatial variability is weak implying that run-on process will not be significant. The non-shaded region shows where influence of run-on process on the mean dimensionless infiltration rate is substantial and cannot be ignored. However, this figure is only valid for a spatially and temporally constant rainfall rate.

8.4 Theoretical Results

8.4.1 Spatial Averages for Cases of Negligible Run-On

By choosing the cumulative infiltration F in Equation 8.5 as the independent variable, that is, as a surrogate for time t , the average infiltration rate at a given F over the whole field can be expressed as:

$$I(F) = \frac{1}{N} \left\{ \sum_{i=1}^N r_i [1 - H(F - F_{pi})] + \sum_{i=1}^N f_i H(F - F_{pi}) \right\} \quad (8.13)$$

where the subscript i denotes the i th cell of Figure 8.1 out of a total of N cells, and the time to ponding and cumulative infiltration at ponding for the i th cell and for r invariant with time are given as:

$$t_{pi} = \frac{K_{si} \psi(\theta_s - \theta_i)}{r_i(r_i - K_{si})} \quad \text{and} \quad F_{pi} = t_{pi} r_i \quad (8.14)$$

The first and the second terms on the right-hand side of Equation 8.13 are the contributions from cells where ponding has not occurred and ponded cells, respectively, and $H(\cdot)$ is the Heaviside step function. Starting from Equation 8.13, as $N \rightarrow \infty$, the expected areal-average infiltration from infinite realizations can be written as:

$$\langle I \rangle = E[I(F)] = \int_0^\infty \int_{K_c}^\infty r f_r(r) f_{K_s}(K) dr dK + \int_0^\infty \int_0^{K_c} \left(1 + \frac{\psi \Delta \theta}{F} \right) K f_r(r) f_{K_s}(K) dr dK \quad (8.15)$$

where $f_r(r)$ is the pdf of r , $f_{K_s}(K)$ is the pdf of K_s , and

$$K_c = \frac{Fr}{\psi(\theta_s - \theta_i) + F} \quad (8.16)$$

Equation 8.15 was simplified by Govindaraju et al. (2006), with $\langle I \rangle$ approximated by $\langle I_n \rangle$ as

$$\begin{aligned} \langle I_n \rangle = E[I(F)] &= \frac{1}{2RF_c^2} \{ G_{K_s}[(r_{min} + R)F_c, 2] - G_{K_s}[r_{min}F_c, 2] \} \\ &\quad - \frac{r_{min}^2}{2R} \{ G_{K_s}[(r_{min} + R)F_c, 0] - G_{K_s}[r_{min}F_c, 0] \} \\ &\quad + \left(r_{min} + \frac{R}{2} \right) \{ 1 - G_{K_s}[(r_{min} + R)F_c, 0] \} \\ &\quad + \frac{1}{F_c} \left(\frac{r_{min} + R}{R} \right) \{ G_{K_s}[(r_{min} + R)F_c, 1] - G_{K_s}[(r_{min}F_c), 1] \} \\ &\quad - \frac{1}{F_c} \left(\frac{1}{RF_c} \right) \{ G_{K_s}[(r_{min} + R)F_c, 2] - G_{K_s}[(r_{min}F_c), 2] \} \\ &\quad + \frac{1}{F_c} G_{K_s}[r_{min}F_c, 1] \end{aligned} \quad (8.17)$$

where the function G_{K_s} is the truncated moment of the log-normal pdf of K_s defined as:

$$\begin{aligned} G_{K_s}(K_1, \xi) &= \int_0^{K_1} K^\xi f_K(K) dK \\ &= \exp\left(\xi \mu_Y + \frac{\sigma_Y^2 \xi^2}{2}\right) \left[1 - \frac{1}{2} \operatorname{erfc}\left(\frac{\ln K_1 - \mu_Y}{\sqrt{2}\sigma_Y} - \frac{\sigma_Y \xi}{\sqrt{2}}\right) \right] \end{aligned} \quad (8.18)$$

Here K_1 and ξ represent the first and the second argument of the G_{K_s} function in Equation 8.17 and $\operatorname{erfc}(\cdot)$ is the complimentary error function (see appendix in Chapter 3). Thus Equation 8.17 allows estimation of the expected areal-average infiltration rate as a function of cumulative infiltration. However, many hydrological applications require the estimate of $\langle I \rangle$ as a function of time t and therefore it is required to relate t to F . We start with the relation between these two quantities at the i th cell:

$$t_i = \frac{F_i}{r_i}, \quad \text{when } F_i < F_{pi} \text{ or } t_i < t_{pi} \quad (8.19a)$$

$$t_i = \frac{1}{K_{si}} \left[F_i + \psi \Delta \theta \ln \left(\frac{\psi \Delta \theta}{\psi \Delta \theta + F_i} \right) \right] + \psi \Delta \theta \sum_{j=1}^{\infty} \frac{K_{si}^j}{(j+1)r^{j+1}}, \quad \text{when } F_i > F_{pi} \text{ or } t_i > t_{pi} \quad (8.19b)$$

Equation 8.19b has been obtained by the classical relation of Green-Ampt for post-ponding conditions (Chow et al., 1988), modified by a series expansion of a log-term and simplification along the lines of Govindaraju et al. (2001). Since F takes on different values in each cell of Figure 8.1, an average time for the whole field may be computed as in Morbidelli et al. (2006):

$$\begin{aligned} E[t; r = \langle r \rangle] &= \frac{F}{\langle r \rangle} \{1 - G_{K_s}[\langle r \rangle F_c, 0]\} + \left[F + \psi \Delta \theta \ln \left(\frac{\psi \Delta \theta}{\psi \Delta \theta + F} \right) \right] \{G_{K_s}[\langle r \rangle F_c, -1]\} \\ &\quad + \psi \Delta \theta \sum_{j=1}^{\infty} \frac{1}{(j+1)\langle r \rangle^{j+1}} \{G_{K_s}[\langle r \rangle F_c, j]\} \end{aligned} \quad (8.20)$$

Using Equation 8.17 and Equation 8.20, one can find the expected areal-average infiltration rate and the corresponding expected time for a given cumulative infiltration depth. The series in the last term of Equation 8.20 converges very rapidly, and the first five terms are sufficient for most practical purposes.

8.4.2 Empirical Averages for Cases of Appreciable Run almost On

The inclusion of run-on process makes the derivation of analytical solutions almost impossible for field scale infiltration. After examining numerous results of field-scale infiltration, with and without run-on, Morbidelli et al. (2006) proposed the following empirical representation with parameters a , b , and c :

$$\langle I(t) \rangle \cong \langle I_n(t) \rangle + \langle r \rangle a t^b \exp(-c t^*) \quad (8.21)$$

where $\langle I_n(t) \rangle$ is obtained by ignoring run-on effect as given in Equation 8.17 and Equation 8.20, and $t^* = t/t_{pa}$, with t_{pa} defined as the ponding time obtained from average values of K_s and r in Equation 8.14. The quantities a , b , and c of Equation 8.21 were found to be well represented by the following relations:

$$a = 2.8[\operatorname{cv}(r) + \operatorname{cv}(K_s)]^{0.36} \quad (8.22)$$

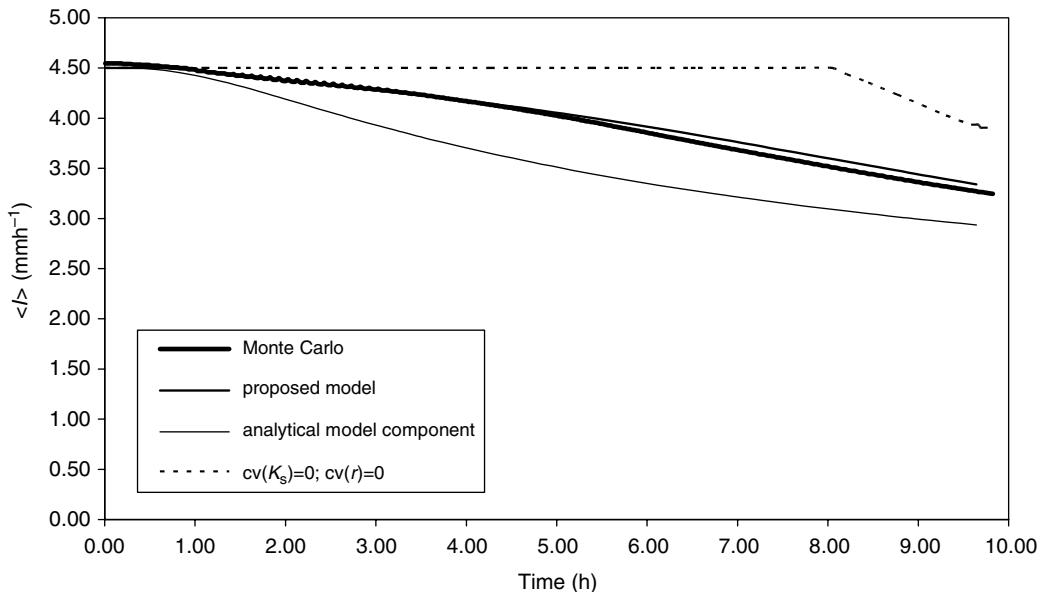

FIGURE 8.4 Comparison of expected field-scale infiltration rate, $\langle I \rangle$, derived by Monte Carlo simulations and obtained by the proposed model. Areal-average rainfall rate, $\langle r \rangle = 4.5 \text{ mm h}^{-1}$, invariant with time over Soil B of areal average saturated hydraulic conductivity $\langle K_s \rangle = 0.75 \text{ mm h}^{-1}$. The coefficients of variation were $cv(r) = 0.45$ and $cv(K_s) = 1.0$. (Adapted from Morbidelli et al., 2006, *Hydrol. Proc.*, John Wiley & Sons. Reproduced with permission.)

$$b = 5.35 - 6.32[cv(r)cv(K_s)] \quad (8.23)$$

$$c = 2.7 + 0.3 \left[\frac{\langle r \rangle / \langle K_s \rangle}{cv(r)cv(K_s)} \right]^{0.3} \quad (8.24)$$

Equations 8.22–8.24 require that both K_s and r be expressed in units of millimeters per hour. Morbidelli et al. (2006) note that much better accuracy is attained by the inclusion of the run-on component in Equation 8.21, thereby illustrating the importance of this component for representing field-scale infiltration. The model of Equation 8.21 was found to be very effective in simulating the expected cumulative infiltration over a wide range of spatial variabilities in K_s and r , with errors less than 5 and 2% over Soil B and SL, respectively. Figure 8.4 shows one example of expected field-scale infiltration rate behavior obtained from Monte-Carlo simulations vs. the models presented here. This figure is representative of cases where (i) the role of spatial variability of r and K_s on the production of effective rainfall is rather pronounced, as can be deduced by observing the difference between the curves from Monte Carlo simulations and from the use of averaged properties, and (ii) the run-on process produces a prominent effect on $\langle I \rangle$. The latter feature is illustrated by the difference between the Monte Carlo results and the analytical component model of Equation 8.17 and Equation 8.20 as first proposed in Govindaraju et al. (2006).

As can be seen here, the proposed model of Equation 8.21 shows a great improvement over Equation 8.17 and Equation 8.20 that ignore run-on. Based on numerous simulation experiments, Morbidelli et al. (2006) concluded that the proposed model Equation 8.21 is well structured because the two components interact appropriately under a wide range of conditions ranging from negligible run-on to those cases where run-on is very significant. For the sake of simplicity, only the case of rainfall rate invariant with time has been discussed here. This is usually not the case for real events. However, by following along the

lines developed by Govindaraju et al. (2001), it is possible to apply the semi-analytical model component for time-varying r as well.

8.5 Conclusions and Recommendations

Based on studies dealing with run-on effect, the following conclusions can be made. The influence of run-on on field-scale infiltration and runoff can be quite substantial in heterogeneous hillslopes, as has been demonstrated in numerous studies by using Monte Carlo simulations. These studies demonstrate that heterogeneity of K_s and r can have a substantial influence on the expected areal-average infiltration and on the surface hydrograph at the slope outlet. Existing infiltration models do not account appropriately for these effects when the run-on process cannot be neglected. The model described in this chapter overcomes this problem by providing accurate estimates of infiltration for the spatial variability in these two quantities. The use of the model does require knowledge of the first two truncated moments of the pdfs of K_s and r . Given the nature of K_s and r , Figure 8.3 may be used to first determine if run-on is important. When run-on is thought to be not important, then equations Equation 8.17 and Equation 8.20 may be used to describe field-scale infiltration. When run-on is taken into account, Equation 8.20 to 8.24 may be used. With the inclusion of run-on, expected field-scale infiltration increases, which in turn, has a significant influence on the hillslope hydrograph.

Glossary

Capillary head gradient: An estimate of the constant suction head that causes vertical water movement in the Green-Ampt model.

Correlation length: A measure of the extent of similarity in statistical properties in a heterogeneous quantity.

Diffusive wave model: An approximation for representing surface water movement where the momentum equation is simplified by equating the friction slope to the bed slope and a diffusive term.

Effective properties: Averaged values of spatially heterogeneous quantities that can be used in a model to describe average behavior at larger scale than the scale of heterogeneity.

Green-Ampt equation: A simplified physical model to represent local infiltration.

Infiltration: The process of water entering the soil through the soil surface.

Kinematic wave model: An approximation for representing surface water movement where the momentum equation is simplified by equating the friction slope to the bed slope.

Monte-Carlo simulations: A method of accounting for uncertainty by first conceptualizing the uncertain quantities to be particular realizations of a random process, and then generating numerous realizations of similar statistical characteristics to assess average behavior.

Overland flow: Movement of water over the land surface usually conceptualized as a thin sheet flow.

Ponding: The collection of the excess rain water on the soil surface.

Random field: A probabilistic model representation for describing quantities that vary in space in an uncertain fashion.

Residual water content: The water content below which water ceases to exist as a continuous phase in the soil.

Runoff: The accounting of water that moves on the soil surface.

Run-On: The process of allowing water from upstream areas to infiltrate into downstream regions where the moisture deficit has not been satisfied.

Saturated hydraulic conductivity: A measure of the ease with which water moves through a porous formation when all the pores are filled with water.

Saturated water content: The water content when all the pores of a porous medium are filled with water.

Storm duration: The time from the start to end of a rainfall event.

Time to ponding: The time it takes for rain water to start collecting on the surface from the start of a rainfall event.

Turning bands method: A technique used for generating random fields.

Upscaling: A method to represent heterogeneous quantities by their averaged or effective properties to be used in a constitutive equation.

Water content: The ratio of the volume of water to bulk volume in a soil.

Further Information

The focus of this chapter has been on clarifying the role of run-on process in field-scale infiltration. Further, only natural variability of rainfall and infiltration properties have been accounted for by representing them as random fields. Despite its importance, there is not much information available on run-on, and how it influences field-scale behavior of water and associated contaminants. This topic has primarily been dealt with as a specialized research problem that appears in journal articles. The question of how man-made land use changes alter field- and watershed-scale infiltration has not been investigated in any detail. At the time of writing of this chapter, an ASCE task committee is being formulated to study and summarize the progress in some of these topics. The report from the task committee should contain more detailed information, but is still two to three years into the future.

9.1 Introduction

Recent experimental research in soil structure and nonideal chemical transport is forcing scientists to refine their analysis of the movement and fate of contaminants in the soil and consider processes that have become important when small concentrations of highly toxic chemicals must be accurately accounted for to protect groundwater reserves from contamination (Stagnitti et al., 1995). The mobility of the

chemicals and contaminants in well-structured soils is affected by the continuity as well as the size of the pores. Networks of interconnected, highly conductive pathways that result from biological and geological activities, such as subsurface erosion, faults and fractures, shrink-swell cracks, animal burrows, wormholes, and decaying roots may be responsible for transmitting moisture, solutes, and contaminants to groundwater at faster velocities than those predicted by the theory based on the convective-dispersive equation (CDE) in which the water velocity is represented by the local average values (Bear, 1972; Sposito et al., 1986). In most cases, the volume of water within the preferential paths is much lower than the volume of the stagnant fluid, and only a small part of the solution (but very significant when the solute is toxic at low concentrations) may be moving within the well-defined preferential paths ahead of the main flow. For example, Smettem and Collis-George (1985) found that a single continuous macropore can conduct more water than a surrounding soil sample 10 cm in diameter. In structured soils, the convective-dispersive model gives unsatisfactory results under field conditions, and the interchange of fluids between the matrix and the fracture or large pore must be modeled explicitly (Steenhuis et al., 1990; Stagnitti et al., 1995; Parlange et al., 1996, 1998).

Contrary to widely held belief, even in relatively uniform sandy or water-repellent soil profiles, water does not necessarily take an average flow path and flow can take place through fingers caused by dynamic instabilities of the wetting front as was first documented by Hill and Parlange (1972). Further research has led to an understanding of many of the mechanisms involved in this phenomenon (Raats, 1973; Philip, 1975; Parlange and Hill, 1976; Hillel and Baker, 1988; Glass et al., 1989a, 1989b, 1989c, 1991; Kluitenberg and Horton, 1990; Selker et al., 1992a, 1992b, 1993; Liu et al., 1993, 1994a, 1994b; Sidle et al., 1998). The phenomena are not only restricted to the laboratory but can also be observed under field conditions. Fingered flow in a field was first noted in the Connecticut valley (Starr et al., 1978) and later by Glass et al. (1989a) on Long Island. Hendrickx and Dekker (1991), using dye-tracing techniques, found that only 10 to 20% of the vadose zone was actually involved in the transport of the dye for a water-repellent soil in Ouddorp (Netherlands). Also, Ritsema and Dekker (1993a, 1993b) and Dekker and Ritsema (1994) found that preferential flow was more the rule than the exception during the late summer and early fall in the Netherlands. Finally, Rice et al. (1991) in the midwestern U.S. found that solutes and herbicides travel at velocities 1.6 to 2.5 times faster than traditional water balance models of piston flow in sandy soils with little or no structure.

Finger properties can be derived from soil physical theory. Analysis of the wetting front instability suggests that the finger diameter, d , is given by

$$d = \frac{\kappa S_F^2}{K_F(\theta_F - \theta_i)} \left[\frac{1}{1 - \frac{Q}{K_F}} \right] \quad (9.1)$$

where θ_i is the water content ahead of the finger and θ_F , K_F , and S_F are the water content, conductivity, and sorptivity at the wettest spot in the finger, respectively, usually close to the tip. Q is the imposed flux at the surface ($Q \geq K_F$) and κ is a constant, which is equal to π in two dimensions (Parlange and Hill, 1976) or 4.8 in three dimensions (Glass et al., 1991). Hillel and Baker (1988) and Baker and Hillel (1990) suggest that at the wettest spot in the tip of the finger, the soil-water potential is at its water entry value. Indeed this seems to be a general result when the soil is initially dry. However, in subsequent infiltration events (using the finger paths created earlier), hysteresis is becoming a dominant factor and the finger becomes dryer (Liu et al., 1994b). The form of Equation 9.1 is physically quite intuitive. $S_F^2/(\theta_F - \theta_i)$ represents the sorptive properties of the soil, and the larger this term is, the wider the finger. K_F , on the other hand, represents the gravity effect, which drives the instability. The larger it is, the thinner the finger. Finally, increasing the imposed flux results in wider fingers. However, the main effect of the imposed flux is on the density of the fingers. The larger the Q , the closer the fingers are spaced. Hence, if Q approaches K_F , the whole space is necessary to carry the water entering the soil. At that point all the fingers merge so that $d \rightarrow \infty$.

Another mechanism for initiation of fingers in field soils is interbedded coarse layers in fine sand. Coarse layers concentrate the water from a large area into a finger-like structure. Kung (1990a, 1990b)

coined the term *funnel flow* for this phenomenon. He found that water and solutes flowed through less than 10% of the total soil matrix between depths of 3.0 and 3.6 m and less than 1% between 5.6 and 6 m. Funnel flow was also observed in Delaware (Boll et al., 1997) and in Massachusetts along the Connecticut River where the water flowed over coarse layers under low flux conditions and then broke through at higher fluxes (Steenhuis et al., 1998).

In contradiction to the fingers or funnel flow — formed by the dynamic instability in sandy soils, and where the shape, size, and distribution of the fingers depend on the imposed flux — the preferential flow paths in structured loamy or clayey soils and in fractured rocks are intrinsically defined as part of the soil and rock profile, respectively, with shape, size, and distribution independent of the fluids involved. In this chapter, we will concentrate on the structural defined flow paths. One of the main difficulties in modeling preferential flow in the “structural” large-pore system is the interaction of the preferentially moving chemicals with the surrounding matrix. To predict the solute distribution in structured soils, one ideally should know the exact spatial distribution, shape, size, and connectiveness of the preferential flow paths. This information is only available for a few soil cores (Heijmans et al., 1996), and not for field soils. Consequently, simplified models that overcome this lack of information are being used to interpret the vast amount of solute concentration data from field and laboratory experiments (Flühler et al., 1996).

In this chapter, we will give a survey of the various mathematical approaches for predicting solute breakthrough curves (BTC) in structured soils and fractured rocks with an emphasis on the effect of the interaction between the moving and the stagnant fluids in the surrounding matrix. Preferential flow in sandy and layered soils has been presented elsewhere (Glass and Nichol, 1996; Ritsema et al., 1996). Dual-porosity models with and without a distribution layer are discussed first, followed by multi-pore group models.

9.2 Dual-Porosity Models for a Sharp Change at the Fracture–Matrix Interface

Flow through cracks and fissures was initially studied in relation to the exploitation of nonhomogeneous groundwater and petroleum reservoirs. The naturally fractured reservoir can be taken as a collection of porous rock blocks, which are usually called the matrix, and an interconnected system of fracture planes. Most of the fluid resides in the matrix, where it moves very slowly, but the small amount of fluid rapidly flowing in the fractures can have a profound effect on the overall solute flow. A common approach to modeling this system mathematically is the dual-porosity concept, first presented by Barenblatt et al. (1960) and Warren and Root (1963). It is based on the assumption that naturally fractured reservoirs behave as two porous structures rather than one. The difference between the dual-porosity media and the usual porous media is that the “solid part” is in itself permeable and both matrix and fracture flow are defined at each point of the matrix. Thus, fluid flow is a combination of general macroscopic motions and takes place within the matrix blocks and also around them. The dual-porosity models have also been used to describe flow and transport in structured porous media where less permeable soil aggregates are analogous to the matrix (Passioura, 1971).

An intensive use in the dual-porosity concept has been made to model the non-ideal BTCs measured at the outlet of soil columns in the laboratory and soil cores from the field. Non-ideal BTCs are asymmetric and characterized by early breakthrough and an extensive tail that indicates that some part of the fluid is moving ahead of a front calculated by the CDE (Biggar and Nielsen, 1962; Krupp and Elrick, 1969; Starr and Parlange, 1977; van Genuchten and Wierenga, 1977; Rao et al., 1980; Nkedi-Kizza et al., 1983; Seyfried and Rao, 1987). The inter-aggregate porosity of aggregated soil and the dead-end pores in structured soils are considered as the low conductivity matrix, while the inter-aggregate porosity consists of the pathways where preferential flow takes place. The advection within the regions with the relatively low hydraulic conductivity is usually assumed zero, therefore, these domains act as sink/source components and the dual-porosity, dual velocity model becomes a mobile–immobile model.

The dissolved chemical transport in a single porosity model is usually described by the CDE (Biggar and Nielsen, 1967)

$$\frac{\partial(\theta_m c_m)}{\partial t} = \frac{\partial}{\partial z} \left[D_e \frac{\partial c_m}{\partial z} \right] - \frac{\partial(J_w c_m)}{\partial z} \quad (9.2)$$

where the subscript m stands for mobile, z is the direction of flow, and c is the solute concentration. D_e is the effective dispersion coefficient, combining the influence of diffusion in the dissolved phase with the long-time dispersion representation of the effect of small-scale convection on the mixing of solute about the center of motion (Jury et al., 1991). J_w is the water flux in the mobile paths. When water flow is steady and there is no chemical exchange with immobile porosity, Equation 9.2 reduces to

$$\frac{\partial c_m}{\partial t} = D \frac{\partial^2 c_m}{\partial z^2} - v \frac{\partial c_m}{\partial z} \quad (9.3)$$

where $D = D_e/\theta_m$ is the effective diffusion-dispersion coefficient and $v = J_w/\theta_m$ is the pore water velocity. Analytical solutions of Equation 9.3 for many initial and boundary conditions can be found in van Genuchten and Alves (1982).

In the mobile-immobile model, exchange takes place between the two regions and the chemical flux to/from the immobile porosity appears as a sink term in Equation 9.2. For the convenience of mathematical presentation, the equations which follow will be written for saturated mobile and immobile porosities, and Equation 9.3 becomes

$$\frac{\partial c_m}{\partial t} + \frac{\theta_{im}}{\theta_m} \frac{\partial \bar{c}_{im}}{\partial t} = D \frac{\partial^2 c_m}{\partial z^2} - v \frac{\partial c_m}{\partial z} \quad (9.4)$$

where the subscript im stands for immobile, $\theta_{im} = \theta - \theta_m$ is the immobile water content, and \bar{c}_{im} is the uniformly distributed solute concentration in the immobile porosity. The dissolved chemical exchange between the mobile and immobile porosities can be represented by two conceptually different mechanisms: a local equilibrium and a rate-limited exchange. The choice between the two is dictated by how fast the rate of exchange is compared with the transport rate in the mobile porosity. The exchange has been usually modeled by a diffusion equation based on Fick's law or by employing a first-order mass transfer approximation which, for particular cases, can be derived directly from a diffusion-based model (Rao et al., 1980; Parker and Valocchi, 1986; van Genuchten and Dalton, 1986). The rate-limited first-order exchange between the mobile and immobile porosities may be written as

$$\theta_{im} \frac{\partial \bar{c}_{im}}{\partial t} = \alpha [c_m - \bar{c}_{im}] \quad (9.5)$$

where α is the rate coefficient describing the mass transfer process between the mobile and immobile regions. A brief review of mass transfer models and their characteristics is presented in Brusseau and Rao (1989) and Brusseau et al. (1994).

Two time scales are involved in the mobile-immobile problem: the convective-dispersive transport in the mobile pores and the rate-limited dissolved chemical exchange between the two regions. For cases where the microscopic processes are rapid enough in relation to the fluids flow rate in the mobile pores, the local equilibrium assumption (LEA) was suggested to replace the rate-limited exchange (Equation 9.5) (Rubin, 1983). This replacement provides conceptual and mathematical simplifications. Models based on LEA have proven to be useful in a variety of solute transport applications, but there is an increasing body of experimental evidence indicating that the LEA may not be applicable under many conditions of interest in the study of solute transport (Jennings and Kirkner, 1984; Valocchi, 1985; Bahr and Rubin, 1987). These studies aimed to express conditions that are based on the flow and transport parameters under which the LEA is valid and provide small deviations from the rate-limited model. The identification

of these parameter values was based on comparing concentration profiles, which were calculated by the LEA model and solutions to the rate-limited model, obtained by different mathematical methods, for different scenarios and conditions. Wallach (1998) took advantage of the different time scales for the two rate-limited processes and defined a set of dimensionless variables that were substituted into the mass balance equations (Equation 9.4 and Equation 9.5). For cases when the characteristic time scale for the lateral solute exchange is faster than the convective transport time scale (as used to define the conditions for LEA), the ratio between the two time scales forms a small dimensionless parameter that multiplies the time derivative in the dimensionless version of Equation 9.5. The method of matched asymptotic expansions can then be used to form a uniform solution for this singular perturbations problem. The leading-order approximation, obtained when this parameter approaches zero, yields the solution obtained by the LEA and is valid only for the longer times ("outer" solution). A transition period exists near $t = 0$ within which the initial concentration equilibrates. The LEA validity, as well as the length of the transition period during which the initial mobile and immobile concentrations reach local equilibrium depends on how small the ratio between the two time scales is.

A closer look at the process of chemical transfer from the moving solute within the crack into the stagnant matrix brings forth the conclusion that the distribution of solute concentration within the moving solute varies only slightly across the crack, perpendicular to the flow, except at the interface with the matrix. The solute transferred across the interface is doing so by diffusion (Tang et al., 1981; Neretnieks et al., 1982; Neretnieks, 1983; Moreno and Rasmussen, 1986; Fujikawa and Fukui, 1990; Maloszewski and Zuber, 1990; and others). A mass balance equation is then written for each medium, and the mass continuity is preserved via the boundary condition at the interface between these two media. The mass balance equation for the preferential path (Tang et al., 1981) is

$$\frac{\partial c_m}{\partial t} - D_m \frac{\partial^2 c_m}{\partial z^2} + v \frac{\partial c_m}{\partial z} = -q \quad (9.6)$$

where D_m is the effective dispersion coefficient for the crack, and q ($\text{ML}^{-3}\text{T}^{-1}$) is the solute flux (concentration per unit time) from the crack to the matrix. The lateral transport in the matrix is described by

$$\frac{\partial c_{im}}{\partial t} = D_{im} \frac{\partial^2 c_{im}}{\partial x^2} \quad (9.7)$$

where x is the length in the matrix perpendicular to the flow direction in the crack, z , and D_{im} is the effective diffusion coefficient for the matrix. The boundary condition at the interface between the crack and the matrix ($x = 0$) is that local equilibrium is valid

$$c_m(z, t) = c_{im}(x = 0, z, t) \quad (9.8)$$

Solutions of this model reveal that the matrix diffusion can be viewed as a beneficial safety mechanism in soil contamination problems involving a concentrated source in fractured media. The dissolved chemicals are not spreading instantaneously throughout the matrix as assumed in the mobile-immobile models. The degree of spreading depends strongly on the difference in the time scales characterizing the dispersive-convective transport in the fracture and the transport by diffusion in the matrix. For example, in a system with large matrix porosity and low fracture fluid velocity the contamination of the matrix soil will be much less than in a system with low matrix porosity and high fracture fluid velocity.

Piquemal (1993) pointed out that it is erroneous, in general, to assume that the concentrations in the crack and the matrix are in local equilibrium. Developing the equations by the volume-averaging technique, he concluded that it applies only when the mean concentration of the flowing fluid is equal to the concentration in the immobile fluid at the boundary separating them. In many models where local equilibrium between the mobile and immobile regions is assumed, the solute flow is described by a

one-dimensional convective-dispersive model which *a priori* ignores the lateral concentration gradient in the mobile region. Therefore, the assumption is self-consistent in these models.

In the mobile-immobile (MIM) model, the preferential-flow paths are not physically determined but have much larger volume than the immobile volume and are assumed to be uniformly distributed throughout the soil profile. On the contrary, in the case of preferential path models the preferential paths are defined and the immobile volume is much larger than the volume of the preferential paths. The second difference is the dissolved chemical distribution in the matrix. Assuming a uniform concentration distribution with the lateral direction within the matrix (Equation 9.5 for the MIM model) rather than a diffusion front that propagates laterally as a function of $-t^{1/2}$ is equivalent to the assumption that concentration changes taking place at any point along the interface between the mobile and immobile domains equilibrate instantaneously with the whole stagnant solution in the horizontal direction. Since the chemical transfer between the mobile and immobile domains is controlled by the concentration difference (Equation 9.5), this assumption has a major effect on the values of α and D estimated by fitting the MIM model to measured BTCs. The fitting-routine of Parker and van Genuchten (1984) is an often-used tool to estimate the MIM model parameters from the measured BTCs. For field soils where dye tracers have shown that only few pores carry most of the solutes, the assumption of instantaneous equilibrium throughout the entire stagnant pore group is poor. The solute cannot move through the large lateral distances between the preferential paths by diffusion in the time frame of the transport in the preferential paths. Application of the MIM model to BTCs measured for soils with well-defined preferential paths provided poor predictions (Anderson and Bouma, 1977).

An important question for modeling flow and transport in preferential paths is whether the flow is laminar or turbulent. It has a great effect on the concentration distribution within the preferential path, especially in the direction perpendicular to the flow. Water flow in soil pores has traditionally been assumed laminar (following Poiseuille's law), but Chen and Wagenet (1992) argue that the flow is turbulent for macropores larger than 0.2 mm in diameter. Ela et al. (1991) measured rates of water flow into individual pores (size not given) ranging from 0 to 2550 ml/sec, and Wang et al. (1991, 1994) have measured inflow rates of 1 to 17 ml/sec into individual worm or ant holes (1.5 to 3.6 mm diameter). Reynolds numbers calculated for these open-channel pores and rates are out of range of laminar flow and into the transitional flow range (Chow, 1964). Turbulent flow theory was developed for large conduits, and laminar flow theory was developed for capillary-size pores. Large macropores are in between these sizes and may be only partially filled (Beven and Germann, 1981); thus, one may argue that there is no reason to assume one or the other type of flow.

Wallach and Steenhuis (1998) proposed a model for such field soils with well-defined preferential paths. The model follows the main assumptions made for the MIM model, that is, the velocity of the mobile fluid in the well-defined preferential paths is constant and the dissolved chemical exchange between the saturated stagnant pore group and the mobile pore group is a rate-limiting process. For the sake of simplicity, the dissolved chemical transport in the crack is modeled by the kinematic-wave approach rather than by the convective-dispersive equation, and analytic solutions are obtained. The model takes advantage of the characteristic time scales for chemical transfer through the boundary layer along the interface between the mobile and immobile domains being faster than the lateral transport of the chemicals within the stagnant porosity by diffusion. This assumption is expressed mathematically as multiplying the immobile concentration in the mass balance equations by a small dimensionless parameter, $\varepsilon' \ll 1$. The mass balance equation for the preferential paths becomes (Wallach and Steenhuis, 1998)

$$\frac{\partial c_m}{\partial t} + v \frac{\partial c_m}{\partial z} = -k_m [c_m - \varepsilon' c_{im}] \quad (9.9)$$

where $k_m = k/\theta_m$. The boundary condition at the inlet to the preferential path is

$$c_m(0, t) = c_0(t) \quad (9.10)$$

Postulating that the concentration within the matrix is not laterally uniform and that it varies significantly only within a short lateral distance from the interface during the travel time of the mobile fluid to the outlet, the solute concentration is assumed to be uniformly distributed only within a thin matrix layer, θ_{im} (defined as the pore volume in this layer per sample volume), located at the interface between the two pore groups. The mass balance equation for this matrix layer is

$$\frac{\partial c_{im}}{\partial t} = k_{im}[c_m - \varepsilon' c_{im}] \quad (9.11)$$

where $k_{im} = k/\theta_{im}$.

Equation 9.9 and Equation 9.11 form a regular perturbations problem whose solution can be expressed by the series

$$c_m(z, t) = \sum_{i=0}^n (\varepsilon')^i A_i = A_0 + \varepsilon' A_1 + (\varepsilon') A_2 + \dots \quad (9.12)$$

$$c_{im}(z, t) = \sum_{i=0}^n (\varepsilon')^i B_i = B_0 + \varepsilon' B_1 + (\varepsilon') B_2 + \dots \quad (9.13)$$

Substituting Equations 9.12 and Equation 9.13 into Equations 9.9 to 9.11 and equating terms that are multiplied by equal powers of ε' , sequences of equations for the different orders of approximations are obtained.

9.2.1 The Zeroth-Order Approximation

This approximation, known also as the leading-order approximation, is obtained by equating terms multiplied by $(\varepsilon')^0$. The mass balance equations for the preferential path and matrix solutes are

$$\frac{\partial A_0}{\partial t} + \nu \frac{\partial A_0}{\partial z} = -\frac{k}{\theta_m} A_0 \quad (9.14)$$

$$\frac{\partial B_0}{\partial t} = \frac{k}{\theta_m} A_0 \quad (9.15)$$

The right-hand side of Equation 9.14 expresses the chemical transfer from the preferential paths to the matrix when the back transfer due to the accumulation of chemicals in the matrix is ignored. As a result, Equation 9.14 and Equation 9.15 include one dependent variable each and can be solved independently, as opposed to Equation 9.4 and Equation 9.7, which contain two dependent variables and, therefore, should be solved simultaneously. The higher-order approximations in the following will account for the dissolved chemical flux from the matrix.

This problem is solved by applying the Laplace transform with respect to time. The transformed mobile concentration is represented as

$$a_i = \int_0^\infty A_i e^{-st} dt; \quad b_i = \int_0^\infty B_i e^{-st} dt \quad (9.16)$$

where s is the transformation variable. Application of Equation 9.16 to Equation 9.14 and Equation 9.15 leads to a pair of ordinary differential equations with a boundary condition in the Laplace domain.

The equation for the preferential path with zero initial concentration is

$$sa_0 + \nu \frac{da_0}{dz} = -\frac{k}{\theta_m} a_0 \quad (9.17)$$

and its boundary condition at the soil surface in the Laplace domain is

$$\bar{c}_0(s) = \frac{c_i}{s} \quad (9.18)$$

The solution of Equation 9.17 with Equation 9.18 in the Laplace domain is

$$a_0(z, s) = \frac{c_i}{s} \exp \left[-\frac{kz}{\theta_m \nu} - \frac{sz}{\nu} \right] \quad (9.19)$$

The solution for A_0 in the time domain is obtained through the application of the inverse Laplace transform to Equation 9.19

$$A_0(z, t) = c_i \exp \left[-\frac{kz}{\theta_m \nu} \right] \cdot u \left(t - \frac{z}{\nu} \right) \quad (9.20)$$

here $u(t)$ is the unit step function. The leading solution for the mobile domain is of an advancing sharp front with a simultaneous transfer of dissolved chemicals to the active matrix layer. The chemical transfer depends only on the mobile concentration and its concentration at any point z as a function of the travel time from the inlet to this point.

Applying the Laplace transform Equation 9.16 to Equation 9.15 with initial zero immobile concentration and substituting $a_0(z, s)$ from Equation 9.19 gives

$$b_0(z, s) = \frac{k}{\theta_{im}} \frac{c_i}{s^2} \exp \left[-\frac{kz}{\theta_m \nu} - \frac{sz}{\nu} \right] \quad (9.21)$$

whose inverse Laplace transform gives the zeroth-order approximation of the chemical distribution in the matrix. As the local concentration in the matrix depends on the local chemical concentration in the preferential path, it also varies with time and depth

$$B_0(z, t) = \frac{c_i k}{\theta_2} \exp \left[-\frac{kz}{\theta_m \nu} \right] \left\{ t - \frac{z}{\nu} \right\} \cdot u \left(t - \frac{z}{\nu} \right) \quad (9.22)$$

9.2.2 The First-Order Approximation

The first-order approximation is obtained by equating terms multiplied by ϵ' when Equation 9.12 and Equation 9.13 are substituted into Equation 9.9 to Equation 9.11.

The mass balance equations for the preferential path and matrix solutions are

$$\frac{\partial A_1}{\partial t} + \nu \frac{\partial A_1}{\partial z} = -\frac{k}{\theta_m} (A_1 - B_0) \quad (9.23a)$$

$$\frac{\partial B_1}{\partial t} = \frac{k}{\theta_{im}} (A_1 - B_0) \quad (9.23b)$$

Applying the Laplace transform Equation 9.16 to Equation 9.23 gives

$$a_1(z, s) = \frac{k^2}{\theta_m \theta_{im}} \frac{c_i}{s^2} \exp \left[-\frac{kz}{\theta_m v} - \frac{sz}{v} \right] \quad (9.24)$$

whose inverse Laplace transform is

$$A_1(z, t) = \frac{c_i k^2}{\theta_m \theta_{im}} \exp \left[-\frac{kz}{\theta_m v} \right] \frac{z}{v} \left[t - \frac{z}{v} \right] \cdot u \left(t - \frac{z}{v} \right) \quad (9.25)$$

Higher-order approximations can be similarly obtained and solved, but the first two terms in the asymptotic expansion provide a sufficiently good approximation. The breakthrough concentration from a soil column of length L is obtained by substituting Equation 9.20 and Equation 9.25 into Equation 9.12 after replacing z by L , as

$$c_1(L, t) = c_i \exp \left[-\frac{kL}{\theta_m v} \right] \left\{ 1 + \varepsilon' \frac{c_i k^2}{\theta_m \theta_{im}} \frac{L}{v} \left[t - \frac{L}{v} \right] \right\} \cdot u \left(t - \frac{L}{v} \right) \quad (9.26)$$

The shape of the BTC predicted by Equation 9.26 is similar to BTCs measured for initially drained undisturbed soil materials with well-defined preferential paths (Anderson and Bouma, 1977; White et al., 1984, 1986; Kluitenberg and Horton, 1990). These BTCs are characterized by a breakthrough at very early times followed by a sharp concentration increase afterward when the chloride concentration increases rapidly from 0 to a higher value after which the concentration increases at a lower rate until the initial concentration is reached. Note that the sharp increase in concentration immediately after the initial breakthrough and sharp break later on is due to the elimination of the diffusion-dispersion term from the mass balance equation for the preferential paths.

Equation 9.26 was fitted to BTCs that were measured by Anderson and Bouma (1977) at the bottom of saturated columns filled with structured soils that were initially drained. The measured BTCs are taken from figure 3 in Anderson and Bouma (1977) and are shown together with the predicted BTCs in Figure 9.1. After determining the velocity v by dividing the column length by the breakthrough time, k is estimated by the concentration where the BTC changes its shape from the vertical increase to a moderate increase, and ε is determined from the slope at which the BTC reaches the initial concentration. The estimated k is close to the values calculated independently for this BTC by Skopp et al. (1981). Equation 9.26 fits well the measured BTCs (Figure 9.1).

9.3 A Dual-Porosity Model for Gradual Change in Matrix Structure and Concentration at the Fracture–Matrix Interface

The widely used assumption in the diffusion models in the previous section was that concentration over crack width is constant and equal to the matrix concentration at the interface between the two domains (Equation 9.10). In the following we focus on the interface between the fracture and the matrix and postulate that there is a boundary layer at the flowing and stagnant fluids (fracture and matrix) and that the matrix porosity is not uniform in the lateral direction (perpendicular to the fracture axis). The sharp porosity decrease at the vicinity of the fracture–matrix interface is denoted herein as “transition layer.” In the following the effect of the boundary and transition layers at the matrix–fracture interface on the solute exchange dynamics between the fracture and matrix is demonstrated by mathematical models and measured data.

The matrix–fracture system is shown on the right-hand side of Figure 9.2. The “matrix” is composed from a thin transition layer at the interface between the matrix and the fracture and the “real” elsewhere. The transition layer has diffusion properties different from those of the rest of the matrix. A close look at

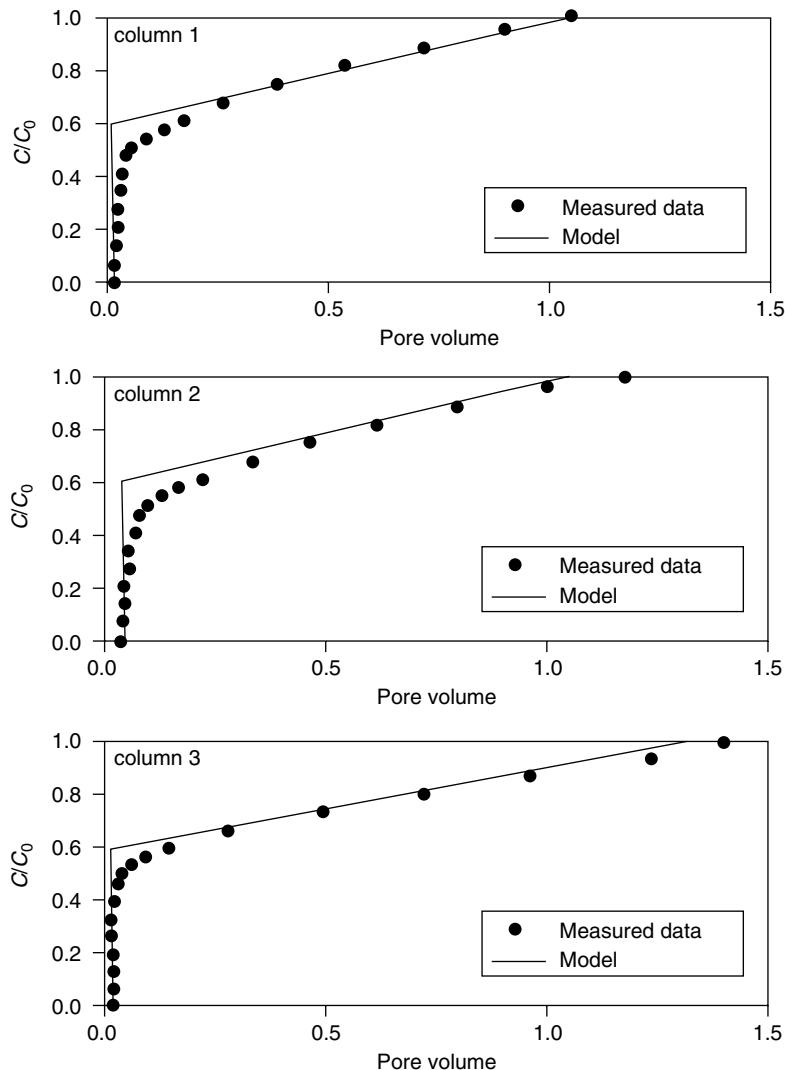

FIGURE 9.1 Measured (Data from Anderson, J. L. and Bouma, J. 1977. *Soil Sci. Soc. Am. J.* 41: 413–418.) and predicted BTCs at the outlet of three initially drained columns.

the fracture–matrix interface on the left-hand side of Figure 9.2 reveals the concentration variation along the fracture, boundary and transition layers, and matrix continuum.

The following mathematical model describes the convection in the fracture and lateral diffusion through the boundary and transition layers into the matrix. We assume that fluid flow through the crack is steady, one-dimensional, and isothermal. The concentration in the fracture is assumed to be laterally uniform beyond the boundary layer. Following the model presented by Wallach and Parlange (1998, 2000), the dissolved chemical transport in the crack is modeled by the kinematic-wave approach and the chemical exchange between the fracture and the matrix through the stagnant boundary layer is rate-limited. The kinematic-wave is a good approximation for the convection–dispersion equation for such system and enables an evaluation of an analytic solution.

$$\frac{\partial c_f}{\partial t} + \nu \frac{\partial c_f}{\partial z} = -k[c_f - c_1(-l, t)] \quad (9.27)$$

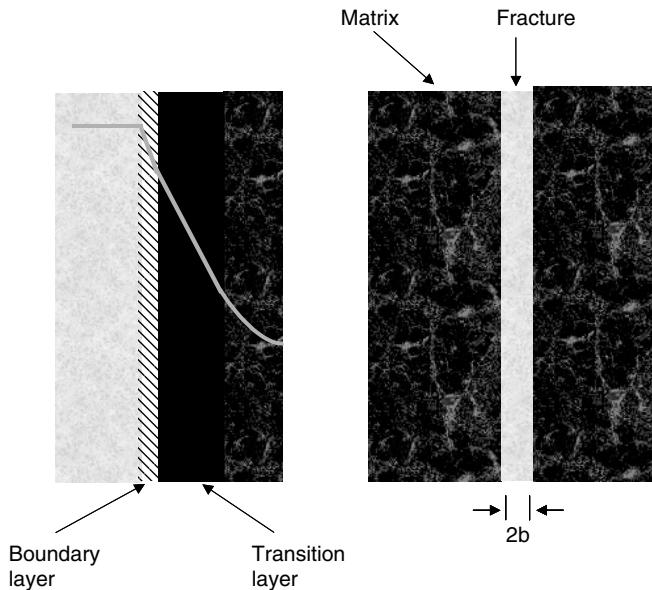

FIGURE 9.2 The fracture–matrix system together with the boundary and transition layers and an illustration of the lateral concentration variation.

where c_f is the dissolved chemical concentrations in the fracture; z is distance in the vertical direction; t is time; and $k [T^{-1}]$ is the mass-transfer coefficient per unit crack width.

The “matrix” is a composite medium. It is composed from a thin transition layer at the interface between the fracture and the matrix and the “real” elsewhere. The transition layer has diffusion properties different from those of the rest of the matrix. For simplicity it is assumed that the matrix is semi-infinite, $-l < x < \infty$, where x is the distance into the matrix perpendicular to the flow direction (Figure 9.2). The diffusion coefficient in the transition layer, $-l < x < 0$ is D_1 and the concentration is defined as c_1 there, while the corresponding quantities in $x > 0$ are D_2 and c_2 .

The differential equation for the transition layer and matrix are

$$\frac{\partial c_1}{\partial t} = D_1 \frac{\partial^2 c_1}{\partial x^2} \quad -l < x < 0, \quad t > 0 \quad (9.28)$$

$$\frac{\partial c_2}{\partial t} = D_2 \frac{\partial^2 c_2}{\partial x^2} \quad x > 0, \quad t > 0 \quad (9.29)$$

The boundary conditions for Equation 9.28 at the interface between the fracture and the transition layer ($x = -l$) is

$$\frac{\theta D_1}{b} \frac{\partial c_1(-l, t)}{\partial x} = k[c_f - c_1(-l, t)] \quad (9.30)$$

where $2b$ is the fracture/crack width and θ is the matrix porosity. Note that the matrix is assumed infinite: see Wallach and Parlange (1998) to remove this constraint if desired.

The boundary layer introduces an additional characteristic time scale to the equilibrium model that postulates an equal concentration over crack width and the matrix interface, namely, rate-limited mass-transfer between the crack and the matrix. Under certain circumstances, this additional time scale plays a major role in determining the concentration distribution along the crack and at its outlet.

The mass-transfer coefficient that describes the chemical transfer driven by a concentration gradient across the hydrodynamic boundary layer is generally described in a simplistic way by the film theory. The concentration is assumed to vary linearly within the boundary layer from its value at the matrix interface and the laterally uniform concentration in the flowing fluid (Figure 9.2). The concentration gradient throughout the boundary layer is not known because the thickness of the concentration boundary layer cannot be measured. The mass-transfer coefficient depends upon relative velocity near the interface and the thickness of the film. If bulk flow in the crack is reasonably steady, then the thickness of the film is essentially constant. The mass-transfer coefficient can be indirectly determined by way of experimental conditions, commonly done by fitting transport models to measured BTCs. Alternatively, a relationship can be obtained directly between the rate of mass-transfer and hydrodynamic conditions at the boundary. For example,

$$b \frac{kL}{D} = 0.626 \left(\frac{Lv\rho}{\mu} \right)^{1/2} \left(\frac{\mu}{\rho D} \right)^{1/3} \quad (9.31)$$

where ρ is the fluid density and μ is its dynamic viscosity, L is the fracture length. Equation 9.31 is written in this form to emphasize its relation to the dimensionless numbers $Sh = kL/D$ (Sherwood number), $Re = Lv\rho/\mu$ (Reynolds number), and $Sc = \mu/\rho D$ (Schmidt number). Different mass-transfer correlations for different fluids, geometries and values of Reynold number are given in Weber and DiGiano (1996). Equation 9.31 can be used in cases where the fracture shape is regular and well-defined with a priori known b , and L .

The boundary condition for Equation 9.29 at the interface between the transition layer and matrix assumes that there is no contact resistance at the surface of separation, $x = 0$.

$$c_1 = c_2 \quad x = 0 \quad (9.32)$$

$$D_1 \frac{\partial c_1}{\partial x} = D_2 \frac{\partial c_2}{\partial x} \quad x = 0 \quad (9.33)$$

An analytic solution of the entire system of differential equations (including the fracture) and associated boundary conditions is complicated. Before an effort to find a solution is allocated it is essential to find out whether the boundary and transition layers exist and what is their effect on the transport dynamics. In the following, intermediate stages of the entire effort are presented. The experimental and mathematical efforts to reach a complete understanding of the transport processes at fracture–matrix interface and their effect on the entire solute transport in the fracture and matrix during contamination and remediation continues.

9.3.1 The Boundary Layer Effect on the Breakthrough Curve at the Fracture Outlet

Wallach and Parlange (2000) presented an analytical solution for the case where the matrix is uniform matrix. The system consists of a fracture a uniform matrix and a boundary layer at their interface (Figure 9.2). The solution was developed by using the Laplace transform. The model was verified by comparing its simulated output to measured BTCs of two experimental studies (Kluitenberg and Horton, 1990; Sidle et al., 1998).

In their study, Kluitenberg and Horton used undisturbed cores of glacial-till-derived soil to displace CaSO_4 with CaCl_2 during saturated, steady fluid flow. The column length was 33 cm and the diameter 18 cm. Following the displacement study, a dye solution was applied at the column inlet and the column was

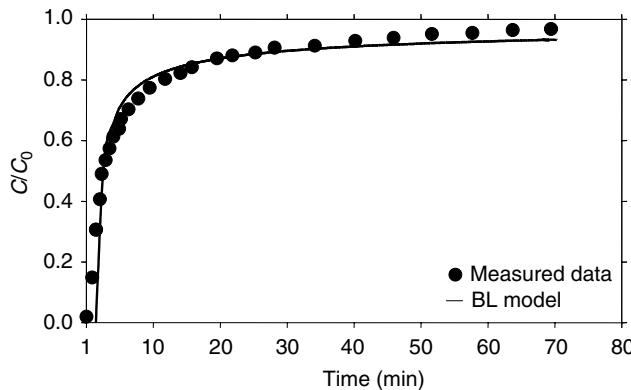

FIGURE 9.3 Comparison between predicted and measured (Kluitenberg and Horton, 1990) BTCs.

sectioned horizontally in 5-cm increments to allow visual characterization of the stained and unstained soil voids. The dye was transmitted through the lower half of the column in one continuous 2-mm diameter channel (column B, table 2 in Kluitenberg and Horton, 1990). As the fracture configuration in column B fit the model assumption of a single-fracture displacement with simultaneous matrix exchange better than the other columns, its BTC was used for the model validation. The predicted BTC fit the measured BTC well: both are shown in Figure 9.3. By using the kinematic wave equation for fracture transport (Equation 9.27), the predicted BTC increases more sharply than the curved, measured BTC increase soon after initial breakthrough. Note that the dispersion in the predicted BTC is formed solely by the solute exchange between the fracture and matrix.

The average pore water velocity, 1.1 cm min^{-1} , determined by Kluitenberg and Horton by the solute flux through the entire soil porosity, is much smaller than the velocity in the preferential flow path determined by the measured first breakthrough time. The flow velocity in the continuous fracture along the entire column length as estimated directly from the measured BTC is $v = 23 \text{ cm min}^{-1}$. This velocity was determined by neglecting hydrodynamic dispersion in the column and assuming a larger first breakthrough time than was actually measured. The model-estimated parameters obtained by best fit between the simulated and measured BTCs were $k = 4.5 \text{ min}^{-1}$, and $b^2/D\theta^2 = 1.4 \text{ min}^{-1}$. Note that the equivalent fracture aperture, b , depends on the matrix diffusion coefficient and vice versa (both unknown). This model was also verified by its successful comparison to natural gradient tracer test of Sidle et al. (1998) which simulated one-dimensional flow in a large ($4 \text{ m} \times 4.8 \text{ m}$ surface area) isolated block of fractured till in Denmark (Wallach and Parlange, 2000).

Recognizing the existence of a boundary layer (BL) at the fracture–matrix interface, rather than assuming an equilibration of concentrations (LE), affects the shapes of BTCs at the fracture outlet. A qualitative analysis of this effect was presented by Wallach and Parlange (1998). The analysis divided the role of the boundary layer resistance on fracture–matrix solute exchange into two stages. The first is soon after displacement initiation, when the lateral chemical flux into the matrix is mostly controlled by boundary layer resistance. Subsequently, the rate of matrix diffusion predominantly controls this flux and the BL model can be replaced by the LE model which involves easy mathematical manipulations and no induction of major errors. The extension of the first stage, during which the boundary layer resistance controls solute exchange, depends on the value of the dimensionless parameter $\varepsilon = kb^2/\theta^2 D$.

The outcome of this quantitative analysis is shown in Figure 9.4 where simulated BTCs at the fracture’s outlet were calculated by the BL and LE models for similar parameters.

The two simulated BTCs deviate initially and come closer as time progresses, as was qualitatively discussed in Wallach and Parlange (1998). Since chemical transport in the crack by both BL and LE models is expressed by the kinematic-wave equation, the first chemical appearance at a certain point along

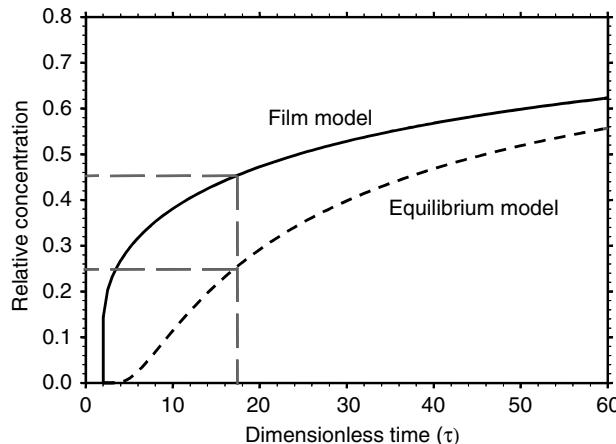

FIGURE 9.4 Comparison between BTCs calculated by the boundary-layer (—) and local-equilibrium (---) models for similar parameter values.

the fracture occurs at the same instant. The BL model predicts lower solute influx into the matrix than does the LE model, owing to the lower predicted concentration at the fracture–matrix interface. The varying concentration-differences between the interface and fracture lead to higher predicted concentrations at the fracture outlet by the BL model. The difference between the concentrations at the fracture–matrix predicted by the two models is initially high and decreases with time as more solute enters the matrix. As time progresses, the differences between the fracture–matrix interface and fracture concentrations converge to a finite value that provides a solute flux equal to the flux predicted by the LE model, the latter being solely controlled by the matrix concentration gradient at the interface.

The parameter ε has a significant effect on the deviation between BTCs predicted by the BL and LE models and its extent during the first stage. This parameter is similar to the Biot number, Bi , used by Crittenden et al. (1986) and others to estimate the role of different rate-limited processes on the adsorption of chemical onto soil aggregates. Larger ε and Bi values denote a higher effect of the mass-transfer coefficient (fast time scale) than matrix diffusion on solute flux to the matrix, and that concentration through the boundary layer becomes rapidly uniform. This can be obtained by relatively large k or small D values. In contrast, high diffusion coefficients in the matrix (smaller ε values) cause rapid removal of solutes from the fracture–matrix interface into the bulk matrix and extend the time during which the mass-transfer coefficient controls the flux. Although not rate-limited parameters, crack width, b , and matrix porosity, θ , have a significant effect on ε since both are raised to the second power.

9.3.2 The Transition Layer Effect on the Concentration Distribution in the Matrix

The verification of models in which diffusion was assumed to control the solute transport in the matrix was widely based on its effect on the breakthrough curves shape at the fracture outlet. A direct evidence of the concentration distribution within the matrix should include concentration measurement at high spatial resolution within the matrix. This can be efficiently and accurately done by non-invasive methods, such as CT, MRI, and others.

Polak et al. (2003a, 2003b) monitored the concentration changes inside a chalk matrix due to NaI diffusion from a vertical and horizontal fracture, respectively, and the back-diffusion process from the contaminated matrix into the fracture using a medical-based X-ray CT scanner. The sample used in the experiment was a 20-cm long, 5-cm diameter chalk core retrieved from a corehole at a depth of ~ 18.3 m. The study area is located in the northern Negev desert of Israel and is underlain by fractured Eocene chalk formations with a thickness of 285 m.

The characteristics of the mass transfer between the fracture and the surrounding matrix were obtained by the concentration distribution within the matrix. The time-dependence of the diffusion and back-diffusion processes was monitored by consecutive scans. The diffusion and back-diffusion experiments were conducted on an artificially fractured chalk core. The confined core was placed in the scanner and the concentration distribution within the core was monitored. The discussion to follow is related to the vertical fracture experiment (Polak et al., 2003a).

Following core saturation, the tracer solution (5% by weight of NaI) was injected into the fracture using a peristaltic pump at a constant concentration and rate of $2.5 \text{ cm}^3 \text{ min}^{-1}$. The volume of the fracture void was about 10 cm^3 , hence it was replaced every 4 min. This injection process lasted for six days, during which the core was scanned eight times (hereafter denoted as sequences 1 through 8). The scanner produces two-dimensional slices through the sample with a thickness of 4 mm and an in-plane pixel resolution of about 0.25 mm. The X-ray energy level used in the experiment was 130 kV at 105 mA and the acquisition time for each scan was 4 sec.

After six days of tracer-solution injection, distilled water was injected using the same peristaltic pump at the same flow rate. The water injection generated a reverse concentration gradient of the tracer from the matrix to the fracture. The flow rate ensured complete removal of the tracer from the fracture without accumulation. This water injection lasted for 11 days, during which the core was scanned 10 times to track tracer migration from the matrix to the fracture.

The tracer's lateral distribution in the matrix for the three selected images during the eight scan sequences is shown (a1, b1, c1) in CT numbers and in Figure 9.5 (a2, b2, c2) in terms of relative concentration, C/C_0 . Figure 9.5a refers to image 38, where both sides of the fracture resembled each other. This resulted in a similar temporal diffusion pattern as evidenced by the identical colored bands in the eight scanning sequences (a1) as well as by the four relative concentration graphs (a2). The effect of the sealed boundaries at the core's top and bottom began dominating tracer diffusion from the third day (fifth scan) through tracer migration from the core edges down and up toward the matrix center. The distribution of C/C_0 across the chalk matrix (a2) formed two distinct zones. The first zone was characterized by a sharp concentration decrease over a thin distance adjacent to the fracture–matrix interface, hereafter denoted transition zone. In the second zone, adjacent to the first one and further into the matrix, the concentration decrease followed a diffusion-type pattern.

Image 12 (Figure 9.5b1) contained a natural fracture, first observed after the core's fracturing, that ran across the upper right face of the artificial fracture. The natural fracture appeared impermeable to water and the saturation of the right face of the natural fracture lagged behind its counterpart on the left. Saturation was finally accomplished by water advecting from the top of the artificial fracture. A similar pattern was observed during tracer injection (b1, second scan on) and was reflected in the sharp relative concentration decrease in the naturally fractured zone (b2, at 3.7 cm along the x-axis). The white circle located at the right edge of image 30 (Figure 9.5c1) demonstrates the effect of a broken core on the diffusion process. The lack of color indicates lack of tracer accumulation, as also evidenced by the zero relative concentration (c2) in this zone. In fact, this hole at the core edge acts like a sink.

The results of the back-diffusion phase measured by Polak et al. (2003a) are exemplified through the same three images used to examine the diffusion phase. Figure 9.6 presents the tracer concentration decrease (in CT numbers) in the matrix of these three images during six of the 10 scan sequences (a1, b1, and c1), as well as the calculated relative concentration (C/C_0) during 4 of these scans (a2, b2, and c2). Note that the first picture and graph for each image represent the last sequence of the diffusion experiment.

Tracer displacement by the water injected into the fracture was documented in image 38 (where both sides of the fracture were almost identical) as a white line in the center of the image (Figure 9.6a1). The relative concentration in the fracture dropped to almost zero as soon as back-diffusion started (Figure 9.6a2, scan sequence 1). However, tracer concentrations away from the fracture did not change much with respect to their distribution during the end of the diffusion phase. Note that while tracer movement from the matrix into the fracture was occurring near the fracture as a result of the reversed concentration gradient, tracer further away from the fracture continued diffusing toward the core edge (scan sequence 3, Figure 9.6a2). By the end of the back-diffusion experiment, tracer concentration inside the core matrix had

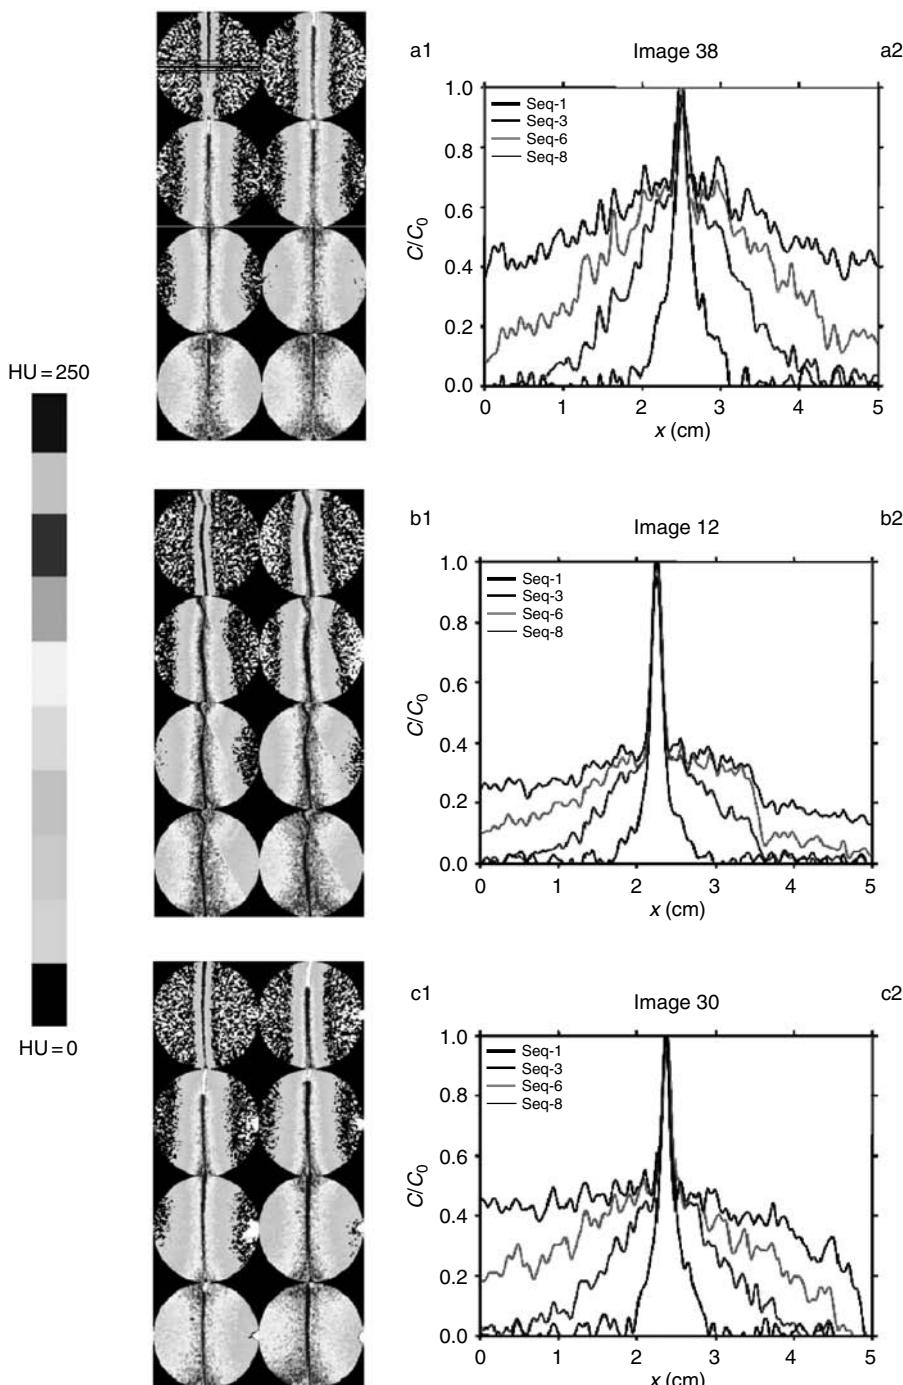

FIGURE 9.5 Tracer distribution during the diffusion phase in the scanned core, presented as both concentrations (in CT numbers) and relative concentrations during scan sequences 1, 3, 6, and 8 in images 38, 12, and 30 (a1,2; b1,2; and c1,2, respectively). The CT numbers refer to the attenuation coefficient, converted to an internationally standardized scale, known as Hounsfield units (HU). The scale is linear, and HU units for air and water are defined as -1000 and 0, respectively. High HU numbers correspond to high-density materials. (From Polak et al., 2003. Chemical diffusion between a fracture and the surrounding matrix: Measurements by computed tomography and modeling. *Water Resour. Res.* 39(4), 1106, doi 10.1029/2001WR000813. With permission)

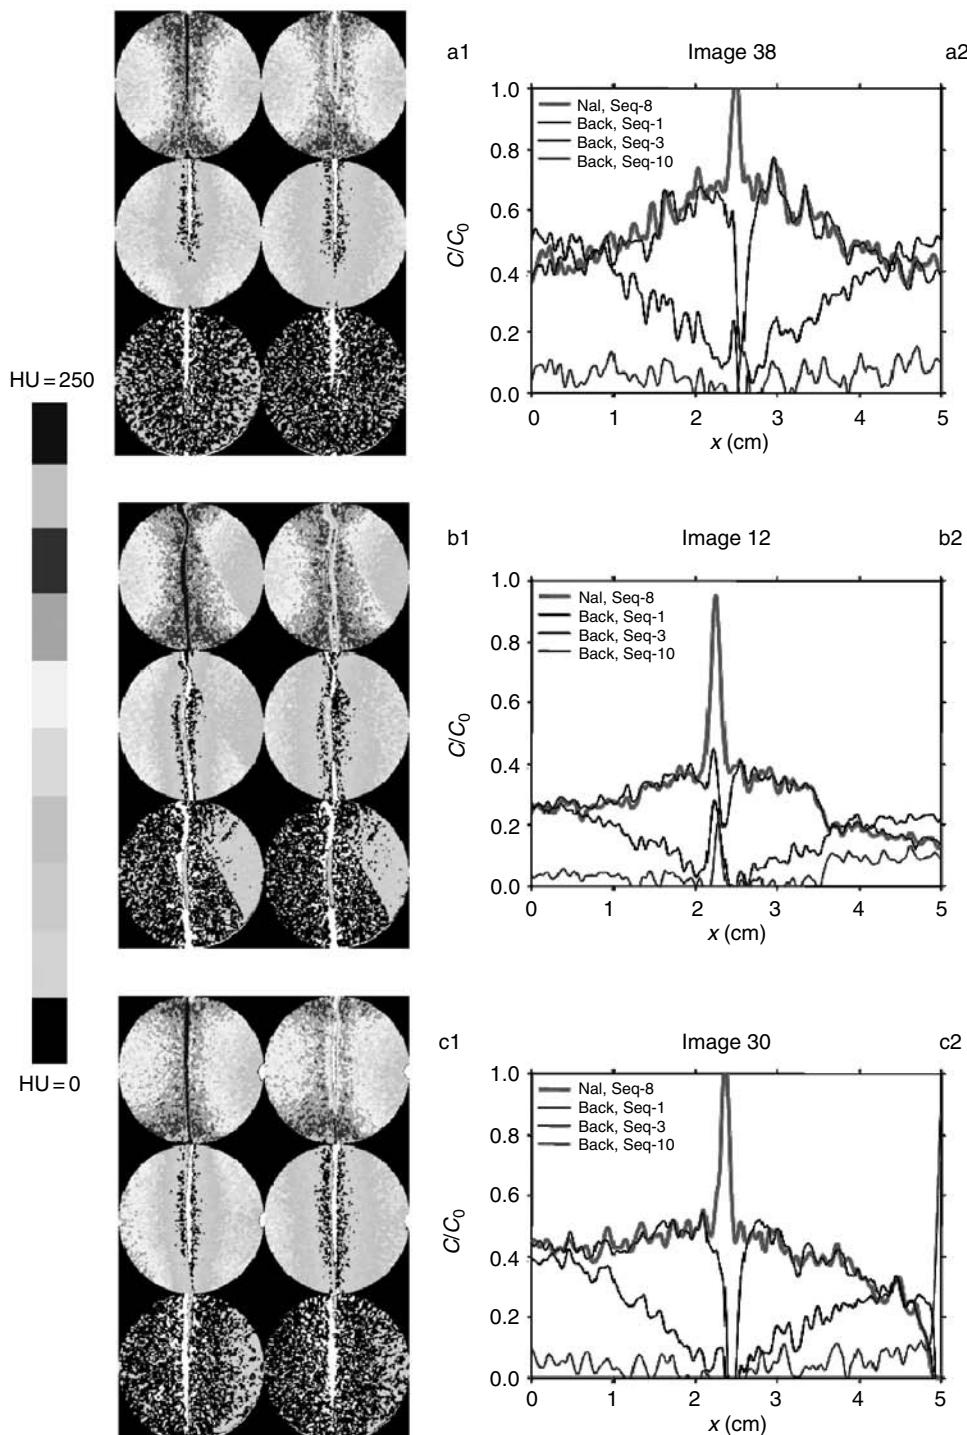

FIGURE 9.6 Tracer distribution during the back-diffusion phase in the scanned core, presented as both concentrations (in CT numbers) and relative concentrations during scan sequences 8 (last for the diffusion phase) and 1, 3, and 10 in images 38, 12, and 30 (a1,2; b1,2; and c1,2, respectively). (From Polak et al., 2003. Chemical diffusion between a fracture and the surrounding matrix: Measurements by computed tomography and modeling. *Water Resour. Res.* 39(4), 1106, doi 10.1029/2001WR000813. With permission)

dropped to almost zero (blue color in scan sequence 10, Figure 9.6a1 and 9.6a2, respectively), although the relative concentration at the core's edges was still higher than that near the fracture. Similar to observations during the diffusion experiment, concentration patterns during back-diffusion in this image were alike on both faces of the fracture. The bottom part of the fracture appears closed (Figure 9.6a1), probably as a result of the confining pressure applied to the core.

The natural impermeable fracture intercepted by image 12 slowed the tracer's back-diffusion (Figure 9.6b). Whereas the left face of the core exhibited a decreasing concentration pattern similar to those observed for image 38, tracer relative concentration simultaneously increased in the right face (Figure 9.6b1, 9.6b2). The reduction in back-diffusion rate was also visible at the end of the experiment (scan sequence 10) where the left side of the artificial fracture was almost tracer-free, while in the right side the relative concentration was much higher (0.02 vs. 0.1, respectively). By the end of the experiment, the tracer had not been completely displaced from the artificial fracture void (Figure 9.6b1 and scan sequence 10 in Figure 9.6b2).

In image 30, the hole in the core's edge that acted like a sink during the tracer diffusion phase turned out to be a tracer source, as evidenced by the spot on the right side of the core (Figure 9.6c1) and the increasing relative concentration (scan sequence 10, Figure 9.6c2).

9.3.3 Modeling the Diffusion and Back-Diffusion — The Transition Layer Concept

Attempts to fit the models of Grisak and Pickens (1980, 1981) and Sudicky and Frind (1982) to the measured concentration distributions failed as they could not simultaneously predict the sharp concentration decrease near the fracture–matrix interface and the concentration decrease further into the matrix (Figure 9.7). These commonly used models for chemical transport along a fracture surrounded by porous matrix assume a continuous concentration variation at the fracture–matrix interface. The simulated curve (using the Sudicky and Frind's model) shown in Figure 9.7 was calculated with a diffusion coefficient of $4 \times 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$ and provides the best fit between the measured and predicted data. This value of the diffusion coefficient used for this simulation is within the range of independently measured values in this chalk (Polak et al., 2002).

The failure of the aforementioned models to simulate the sharp concentration decrease near the fracture–matrix interface possibly indicates that the assumption of equal fracture and matrix

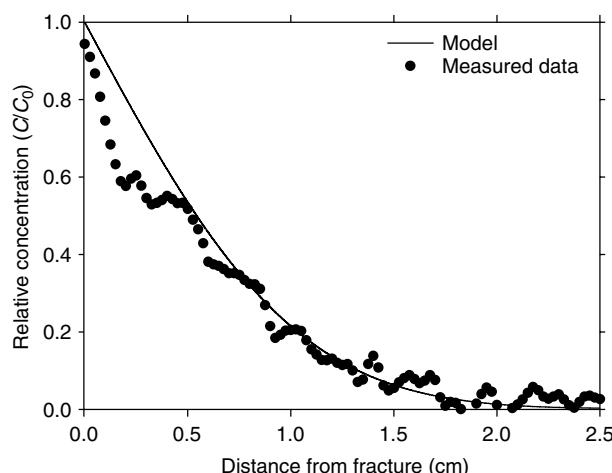

FIGURE 9.7 Measured (scanned) NaI concentrations along the right side of image 38 and its predicted concentrations using the model of Sudicky and Frind (1982). (From Polak et al., 2003. Chemical diffusion between a fracture and the surrounding matrix: Measurements by computed tomography and modeling. *Water Resour. Res.* 39(4), 1106, doi 10.1029/2001WR000813. With permission)

concentrations at their interface should be replaced by a different approach in that zone. The sharp concentration decrease near the matrix–fracture interface indicates the presence of a transition layer, the diffusion coefficient of which is significantly higher than that of the bulk matrix, but lower than that in the fracture. This transition layer consists of mini-fissures and small fractures that developed when the fracture was formed (Labuz et al., 1987; Huang and Kim, 1993). These mini-fissures and small fractures have a higher porosity, which leads to a higher diffusion coefficient.

As a first approximation, it is assumed that the transition-layer concept (Equation 9.32 and Equation 9.33) for this experiment will be simplified and conceptually treated as a boundary-layer (Equation 9.31), in which the concentration varies linearly between its value at the fracture and its value at the interface between the transition layer and the bulk matrix. This approximation is related to the fact that the fracture concentration in this experiment was kept artificially constant. The concept of a thin layer having no storage but with a fixed resistance to diffusion is identical to the concept of well-bore skin in groundwater hydrology and petroleum engineering. The simplified approach for the transition layer to predict the measured concentration distribution within the matrix (Figure 9.5 and Figure 9.6) was used in Polak et al. (2003a). This approach postulates that the transition layer is thin and that the concentration varies linearly within this layer (similar to the assumption used previously by Wallach and Parlange [2000] for the boundary layer). The concentration distribution within the matrix $c_2(x, t)$ for the finite core matrix dimension was obtained by applying the numerical inversion to equation (12) in Wallach and Parlange (2000) and equation (19) in Polak et al. (2003a). The Stehfest algorithm (Stehfest, 1970) for inverse Laplace transform was used for this purpose.

The analysis of the measured data and the model predictions presented from hereon are relevant to either side of the fracture (left or right) of each image. The origin of the x -axis in the following figures is at the interface between the transition layer and the bulk matrix. The transition layer width was determined from the measured lateral concentration distribution within the matrix in the region where the concentration sharply decreased. As it turns out, this layer contained two to three CT pixels (0.5 to 0.75 mm). Figure 9.8a presents the measured concentrations and fitted curves for image 38 at three of the eight scan times run during the diffusion phase. The fitted values for the three time steps were $D = 4 \times 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$ and $\varepsilon = 0.18$. Note that each curve in Figure 9.8a represents the average of five cross-sections in the middle of the sample. The fitted diffusion coefficient, D , was kept constant for the entire core whereas the value of ε was changed for the different images in order to obtain the best fit to the measured data. As D is constant ($4 \times 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$), $b = 0.05 \text{ cm}$ (half the fracture width as estimated in prior experiments), and L and θ are calculated from the CT measurements, the fitted ε values actually provide the fitted values of the mass-transfer coefficient, k (Equation 9.8). The measured and fitted values for images 38, 42, and 47 are presented in Table 3 in Polak et al. (2003a), where it can be seen that the variations among the fitted k values are small.

The initial tracer concentration inside the rock matrix at the beginning of the back-diffusion phase in Polak et al. (2003a) was identical to that at the end of the diffusion phase. As the results were calculated in the Laplace domain and the inversion back to the time domain was performed numerically, the superposition principle was applied to replace the initial condition into a boundary conditions. The diffusion model was run for each image from the beginning of the diffusion phase, using fitting parameters identical to those used during the diffusion phase for each image. The model was then run again from the beginning of the back-diffusion phase without changing the parameters' values. The concentration distribution for the back-diffusion phase was obtained by subtracting the latter from the former. Consequently, the initial condition of the back-diffusion phase was modified into two new boundary conditions (the concentration values at different times).

Figure 9.9a–c presents the measured (CT scanned) and predicted relative tracer concentrations for images 38, 42, and 47 at the beginning of the back-diffusion phase (scan sequence 1) and during two more of the 10 scans performed. The model successfully predicted the concentration decrease near the transition layer–matrix boundary from $c/c_0 = 0.6$ in scan sequence 1 down to 0.1 in scan sequences 3 and 5. It also successfully simulated the before discussed relative concentration increase at the core's edge (sealed boundary) for sequence 3.

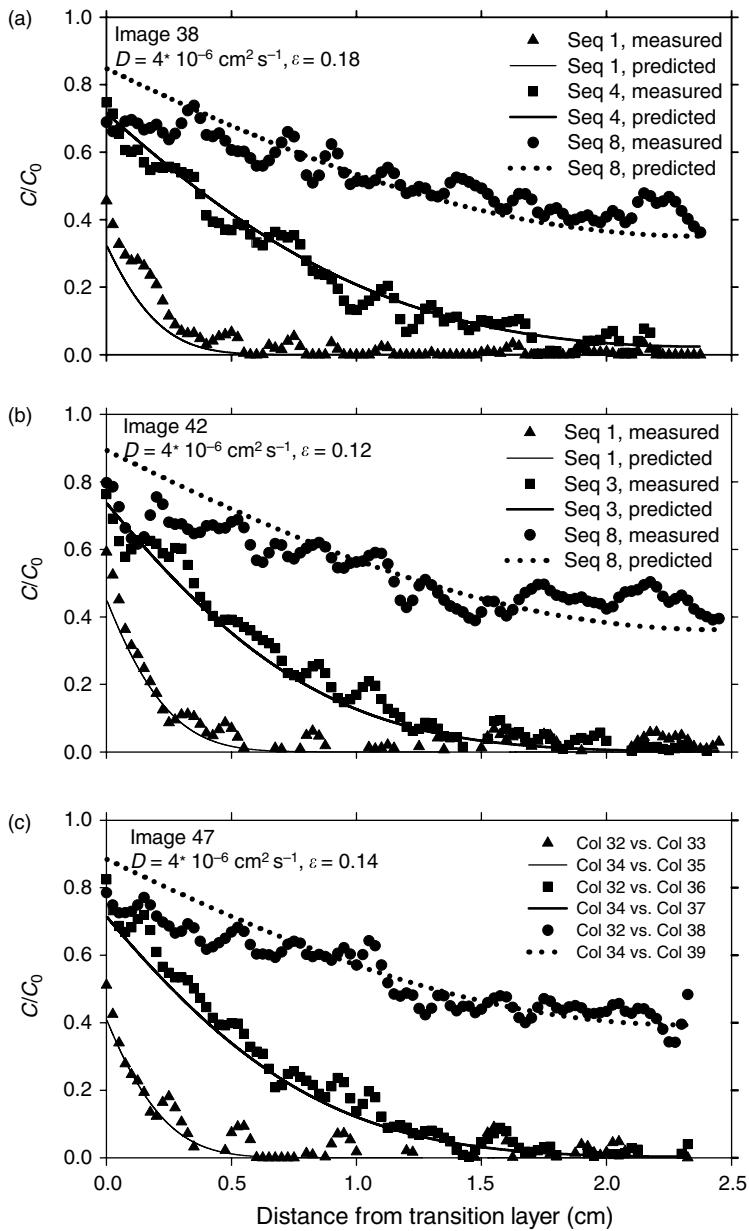

FIGURE 9.8 Measured (scanned) and modeled NaI concentrations in the diffusion experiment along image 38 (a), 42 (b), and 47 (c) in three different scan sequences. (From Polak et al., 2003. Chemical diffusion between a fracture and the surrounding matrix: Measurements by computed tomography and modeling. *Water Resour. Res.* 39(4), 1106, doi 10.1029/2001WR000813. With permission.)

Following the successful prediction of the measured data, the mathematical model was used in Polak et al. (2003a) to estimate the probable duration of remediation efforts on a field scale. The study area used for this purpose is an industrial complex in the northern Negev desert, Israel. It hosts chemical plants as well as many solid- and liquid-waste-disposal sites that have been continuous contamination sources for the 27 years of its operation. This complex was constructed on fractured chalk formations with fracture spacing of ~ 5 m. These fractures are considered the main conduits for contaminant transport to the subsurface (Nativ et al., 1999). The core used for the diffusion and back-diffusion experiments was taken

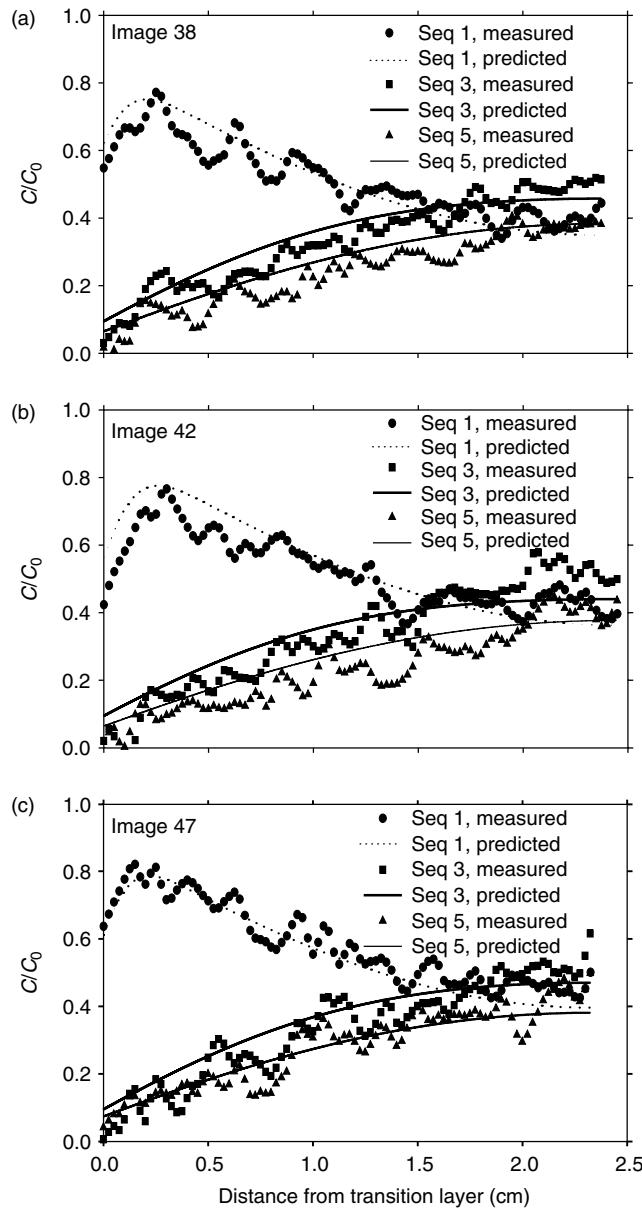

FIGURE 9.9 Measured and modeled NaI concentrations in the back-diffusion experiment along image 38 (a), 42 (b), and 47 (c) in three different scan sequences. (From Polak et al., 2003. Chemical diffusion between a fracture and the surrounding matrix: Measurements by computed tomography and modeling. *Water Resour. Res.* 39(4), 1106, doi 10.1029/2001WR000813. With permission.)

from a corehole located on site. Figure 9.10a displays the modeled tracer relative concentrations in the rock matrix following 1, 2.5, 5, 10, and 20 yr of its diffusion from the fracture. The model was applied to a lateral distance of 250 cm (half the typical fracture spacing on site) of unfractured chalk block (with a sealed boundary at its end) and with $\varepsilon = 0.15$ and $D = 4 \times 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$ as the fitting parameters. The modeling results followed a typical diffusion pattern in the chalk matrix and 20 yr of tracer diffusion resulted in a calculated lateral penetration of ~ 150 cm into the matrix.

Figure 9.10b displays the modeled distribution of the relative tracer concentrations (in logarithmic scale) inside the rock matrix for the back-diffusion phase, thereby simulating the impact of flushing clean

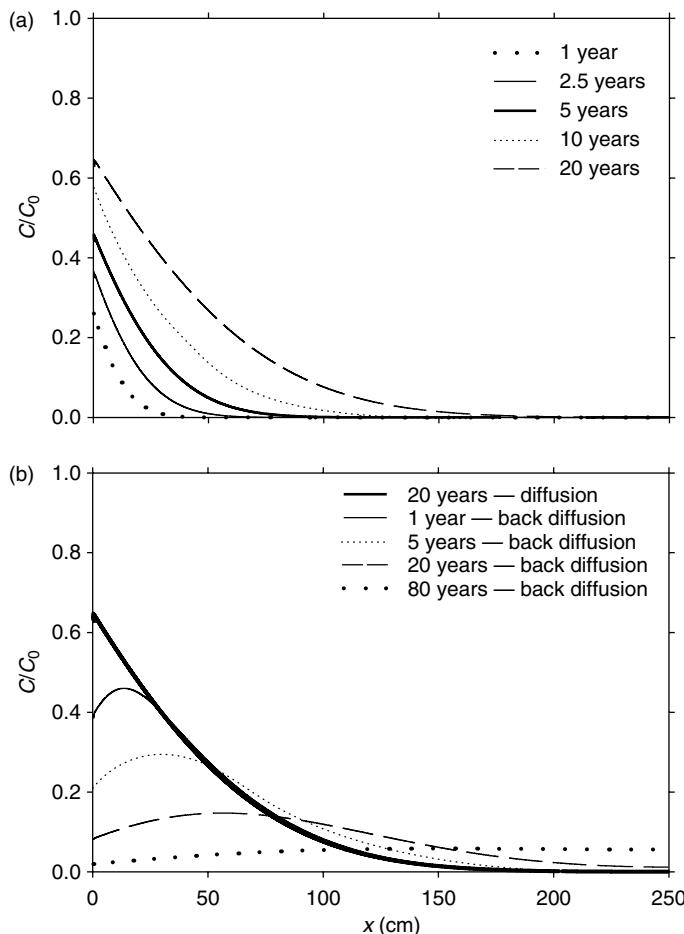

FIGURE 9.10 (a) Model prediction of tracer distribution in the 250-cm wide rock matrix following its diffusion during five different time periods, and (b) its redistribution following back diffusion during different time periods. (From Polak et al., 2003. Chemical diffusion between a fracture and the surrounding matrix: Measurements by computed tomography and modeling. *Water Resour. Res.* 39(4), 1106, doi 10.1029/2001WR000813. With permission.)

water into the fractures (e.g., pump-and-treat practice). The model parameters (ε and D) were kept identical to those used in the diffusion phase. Whereas the bold line represents the distribution of the relative tracer concentration following 20 yr of diffusion (initial condition), the other lines display the calculated distributions following 1, 5, 20, and 80 yr of back-diffusion. These simulations clearly show that while the relative tracer concentration near the fracture drops to almost zero after a long flushing, it continues to progress deeper into the rock matrix further away from the fracture. In fact, according to the model, the tracer is expected to reach the sealed boundary at 250 cm 20 yr after flushing of the fracture is initiated, thereby transforming the rock matrix into a long-term contaminant source for the fracture. Obviously, according to these calculations, remediation through clean-water injection into the fractures would take hundreds of years, rendering it practically impossible.

9.4 Dual-Porosity Models with a Distribution Layer at the Soil Surface

The models presented in the previous section assume that the soil surface layer has a structure similar to that of the subsoil and preferential flow takes place along the whole soil pedon. Recent observations

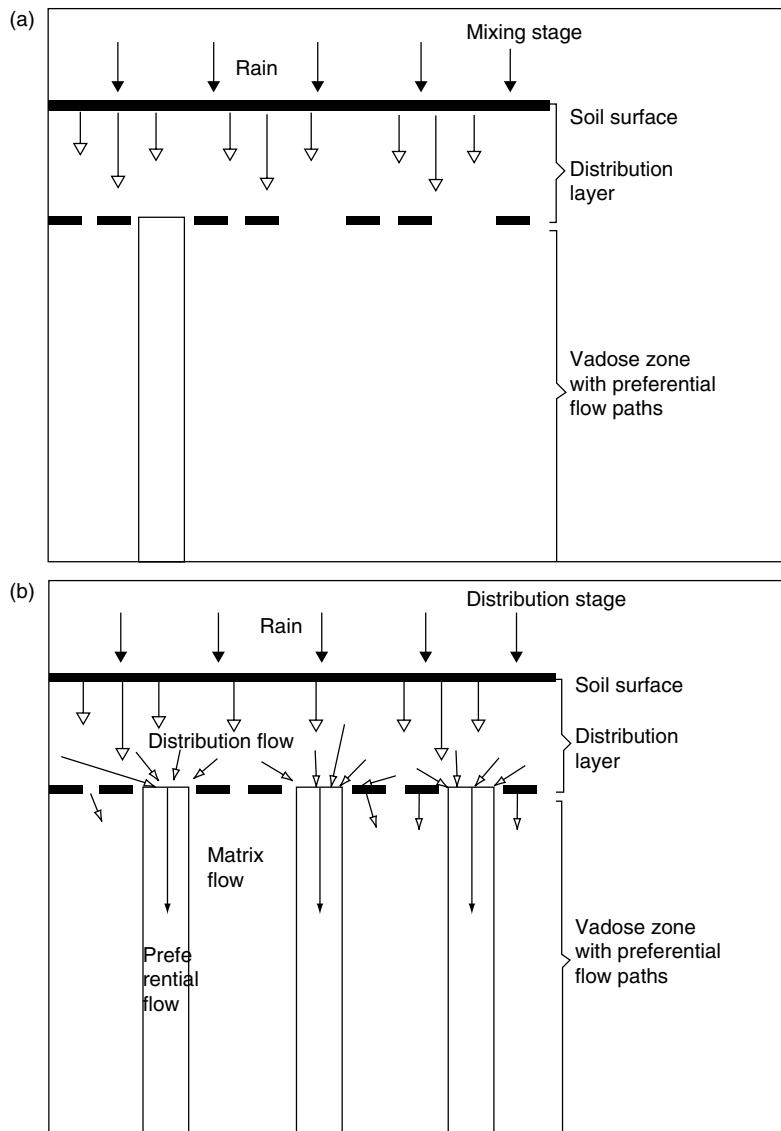

FIGURE 9.11 Conceptual framework of preferential flow model. (a) The mixing stage in the distribution layer and (b) the distribution into the preferential flow paths.

(Parlange et al., 1988; Steenhuis et al., 1994; Ritsema and Dekker, 1995; and others) have shown that a thin (2–30 cm) soil surface layer (distribution layer) exists in many cases at the soil surface where flow takes place throughout this layer. The precipitation in the distribution layer is funneled into the preferential paths in the subsoil (Figure 9.11). The distribution layer typically has a higher conductivity (especially in the horizontal direction) than the soil profile below it. Its thickness depends on various factors such as tillage, vegetation, and bioturbation. One of the approaches to model the distribution layer is to assume that it is a linear reservoir (Steenhuis et al., 1994). A linear reservoir is equivalent to a well-mixed reservoir where the momentary solute concentration is uniformly distributed throughout its depth. The lumped mass balance equation for the distribution layer is

$$\frac{dc_0}{dt'} = -\frac{J_w}{\theta_s l} c_0 \quad (9.34)$$

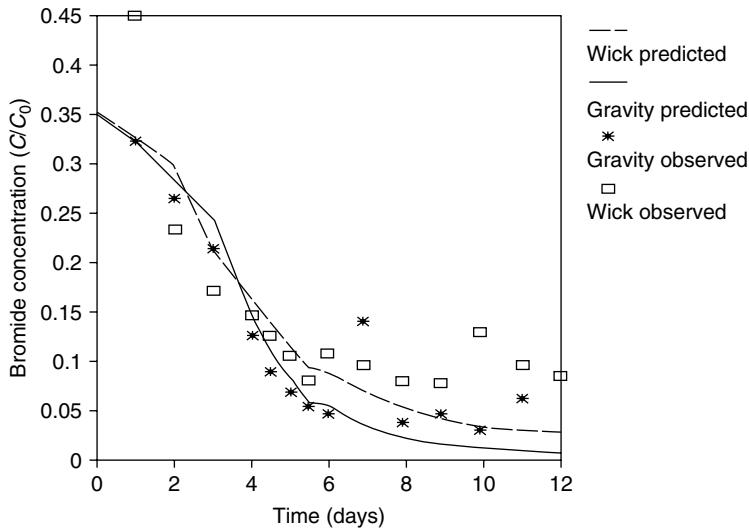

FIGURE 9.12 Observed and predicted outflow concentrations of the wick and gravity pan samplers for the Cornell Orchard site.

where θ_s is its saturated water content, J_w is the flux leaving the distribution zone, and l is the depth of the distribution layer. $c_0(t)$ is the dissolved chemical concentration in the distribution layer. Steenhuis et al. (1994) assumed that there was no interaction in preferential flow paths between the preferentially moving water and the matrix. The concentration of solutes leaving the distribution layer (and in preferential flow paths) after the solute is completely mixed in the distribution zone is

$$c_0 = \frac{M}{\theta_s l} \exp \left(-\frac{\int J_w dt}{\theta_s l} \right) \quad (9.35)$$

where M is the amount of solute applied per unit area. Figure 9.12 shows the results of an experiment carried out in the Cornell Orchard on a Rhinebeck loamy soil with a 30-cm distribution zone on top of a glacial till with macropores in the structural cracks. A pulse of chloride was added on day zero followed by daily irrigations of 3 cm. The concentration in the preferential flow paths was measured in wick and gravity pan samplers at 60 cm depth. Although the fit is quite good, it is obvious that it cannot fit the BTCs such as were obtained by Anderson and Bouma (1977). A more complicated model is needed in which the distribution layer as well as the interaction in the subsoil between macropores and matrix (introduced above) is taken into account.

In order to do so, assume a time interval, τ , when the solutes that enter the soil surface enter the preferential paths. Thus, the concentration that enters the preferential flow paths (not assuming instantaneous mixing) is

$$c_0(\tau) = c_i(1 - e^{-\alpha\tau}) \quad (9.36)$$

to be used in Equation 9.10. Following the small perturbation solution above, Wallach and Steenhuis (1998) obtained the *zeroth* and first approximations concentration in the preferential paths at point z

$$A_0(z, t) = c_i \exp \left[-\frac{kz}{\theta_m v} \right] \left\{ 1 - \exp \left[-\beta \left(t + \tau - \frac{z}{v} \right) \right] \right\} \cdot u \left(t - \frac{z}{v} \right) \quad (9.37)$$

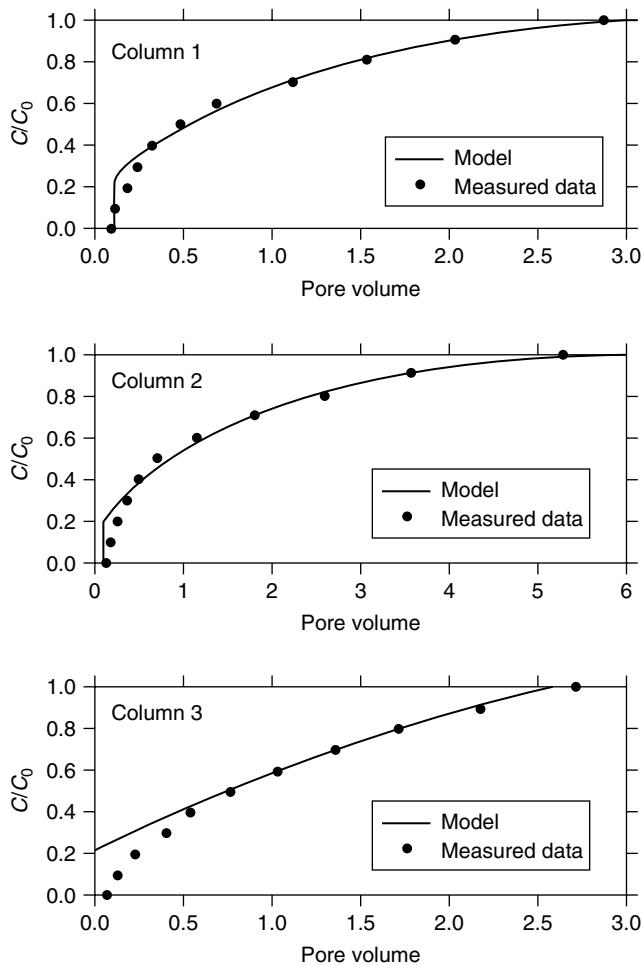

FIGURE 9.13 Measured (Data from Anderson, J. L. and Bouma, J. 1977. *Soil Sci. Soc. Am. J.* 41: 413–418.) and predicted BTCs at the outlet of three initially-saturated columns.

$$A_1(z, t) = \frac{c_i k^2}{\theta_m \theta_{im}} \exp\left[-\frac{kz}{\theta_m v}\right] \frac{z}{v} \left\{ t - \frac{z}{v} - \frac{\exp[-\beta\tau]}{\beta} \left[1 - \exp\left[-\beta\left(t + \tau - \frac{z}{v}\right)\right] \right] \right\} \cdot u\left(t - \frac{z}{v}\right) \quad (9.38)$$

This model was also validated by using BTCs that were measured by Anderson and Bouma (1977) for initially saturated columns containing structured soils. Both, measured (figure 1 in Anderson and Bouma, 1977) and predicted BTCs (Equation 9.38) are shown in Figure 9.13. The initially saturated experimental runs have much longer initial breakthrough times and BTCs tailing compared with the initially drained runs where the now air-filled large pores were drained quickly. Emptying these paths by draining the columns prior to the runs enables the infiltrating solute in the initially drained columns to flow directly through them and bypass most of the columns matrix. A very good fit is obtained between the model output and the measured BTCs. While τ expresses the travel time in the vertical direction within the distribution layer prior to entering the preferential path, the average residence time in the distribution layer, β^{-1} , expresses both the vertical flow and the horizontal travel time to the preferential paths beneath it. In all three columns (Figure 9.13) $\alpha^{-1} > \tau$, which indicates that the average residence

time of the converging flow in the distribution layer is larger than the time for downward vertical flow. Note that the dispersion in the BTCs in Figure 9.13 is only due to the interaction between the mobile and stagnant solutions and is not the result of the dispersion during the transport in the preferential paths, since this transport was modeled by the kinematic-wave model (Equation 9.4) using $D = 0$ in the convective-dispersive equation.

9.5 Multi-Pore Group Models

The main purpose of the models described above was to find the relationship between the flowing fluid in the preferential paths and the stagnant fluid within the matrix and its effect on the BTC. As will be described now, the matrix fluid, which was assumed to be immobile in the models above, may be mobile as well and appear later at the outlet with lower concentration during a longer time period. However, even if the matrix fluid flows with much lower velocities than the preferential flow, its main effect on the BTC at earlier times will be as if it were stagnant. Dye infiltration experiments by Omoti and Wild (1979) revealed rapid transport through pores too small to be considered macropores. A secondary micropore system (smaller than the macropores), also contributes to preferential flow under variably saturated-unsaturated conditions and was also observed by Germann and Beven (1981). Roth et al. (1991) found that rainfall-driven movement of a single surface-applied tracer pulse separated into a slowly moving pulse through the soil matrix and a series of fast preferential flow pulses. The sporadic preferential flow pulses resulted in rapid solute transport to 220 cm and accounted for 58% of the total mass. However, flow through the secondary pore system within the soil matrix accounted for the remaining 42% and moved the solutes to 84 cm. Jardin et al. (1990) monitored rainfall-driven vertical movement of bromide through a large soil pedon and found a rather continuous movement through a small-pore region that lasted for several days following rainfall, while rapid movement occurred as discrete pulses through the large-pore region during events. Jury and Flühler (1992) noted that substantial water flow may be occurring in the surrounding matrix as well as in the preferential flow region. They also noted that solutes partition into a rapid or preferential flow region and a slower but still mobile matrix flow region, each of which may embody a smaller but significant degree of water flow, and concluded that the dual-porosity model is unsatisfactory for representing media wherein transport occurs both in the preferential flow region and in the bulk matrix.

To model preferential flow through a soil profile with multi-pore groups is to assume that the soil is a composite of flow paths with different velocities where mixing may or may not take place among the different flow paths. Dependent on the scale of observation, such flow regions may be pores, fissures, wetted fingers, fine porous matrix, or any region with a relatively well-defined velocity. If the flow regions are non-interacting, meaning that the boundaries of each region are impermeable for solute transfer, an individual solute parcel remains for its entire travel time within the region it entered. If the particle can move laterally through the boundary of its flow region, it experiences the velocities of other flow regions. The velocity, assumed constant within a flow region, can be a deterministic or a random variable distributed over the entire flow cross-section. The fate of a particle that enters a bundle of hypothetically parallel flow regions at the inlet end is now considered.

The straightforward extension of the mobile-immobile model is a two-region convective-dispersive model in which mass is transported from one region to the other in response to differences in the residence fluid concentration. Approximate solutions to this problem have been obtained by Skopp et al. (1981), Van Duin and van der Zee (1986), and Gerke and van Genuchten (1993). Skopp et al. (1981) developed a model where the liquid-filled pores are partitioned into two distinct pore size classes. One region represents macro- or inter-aggregate porosity, and the other represents a mobile matrix porosity. The regions have different hydraulic and transport characteristics and an interaction coefficient characterizes the linear transfer between them. A small interaction coefficient was assumed, and a regular perturbation method was used to solve the model equations. The leading-order solution ignores interaction between the two regions, and flow and transport take place in each one of them independently. The interaction between

the two regions appears in the higher order approximations. If the interaction coefficient is sufficiently large, the convective-dispersive equation is obtained. Comparing the model's output to the measured data of Anderson and Bouma (1977) showed that the interaction term between the two regions is higher than anticipated and the concentration distribution just after the breakthrough time was not well described. Gerke and van Genuchten (1993) also used the two-mobile porosity concept to separate non-steady water flow and transport equations for the matrix and macropore. The chemical exchange between the two regions is described by transfer coefficients which are often functions of the pore size.

Lindstrom and Boersma (1971) separated the pore space of a saturated soil into a finite number of subdomains with characteristic pore sizes. They estimated the flow velocity in each pore domain by Poiseuille's law and calculated total transport by superimposing analytical solutions of the convection-dispersion equation. Their model was not successful in describing experimental breakthrough curves (Rao et al., 1976) as it did not include any mixing of solutes between the pore classes. Steenhuis et al. (1990) followed a similar conceptual framework and proposed a mathematical model that considers many flow and transport domains. Extensions and improvements to the model were later proposed by Stagnitti et al. (1991, 1995) and Durner and Flühler (1996). The preferential flow paths were characterized by taking piecewise linear approximations of the hydraulic conductivity, resulting in a number of pore groups with a mobile transport velocity in each.

Exchange processes between pore groups require a calibration to a particular field or laboratory experiment. Unlike the usual modeling assumptions applied in the CDE, the concentration of solutes in the percolating water is dependent on the varying rate of applied water and the time period between rainfall and chemical application. This is achieved by relating the solute flux to the water flux. Thus, transient field conditions can be simulated. The model can be applied to both large-scale field experiments and small-scale laboratory experiments. As the model has been fully described elsewhere (Steenhuis et al., 1990; Stagnitti et al., 1995; Parlange et al., 1996), we will present only a brief description here.

The total amount of moisture, $\theta(x, t)$ in the soil at time, t , and point, x , is the sum of all individual moisture contents for each capillary bundle, p

$$\theta(x, t) = \sum_{p=0}^N \theta_p(x, t) \quad (9.39)$$

where θ_p is the individual moisture content for the p th pore group. The maximum amount of moisture that each group can hold and transmit is $\Delta M_p = M_p - M_{p-1}$, where M_p and M_{p-1} are various moisture contents representing upper and lower limiting values for the p th group and are a function of the size of pores in each group. When $\theta_p = \Delta M_p$ then all the pathways for the p th group are completely saturated with soil moisture. The group's moisture content, θ_p , is a function of the vertical percolation rate, q_p , effects of precipitation and evapotranspiration, and loss or gain of moisture from interaction and exchanges with other groups. The mass balance equations for the water and solute in the different pore groups and the algorithm to get the moisture and BTCs for different scenarios are presented in detail in Stagnitti et al. (1995). As the networks of flow paths in the soil are interconnected, the exchange of moisture and solutes between the various capillary bundles ranges from a complete exchange of moisture and solute to no exchange or mixing. The basic idea behind the different mixing degrees is the existence of a virtual "common" pool where moisture can be extracted from any group and placed into it, while any fraction of moisture may move back from the common pool into the p th group after mixing. The values of the mixing coefficients depend on the soil type and would normally have to be found by careful experimentation. The preferential flow model has been successfully applied to a number of field and laboratory experiments (e.g., Steenhuis et al., 1990; Nijssen et al., 1991; Stagnitti et al., 1991, 1995; Parlange et al., 1996).

Recently, Skopp and Gardner (1992), who generalized the model of Skopp et al. (1981), and Durner (1992) presented an analytical model for a continuous distribution of local flow velocities perpendicular on an axis orthogonal to the main transport direction. Skopp and Gardner (1992) used the method of moments to relate the dispersion coefficient to flow velocity, which can then be substituted into the

convective-dispersive equation for large interaction between the flow domain perpendicular to the main flow direction.

Durner and Flühler (1996) expanded the previous model by presenting a numerical solution to a conceptual multi-domain model for the transport of solutes in saturated-unsaturated soils. The pore space in this model is represented by a continuous distribution of pore size on a virtual structural coordinate, orthogonal to the spatial coordinate. The chemical transport is simulated by the CDE. Following the method of Steenhuis et al. (1990) a two-step procedure for convective transport and mixing was applied. In the first step, the transport in each pore domain along the spatial axis is solved. In the second step, solute exchange between the pore domains is modeled by a finite difference approximation of the diffusion equation. The model presents the gradual change of convection dominated transport to convective-dispersive transport with time and depth. The length scale where this change takes place depends on the pore size distribution of the porous medium, on the intensity of lateral mixing, and on the degree of saturation.

Symbols

α	rate coefficient describing mass-transfer between the mobile and immobile regions
a, b	Laplace transform of A, B
β^{-1}	average residence time in distribution layer
b	fracture/crack width
c	solute concentration
d	finger diameter
D	dispersion coefficient
$\varepsilon, \varepsilon'$	small dimensionless parameter
J	mass flux
κ	π or 4.8 in 2 and 3 dimensions, respectively
k	rate coefficient describing mass-transfer between mobile and mobile regions in Wallach and Steenhuis (1998) model, mass-transfer coefficient per unit crack width in Wallach and Parlange (1998, 2000)
K	soil hydraulic conductivity
l	depth of distribution layer
L	column/fracture length
M	applied mass per unit area
μ	fluid dynamic viscosity
N	number of pore groups
θ	moisture content, matrix porosity
q	solute flux
Q	imposed surface water flux
ρ	fluid density
Re	Reynolds number
s	Laplace variable
S	sorptivity
Sc	Schmidt number
Sh	Sherwood number
τ	mixing zone
t	time
u	step-function
v	pore water velocity
x	direction perpendicular to flow
z	direction of flow
Sc	$=\mu/\rho D$ (Schmidt number)

Subscripts

e	effective porosity
f	fracture
F	finger tip
I	initial
im	immobile
m	mobile
n	order of expansion
p	pore group
w	water
0	zeroth-order approximation
1	first-order approximation, transition layer at the fracture–matrix interface

Further Information

Preferential flow is a fast-developing science. Summaries of the work can be found in conference proceedings and special issues of journals. A special issue of *Geoderma* (Steenhuis et al., 1996) covers the range from field experiments, where preferential flow was found, to theoretical development. In an older publication, Gish and Shirmohammadi (1991) summarize the preferential flow research up to 1991. A very good overview article about the occurrence of preferential flow was written by Flury (1996). The other references on the different types of preferential flow are mentioned in the text.

10.1 Introduction

Estimating the physical properties of water-bearing layers is an essential part of groundwater studies. One of the most effective ways of determining these properties is to conduct and analyze aquifer tests. The principle of an aquifer test is simple: water is pumped from a well tapping the *aquifer* and the discharge of the well and the changes in water levels in the well and in *piezometers* at known distances from the well are measured. The change in water level induced by the pumping is known as the *drawdown*. In the literature, aquifer tests based on the analysis of drawdowns during pumping are commonly referred to as “pumping tests.”

The physical properties can also be found from a recovery test. In such a test, a well that has been discharging for some time is shut down, and thereafter the recovery of the aquifer’s hydraulic head is measured in the wells; the change in water level during this recovery period is known as the *residual drawdown*.

Owing to the high costs of aquifer tests, the number that can be performed in most groundwater studies has to be restricted. Nevertheless, one can perform an aquifer test without using piezometers, thereby cutting costs, although one must then accept a certain, sometimes appreciable, error. To distinguish such tests from normal aquifer tests, they are called single-well tests. In these tests, measurements are only taken inside the pumped well.

Analyzing and evaluating aquifer-test data is as much an art as a science. It is a science as it is based on theoretical models that the geologist or engineer must understand and on thorough investigations that he must conduct into the geological formations in the area of the test. It is an art as different types of aquifers can exhibit similar drawdown behaviors that demand interpretational skills on the part of the geologist or engineer.

The well-flow equations presented in Section 10.2 are from well hydraulics. Any lengthy derivations of the equations have been omitted as these can be found in the original publications listed in the references. The equations are presented in their final form, emphasizing the assumptions and conditions that underlie them. The essentials of how to conduct an aquifer test are summarized in Section 10.3. The remaining sections deal with the analysis and evaluation of aquifer-test data from a variety of aquifer types and analysis methods, outlining the procedures that are to be followed for their successful application. All these procedures are illustrated with field data.

10.1.1 Aquifer Types

In the analysis and evaluation of aquifer-test data, three main types of aquifer are distinguished: the confined, unconfined, and leaky aquifer (Figure 10.1).

A confined aquifer is a completely saturated aquifer whose upper and lower boundaries are *aquiclude*s. In confined aquifers the pressure of the water is usually higher than that of the atmosphere and the water level in wells tapping such aquifers stands above the top of the aquifer (see Figure 10.1a). The piezometric surface is the imaginary surface to which the water will rise in wells penetrating the aquifer. When the water level in wells tapping such aquifers stands above the ground surface, they are called free-flowing wells or artesian wells.

An unconfined aquifer is a partly saturated aquifer bounded below by an aquiclude and above by the free water table or phreatic surface (see Figure 10.1b). At the free water table, the pressure of the groundwater equals that of the atmosphere. The water level in a well penetrating an unconfined aquifer does not, in general, rise above the water table, except when there is a vertical flow.

A leaky aquifer, also known as a semi-confined aquifer, is a completely saturated aquifer that is bounded below by an aquiclude and above by an *aquitard*. The overlying aquitard may be partly saturated when it extends to the land surface (see Figure 10.1c) or is fully saturated when it is overlain by an unconfined aquifer that is bounded above by the water table (see Figure 10.1d). The piezometric level in a well tapping a leaky aquifer may coincide with the water table if there is a hydrologic equilibrium between the aquifer's recharge and discharge; it may rise or fall below the water table in areas with upward or downward flow, in other words, in discharge or recharge areas.

A multilayered aquifer is a special case of the leaky aquifer. The aquiclude in Figure 10.1c and Figure 10.1d are then aquitards with other aquifers occurring at larger depths. In deep sedimentary basins such an interbedded system of permeable and less permeable layers is very common.

10.1.2 Physical Properties

This section summarizes the physical properties and derived parameters of aquifers and aquitards that appear in the various well-flow equations.

The hydraulic conductivity is the constant of proportionality in Darcy's law and is defined as the volume of water that will move through a porous medium in unit time under a unit hydraulic gradient through a unit area measured at right angles to the direction of flow. The hydraulic conductivity of an aquifer

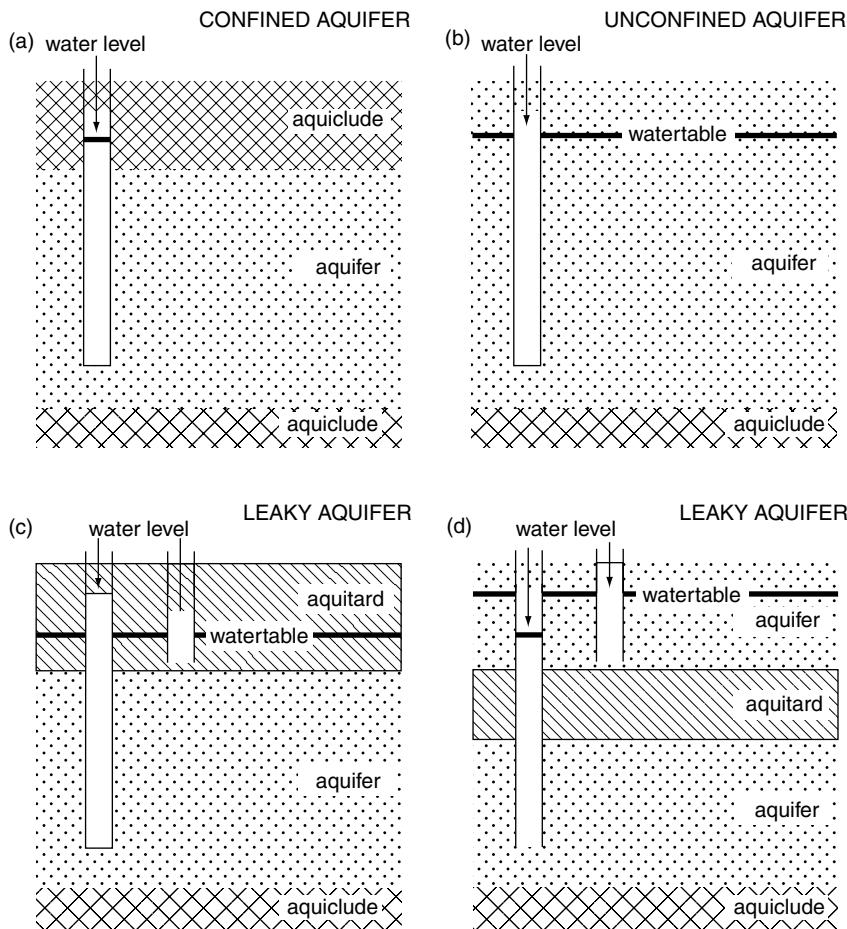

FIGURE 10.1 Different types of aquifers.

is denoted by the symbol K . Common orders of magnitude of the hydraulic conductivities for different aquifer materials range from 10^{-8} m/d for clay deposits to 10^3 m/d for coarse sands.

For confined aquifers, the saturated thickness is equal to the physical thickness of an aquifer between the aquiclude above and below it (see Figure 10.1a). The same is true for the confined parts of a leaky aquifer bounded by an aquitard and an aquiclude (see Figures 10.1c and 10.1d). In both these cases, the saturated thickness is a constant.

For unconfined aquifers, the saturated thickness is equal to the difference between the free water table and the aquiclude (see Figure 10.1b). As the water table changes its position with time, the saturated thickness of an unconfined aquifer is not constant, but variable. Whether constant or variable, the saturated thickness of an aquifer is denoted by the symbol D . Its order of magnitude can range from several meters to hundreds or even thousands of meters.

For aquitards in leaky aquifers, the saturated thickness can be variable or constant. In Figure 10.1c, the aquitard is partly saturated and has a free water table. Its saturated thickness depends upon the position of the water table. In Figure 10.1d, the aquitard is bounded by two aquifers and is fully saturated. Its saturated thickness is physically determined and thus constant. The saturated thickness of an aquitard is denoted by the symbol D' . It may range from a few meters to hundreds of meters.

The transmissivity is the product of the average hydraulic conductivity and the saturated thickness of the aquifer. Consequently, the transmissivity is the rate of flow under a hydraulic gradient equal to unity through a cross-section of unit width over the whole saturated thickness of the water-bearing

layer. The transmissivity of an aquifer is denoted by the symbol T . Its order of magnitude can be derived from those of K and D , and may range from hundreds to tens of thousands of square meter per day.

The specific storage of a saturated confined aquifer is the volume of water that a unit volume of aquifer releases from storage under a unit decline in head. This release of water under conditions of decreasing hydraulic head stems from the compaction of the aquifer due to increasing effective stress and from the expansion of the water due to decreasing water pressure. The specific storage depends on the elasticity of both the aquifer material and the water. For a certain location it can be regarded as a constant. It is denoted by the symbol S_s ; its order of magnitude is 10^{-6} to 10^{-4} d^{-1} .

The storativity of a saturated confined aquifer of thickness D is defined as the volume of water released from storage per unit surface area of the aquifer per unit decline in the component of hydraulic head normal to that surface. In a vertical column of unit area extending through the confined aquifer, the storativity equals the volume of water released from the aquifer when the piezometric surface drops over a unit distance. Storativity is thus defined as $S = S_s D$. The storativity of a saturated aquifer is a function of its thickness. Storativity is a dimensionless quantity, as it involves a volume of water per volume of aquifer. Its values in confined aquifers range from 5×10^{-5} to 5×10^{-3} .

The specific yield is the volume of water that an unconfined aquifer releases from storage per unit surface area of aquifer per unit decline of the water table. In unconfined aquifers, the effects of the elasticity of the aquifer material and the water are negligible, except for a short time after the start of pumping. Values of the specific yield of unconfined aquifers are much higher than the storativities of confined aquifers. The orders of magnitude of the specific yield denoted by the symbol S_y range from 0.01 for clay deposits to 0.47 for coarse sands. Specific yield is also referred to as effective porosity, unconfined storativity, or drainable pore space. Small interstices do not contribute to the effective porosity, as the retention forces in them are greater than the weight of water. Hence, no groundwater will be released from these small interstices by gravity drainage.

The hydraulic resistance characterizes the resistance of an aquitard to vertical flow, either upward or downward. It is the ratio of the saturated thickness of the aquitard D' and its hydraulic conductivity for vertical flow K' and is thus defined as $c = D'/K'$. Its order of magnitude may range from a few tens to thousands of days. Aquitards having c -values of 2500 d or more are regarded to act as aquiclude, although theoretically an aquiclude has an infinitely high c -value.

The leakage factor describes the spatial distribution of leakage through one or two aquitards into a leaky aquifer or vice versa. It is the square root of the product of the aquifer's transmissivity and the aquitard's hydraulic resistance and is thus defined as $L = \sqrt{(Tc)}$; it is expressed in meters. Large values of L originate from a high transmissivity of the aquifer and a high hydraulic resistance of the aquitard. In both cases, the influence of leakage will be small and the area over which leakage takes place, large.

10.2 Well-Flow Equations

The well-flow equations presented in this section were developed under the following common assumptions and conditions (1) the aquifer has a seemingly infinite areal extent; (2) the aquifer is *homogeneous, isotropic*, and of uniform thickness over the area influenced by the test; (3) prior to pumping, the hydraulic head is horizontal (or nearly so) over the area that will be influenced by the test; (4) the pumped well penetrates the entire thickness of the aquifer and thus receives water by horizontal flow; (5) the aquifer is pumped at a constant-discharge rate; (6) the water removed from storage is discharged instantaneously with decline of head; and (7) the diameter of the pumped well is small, that is, the storage inside the well can be neglected.

The above mentioned simplifying assumptions and limiting conditions cannot always be fulfilled in the field. In these cases, special well-flow equations for bounded, sloping, or anisotropic aquifers or for large-diameter wells can be used; these can be found in Kruseman and de Ridder (1994).

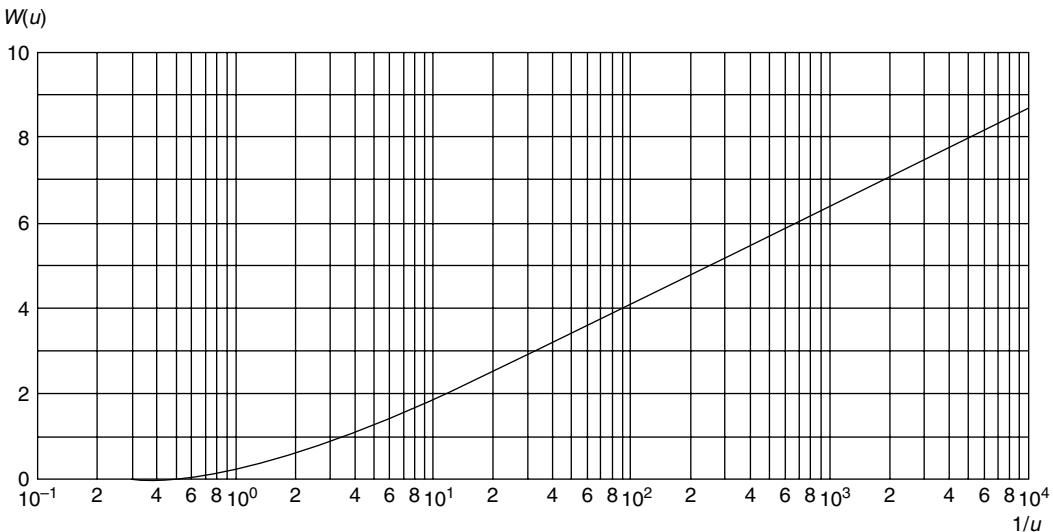

FIGURE 10.2 Theis well function $W(u)$ vs. $1/u$ for fully-penetrating wells in confined aquifers.

10.2.1 Confined Aquifers

Theis (1935) was the first to develop an equation for unsteady-state flow that introduced the time factor and the storativity. He noted that when a fully penetrating well pumps an extensive confined aquifer at a constant rate, the influence of the discharge extends outward with time. The rate of decline of head, multiplied by the storativity and summed over the area of influence, equals the discharge. The Theis equation, which was derived from the analogy between the flow of groundwater and the conduction of heat, is written as

$$s(r, t) = \frac{Q}{4\pi T} \int_u^\infty \frac{e^{-y}}{y} dy = \frac{Q}{4\pi T} W(u) \quad (10.1)$$

with

$$u = \frac{r^2 S}{4Tt} \quad (10.2)$$

where $s(r, t)$ is the drawdown in meters measured in a well, Q is the constant well discharge in m^3/d , T is the transmissivity of the aquifer in m^2/d , $W(u)$ is the dimensionless Theis well function, r is the distance in meters from the pumped well, S is the dimensionless storativity of the aquifer, and t is the time in days since pumping started. In Figure 10.2, the Theis well function $W(u)$ is plotted vs. $1/u$ on semi-log paper. This figure shows that, for large values of $1/u$, the Theis well function exhibits a straight-line segment. The Jacob method is based on this phenomenon. Cooper and Jacob (1946) showed that, for the straight-line segment, Equation 10.1 can be approximated by

$$s(r, t) = \frac{2.3Q}{4\pi T} \log \frac{2.25Tt}{r^2 S} \quad (10.3)$$

with an error less than 1%, 2%, 5%, and 10% for $1/u$ larger than 30, 20, 10, and 7, respectively.

In most handbooks on this subject, the condition to use Equation 10.3 is taken as $1/u > 100$. From personal experience, this limiting condition can often be relaxed to $1/u > 10$.

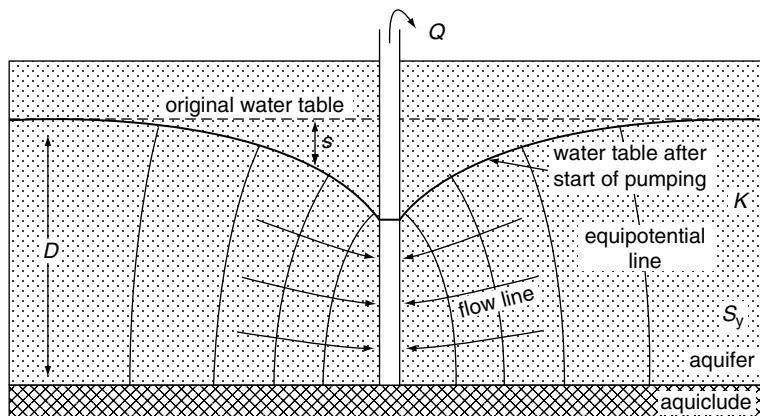

FIGURE 10.3 Schematic cross-section of a pumped unconfined aquifer.

When a confined aquifer is pumped, the cone of depression will continuously deepen and expand. Even at late pumping times, the water levels in the piezometers will never stabilize to a real steady state. Although the water levels continue to drop, the cone of depression will eventually deepen uniformly over the area influenced by the pumping. At that stage, the hydraulic gradient has become constant; this phenomenon is called pseudo-steady state. For this situation, Thiem (1906), using two or more piezometers, developed an equation, the so-called Thiem–Dupuit equation that can be written as

$$s(r_1, t) - s(r_2, t) = \frac{2.3Q}{2\pi T} \log \frac{r_2}{r_1} \quad (10.4)$$

Equation 10.4 can also be derived by applying Equation 10.3 to two piezometers at distances r_1 and r_2 at large times.

10.2.2 Unconfined Aquifers

Figure 10.3 shows a pumped unconfined aquifer underlain by an aquiclude. These are the following basic differences between unconfined and confined aquifers when they are pumped: (1) an unconfined aquifer is partly dewatered during pumping resulting in a decreasing saturated aquifer thickness, whereas a confined aquifer remains fully saturated, (2) the water produced by a well in an unconfined aquifer comes from the physical dewatering of the aquifer, whereas in a confined aquifer it comes from the expansion of the water in the aquifer due to a reduction of the water pressure (although in some hydrological theories, water is assumed to be an incompressible fluid), and from the compaction of the aquifer due to increased effective stresses, and (3) the flow toward a well in an unconfined aquifer has clear vertical components near the pumped well, whereas there are no such vertical flow components in a confined aquifer, provided, of course, that the well is fully penetrating.

In an unconfined aquifer, the water levels in piezometers near the well often tend to decline at a slower rate than that described by the Theis equation. Time–drawdown curves on semi-log paper therefore usually show a typical S shape: a relatively steep early-time segment, a flat intermediate segment, and a relatively steep segment again at later times as is shown in Figure 10.4. Nowadays, the widely used explanation of this S-shaped time–drawdown curve is based on the concept of delayed yield (Neuman, 1972). It is caused by a time lag between the early elastic response of the aquifer and the subsequent downward movement of the water table due to gravity drainage.

During the early stage of an aquifer test — a stage that may last for only a few minutes — the discharge of the pumped well is derived uniquely from the elastic storage within the aquifer. Hence, the reaction of the unconfined aquifer immediately after the start of pumping is similar to the reaction of a confined aquifer as described by the flow equation of Theis.

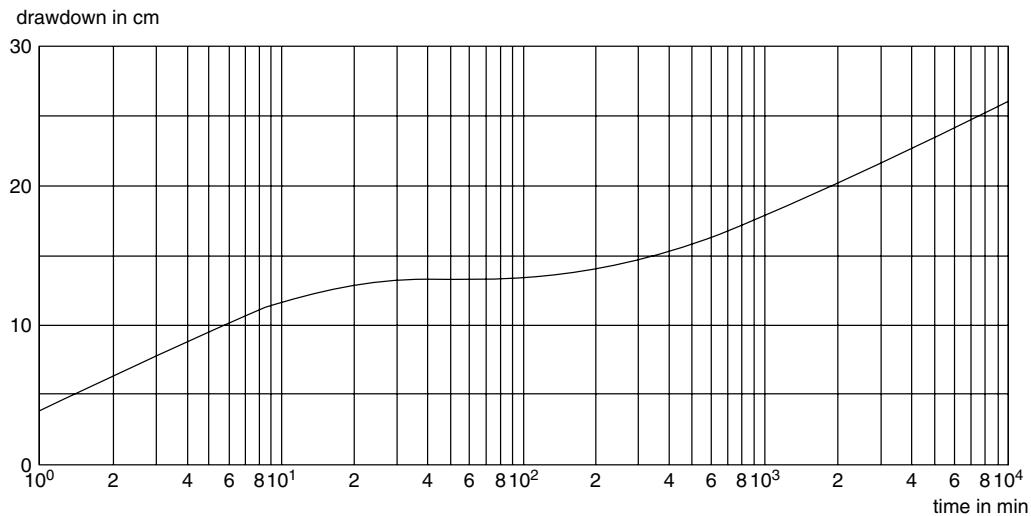

FIGURE 10.4 Time–drawdown plot in an unconfined aquifer showing delayed yield.

Only later the water table starts to fall and the effect of the delayed yield becomes apparent. The influence of the delayed yield is comparable to that of leakage: the average drawdown slows down with time and no longer conforms to the Theis curve. After a few minutes to a few hours of pumping, the time–drawdown curve approaches a horizontal position.

The late-time segment of the time–drawdown curve may start from several minutes to several days after the start of pumping. The declining water table can now keep pace with the increase in the average drawdown. The flow in the aquifer is essentially horizontal again and as in the early pumping time the time–drawdown curve approaches the Theis curve.

Jacob (1950) showed that if the drawdowns in an unconfined aquifer are small compared to the initial saturated thickness of the aquifer, the condition of horizontal flow toward the well is approximately satisfied, so that Equation 10.1 to Equation 10.3 can also be applied to determine the physical properties. The only changes required are that the storativity S be replaced by the specific yield S_y of the unconfined aquifer, and that the transmissivity T be defined as the transmissivity of the initial saturated thickness of the aquifer.

When the drawdowns in an unconfined aquifer are large compared with the aquifer's original saturated thickness, the observed drawdowns need to be corrected before this equation can be used. Jacob (1944) proposed the following correction

$$s_c(r, t) = s(r, t) - \frac{s^2(r, t)}{2D} \quad (10.5)$$

where $s_c(r, t)$ is the corrected drawdown in meters, $s(r, t)$ is the observed drawdown in meters, and D is the saturated aquifer thickness in meters prior to pumping. This correction is only needed when the maximum drawdown at the end of the test is larger than 5% of the original saturated aquifer thickness.

As with confined aquifers, the cone of depression will continuously deepen and expand in unconfined aquifers. For pseudo-steady state conditions, Equation 10.4 can also be used to describe the drawdown behavior in two piezometers in an unconfined aquifer, provided that the observed drawdowns are corrected according to Equation 10.5.

10.2.3 Leaky Aquifers

When a leaky aquifer is pumped (Figure 10.5), the piezometric level of the aquifer in the well is lowered. This lowering spreads radially outward as pumping continues, creating a difference in hydraulic head

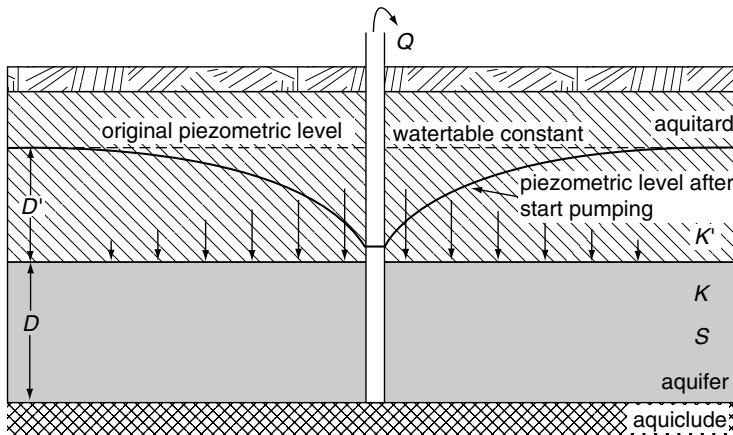

FIGURE 10.5 Schematic cross-section of a pumped leaky aquifer.

between the aquifer and the aquitard. Consequently, the groundwater in the aquitard will start moving vertically downward to join the water in the aquifer. The aquifer is thus partially recharged by downward percolation from the aquitard. As pumping continues, the percentage of the total discharge derived from this percolation increases. After a certain period of pumping, equilibrium will be established between the discharge rate of the pump and the recharge rate by vertical flow through the aquitard. This steady state will be maintained as long as the water table in the aquitard is kept constant.

According to Hantush and Jacob (1955), the drawdown due to pumping a leaky aquifer can be described by the following equation

$$s(r, t) = \frac{Q}{4\pi T} \int_u^{\infty} \frac{1}{y} \exp\left(-y - \frac{r^2}{4L^2 y}\right) dy = \frac{Q}{4\pi T} W(u, r/L) \quad (10.6)$$

where $W(u, r/L)$ is the dimensionless Hantush well function, $L (= \sqrt{Tc})$ is the leakage factor or characteristic length in meters, $c (= D'/K')$ is the hydraulic resistance of the aquitard in d, D' is the saturated thickness of the aquitard in meters, K' is the vertical hydraulic conductivity of the aquitard in m/d, and the other symbols as defined earlier.

Equation 10.6 has the same form as the Theis equation (Equation 10.1), but there are two parameters in the integral: u and r/L . Equation 10.6 approaches the Theis equation for large values of L , when the exponential term $r^2/(4L^2 y)$ approaches zero. In Figure 10.6, the Hantush well function $W(u, r/L)$ is plotted vs. $1/u$ on semi-log paper for an arbitrary value of r/L . This figure shows that the Hantush well function exhibits an S shape and, for large values of $1/u$, a horizontal straight-line segment indicating steady-state flow.

For the steady-state drawdown in a leaky aquifer, De Glee (1930, 1951) derived the following equation

$$s_m(r) = \frac{Q}{2\pi T} K_0\left(\frac{r}{L}\right) \quad (10.7)$$

where $s_m(r)$ is the steady-state, stabilized drawdown in meters and $K_0(r/L)$ is the dimensionless modified Bessel function of the second kind and of zero order (Hankel function). Hantush (1956, 1964) noted that if r/L is small ($r/L < 0.05$) and $L > 3D$, Equation 10.7 can, for all practical purposes, be approximated by

$$s_m(r) = \frac{2.3Q}{2\pi T} \log \frac{1.12L}{r} \quad (10.8)$$

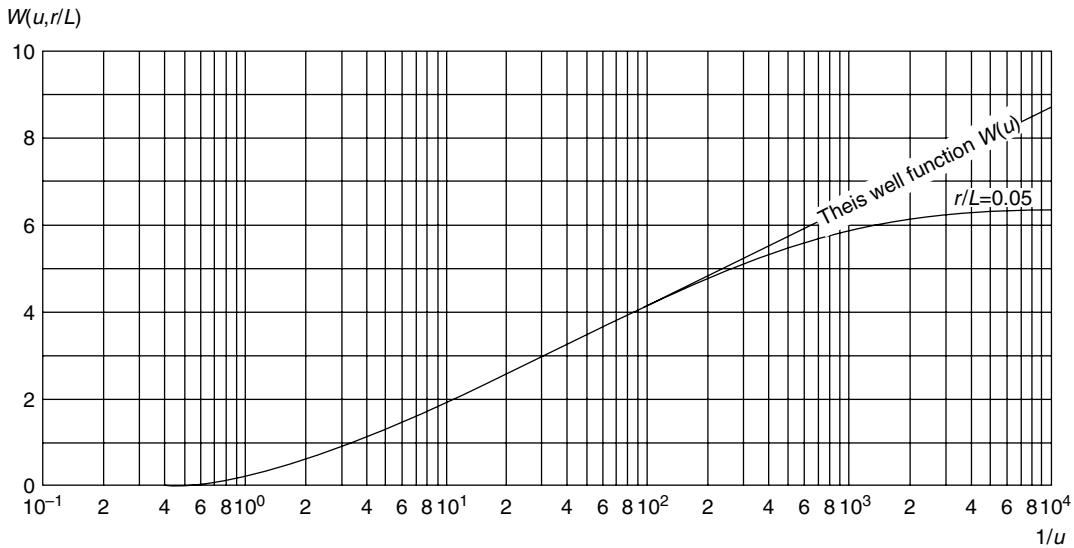

FIGURE 10.6 Hantush well function $W(u, r/L)$ vs. $1/u$ for fully penetrating wells in leaky aquifers.

It is important to note that the flow system in a pumped leaky aquifer consists of a vertical component in the overlying aquitard and a horizontal component in the aquifer. In reality, the flow lines in the aquifer are not horizontal but curved (i.e., there are both vertical and horizontal-flow components in the aquifer). The above equations can therefore only be used when the vertical-flow component in the aquifer is so small compared to the horizontal-flow component that it can be neglected. In practice, this condition is fulfilled when $L > 3D$.

10.2.4 Partial Penetration

When an aquifer is pumped by a partially penetrating well, the assumption that the well receives water from horizontal flow is no longer valid. Hence, the previous equations cannot be used to describe the flow to pumped wells. Due to a contraction of flow lines, partial penetration causes the flow velocity in the immediate vicinity of the well to be higher than it would be otherwise, leading to an extra loss of head. This effect is strongest at the well face, and decreases with increasing distance from the well. According to Hantush (1962) the drawdown due to pumping in a confined aquifer can be described by the following equation

$$s(r, t) = \frac{Q}{4\pi T} [W(u) + f_s] \quad (10.9)$$

and

$$f_s = \frac{2D}{\pi(b-d)} \sum_{n=1}^{\infty} \left(\frac{1}{n} \right) W \left(u, \frac{n\pi r}{D} \right) \times \left[\sin \left(\frac{n\pi b}{D} \right) - \sin \left(\frac{n\pi d}{D} \right) \right] \left(\cos \frac{n\pi z}{D} \right) \quad (10.10)$$

where $W(u, n\pi r/D)$ is the dimensionless Hantush well function, b and b' are the penetration depths in meters of the pumped well and of the piezometer, d and d' are the non-screened parts in meters of the pumped well and of the piezometer, and $z = (b' + d')/2$ (see Figure 10.7).

In Figure 10.8, the expression $W(u) + f_s$ is plotted vs. $1/u$ on semi-log paper. This figure shows that, for large values of $1/u$, this expression exhibits a straight-line segment. For this segment Equation 10.10

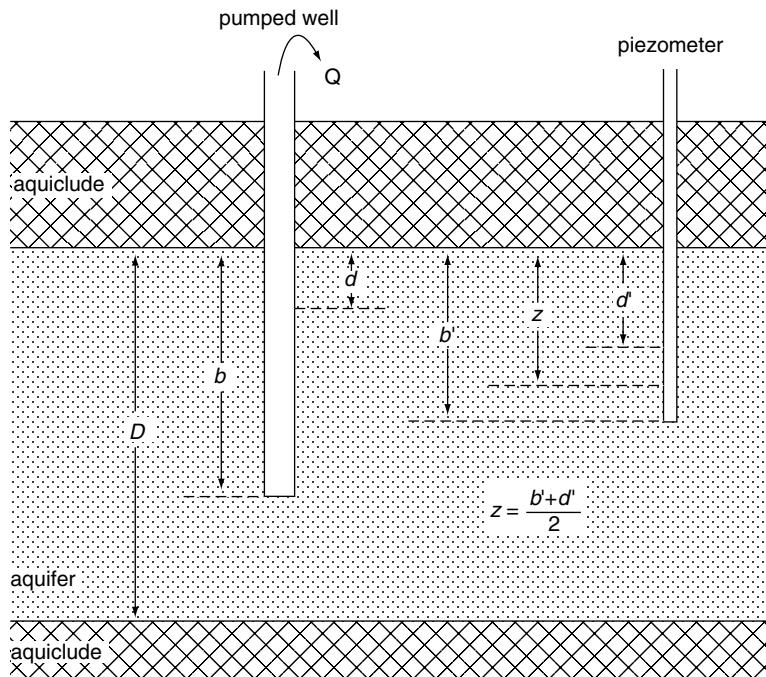

FIGURE 10.7 Schematic illustration of the parameters used for the analysis of partially penetrating wells.

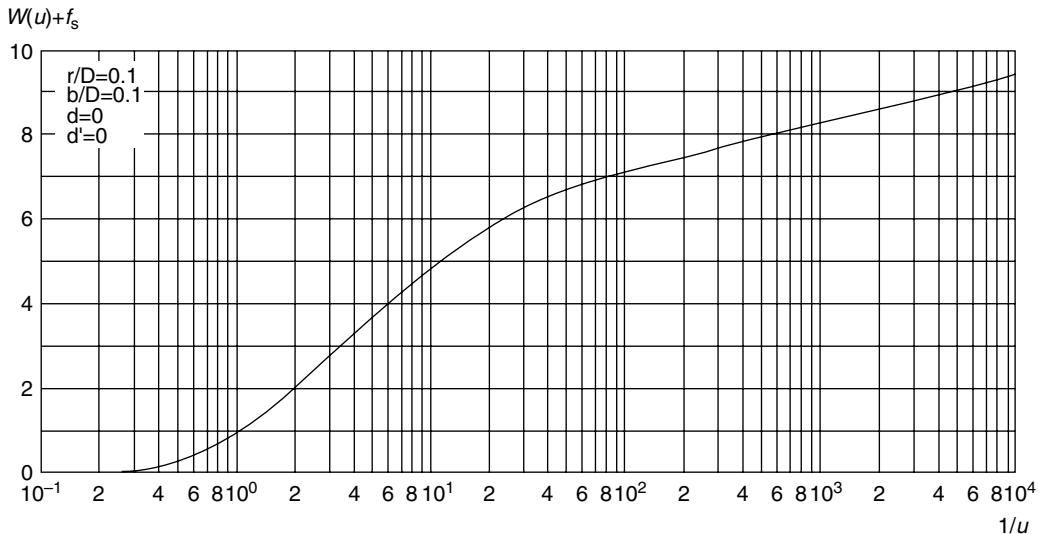

FIGURE 10.8 Hantush well function $W(u) + f_s$ vs. $1/u$ for partially penetrating wells in confined aquifers.

reduces to

$$f_s = \frac{4D}{\pi(b-d)} \sum_{n=1}^{\infty} \left(\frac{1}{n} \right) K_0 \left(\frac{n\pi r}{D} \right) \left[\sin \left(\frac{n\pi b}{D} \right) - \sin \left(\frac{n\pi d}{D} \right) \right] \left[\cos \left(\frac{n\pi z}{D} \right) \right] \quad (10.11)$$

For a particular well/piezometer configuration Equation 10.11 yields constant values for f_s . The Hantush's modification of the Jacob equation was based on this phenomenon. Hantush (1962) showed that for the

straight-line segment Equation 10.9 can be approximated by

$$s(r, t) = \frac{2.3Q}{4\pi T} \log \frac{2.25Tt}{r^2 S} e^{f_s} \quad (10.12)$$

Equation 10.12 can be used to describe the drawdown behavior in a confined aquifer with a partially penetrating well, provided that $t > D^2 S / 2T$. Equation 10.12 can also be applied to unconfined aquifers. It is then assumed that due to partial penetration the drawdowns are small compared with the initial saturated thickness of the aquifer. The only changes required are that the storativity S be replaced by the specific yield S_y of the unconfined aquifer, and that the transmissivity T be defined as the transmissivity of the initial saturated thickness of the aquifer.

For leaky aquifers, the drawdown behavior can be described by Weeks (1969)

$$s(r, t) = \frac{Q}{4\pi T} [W(u, r/L) + f_s] \quad (10.13)$$

The pumping time should also be long to apply Equation 10.13 ($t > D^2 S / 2T$).

10.2.5 Recovery Well-Flow Equations

The well-flow equations describing the drawdown behavior during the recovery period are based on the principle of superposition. Applying this principle, it is assumed that, after the pump has been shut down, the well continues to be pumped at the same discharge as before, and that an imaginary recharge, equal to the discharge, is injected into the well. The recharge and discharge thus cancel each other, resulting in an idle well as is required for the recovery period. For any of the well-flow equations presented in the previous sections, a corresponding recovery equation can be formulated.

On the basis of Equation 10.1, Theis (1935) developed his recovery method for confined aquifers. After a constant-rate pumping test, the residual drawdown during the recovery period is given by

$$s'(r, t/t') = \frac{Q}{4\pi T} \{W(u) - W(u')\} \quad (10.14)$$

where $s'(r, t)$ is the residual drawdown in meters, $u' = r^2 S' / (4Tt')$, S' is the dimensionless storativity of the aquifer during recovery, and t' is the time in days since pumping stopped. In Figure 10.9, the Theis recovery well function $W(u) - W(u')$ is plotted vs. u'/u on semi-log paper. This figure shows that, for small values of u'/u , the expression exhibits a straight-line segment. For this segment, Equation 10.14 can be approximated by

$$s'(r, t/t') = \frac{2.3Q}{4\pi T} \log \frac{S't}{S't'} \quad (10.15)$$

Neuman (1975) showed that Equation 10.15 can also be used to describe the residual drawdown behavior in unconfined aquifers, as its delayed water table response to pumping is fully reversible (no hysteresis effects). The only changes required are that the storativity S be replaced by the specific yield S_y of the unconfined aquifer, and that the transmissivity T be defined as the transmissivity of the initial saturated thickness of the aquifer.

For leaky aquifers, the principle of superposition can also be applied. This results in the following equation

$$s'(r, t') = \frac{Q}{4\pi T} \left[W\left(u, \frac{r}{L}\right) - W\left(u', \frac{r}{L}\right) \right] \quad (10.16)$$

Equation 10.16 can only be solved by numerical simulation. Hantush (1964) showed that, if pumping and recovery times are short, that is, if $t + t' < (L^2 S) / 20T$ or $t + t' < cS / 20$, Equation 10.14 can also be used.

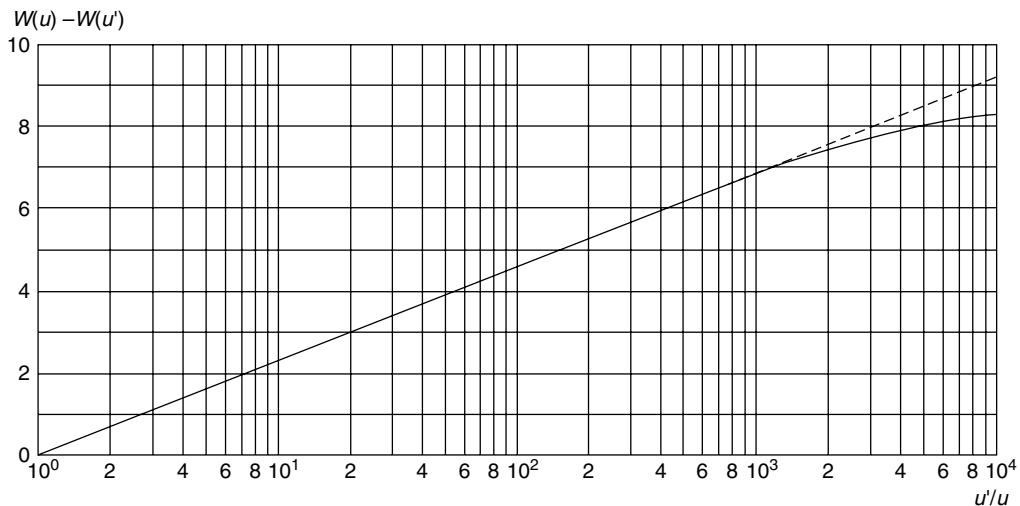

FIGURE 10.9 Theis recovery well function $W(u) - W(u')$ vs. u'/u for fully penetrating wells in confined aquifers.

10.3 Performance of an Aquifer Test

The changes of water levels observed in both aquifer tests and single-well tests can be analyzed by using the time–drawdown and time–residual–drawdown relationships of the well-flow equations of Section 10.2. Figure 10.10a gives an example of the time–drawdown relationship for the pumped well or a piezometer during a pumping test followed by a recovery test. With aquifer tests, the above relationships can be used to make time–drawdown analyses (Section 10.4) for each piezometer separately. In addition, the distance–drawdown relationship (see Figure 10.10b) can be used to make a distance–drawdown analysis (Section 10.5), provided that drawdown data in at least two piezometers are available. The advantage of aquifer tests is thus that the various estimates of the aquifer’s physical properties obtained from the time–drawdown analyses of each piezometer can be compared with an independent estimate of the physical properties obtained from a distance–drawdown analysis.

With single-well tests, only a single time–drawdown analysis based on the drawdowns of the pumped well can be made, that is, no comparison of results from different time–drawdown analyses is possible, and no distance–drawdown analysis can be made. Consequently, the results of aquifer tests will be more accurate than the results of single-well tests. Moreover, aquifer-test results are representative of a larger volume of the aquifer than single-well test results.

The question of how many piezometers should be employed depends not only on the amount of information desired and the required degree of accuracy, but also on the funds available for the test. It is always best to have as many piezometers as conditions permit and to place them in various directions and distances from the pumped well.

Although no fixed rule can be given, placing piezometers at distances of between 10 and 100 m from the well will usually give reliable data. For thick or stratified confined aquifers, these distances must be greater, say between 100 and 250 m or more. An optimum result in determining the physical properties of the aquifer can be obtained by placing the screen of the piezometer at half the depth of the screen of the pumped well.

The design and construction of the pumped well and the piezometers will be discussed in Chapter 11; for the site selection, reference is made to Kruseman and de Ridder (1994).

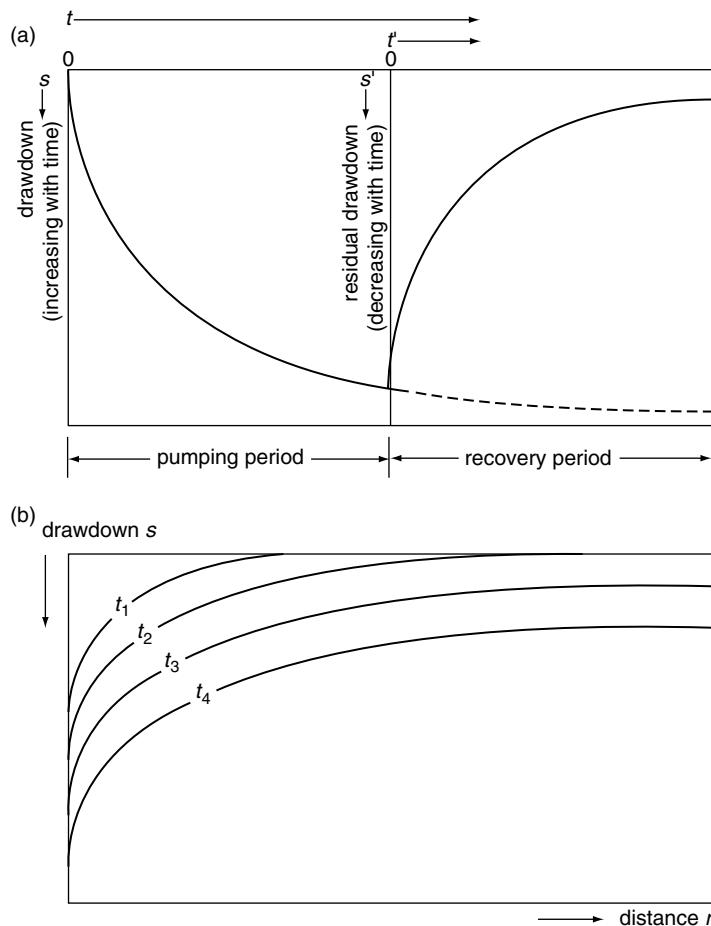

FIGURE 10.10 (a) Time–drawdown relationship during a pumping test, followed by a recovery test; (b) distance–drawdown relationship during a pumping test.

10.3.1 Measurements

Ideally, an aquifer test should be performed under the natural conditions of a stable water table. This is, however, not always possible. Water tables rise and fall due to natural recharge and discharge of the groundwater reservoir (precipitation and evaporation), manmade recharge and discharge of the groundwater reservoir (irrigation losses and pumping from wells), changes in barometric pressure, and tidal movements in coastal aquifers. Such short-term variations of the water table have an adverse effect on the drawdown and recovery of the water table during testing. Hence, for some days prior to the actual test, the water levels in the well and the piezometers should be measured, say twice a day. For each observation point, a time-vs.-water-level curve, or hydrograph, should be drawn. From these, the trend and rate of water-level changes can be read. At the end of the test, that is, after complete recovery, water-level readings should be continued at the observation points for one or two days. With these data, the hydrographs can be completed and the rate of water-level change during the test can be determined. This information can then be used to correct the drawdowns observed during the test itself.

The water-level measurements must be taken many times during the course of a test, and with as much accuracy as possible. As water levels drop fast during the first hour or two of the test, readings should first be taken at brief intervals. These intervals should be gradually increased as pumping continues. As in all the analysis procedures the time is plotted on a logarithmic scale, it is recommended to have the same

TABLE 10.1 Typical Time Sequence for Taking Water-Level Measurements in an Aquifer Test

Time (sec)	Time (min)	Time (min)	Time (h)	Time (h)
10	2.5	20	2.5	22
20	3.0	25	3.0	27
30	4.0	30	4.0	33
40	5.0	40	5.0	42
50	6.5	50	7.0	53
60	8.0	65	8.5	67
80	10.0	80	11.0	103
100	13.0	90	13.0	108
120	16.0	120	17.0	133

Note: Aim is to get equal number of observations in each log cycle of time.

number of readings in each log cycle of time. Table 10.1 shows an example of the sequence in time for taking water-level measurements, based on ten readings in each log cycle and resulting in approximately equidistant plotting positions. For piezometers far from the well and for those in aquitards above or below the aquifer, the brief time intervals in the first minutes of the pumping test can be disregarded.

After the pump has been shut down, the water levels in the well and the piezometers will start to rise. In the first hour, they will rise rapidly, but as time goes on, the rate of rise decreases. These rises can be measured in a recovery test. If the yield of the well was not constant throughout the pumping test, recovery-test data are more consistent than the drawdown data collected during pumping. Recovery-test data can thus be used as a check on the calculations that are based on the drawdown data. The schedule for recovery measurements is the same as that for the pumping period.

Water-level measurements can be taken in various ways, that is, wetted-tape method, mechanical sounder, electric water-level indicator, floating-level indicator or recorder, pressure gauge, or pressure logger. For detailed information on these devices, reference is made to Kruseman and de Ridder (1994) and Driscoll (1986). Fairly accurate measurements of water levels can be made manually, but then the instant of each reading should be recorded with a chronometer. Experience has shown that it is possible to measure the depth to water within 2 mm. For piezometers close to the well, the wetted-tape method and the mechanical sounder cannot be used due to the rapid water-level changes and the noise of the pump, respectively.

Although the pressure-gauge method is less accurate than the other methods (within 6 cm), it is the most practical method for measuring water levels in a pumped well. It should, however, not be used for measuring water levels in piezometers, as the drop in water levels during the initial stage of pumping will be small in these wells. Electronic self-logging pressure transducers with high sampling interval (20 sec) and high accuracy (1 to 6 mm) can be used when funds are available.

Among the arrangements to be made for a pumping test is the control of the discharge rate. To avoid complicated calculations later, the discharge rate should preferably be kept constant throughout the test. The discharge should be kept constant by manipulating a valve in the discharge pipe. This gives more accurate control than changing the speed of the pump. During pumping tests, the discharge rate should be measured at least once every hour, and adjustments necessary to keep it constant should be made. The discharge rate can be measured with various devices, that is, commercial water meter, flume, container, orifice weir, orifice bucket, or jet-stream method. For detailed information on these devices, reference is also made to Kruseman and de Ridder (1994) and Bos (1989). The water delivered by the well should be prevented from returning to the aquifer. This can be done by conveying the water through a large-diameter pipe over a convenient distance, at least 300 m, depending on the location of the piezometers, and then discharging it into a canal or natural channel. Preferably, the water should be discharged

away from the line of piezometers. The pumped water can also be conveyed through a shallow ditch, but precautionary measures should be taken to seal the bottom of the ditch with clay or plastic sheets to prevent leakage.

10.3.2 Duration of a Pumping Test

The question of how long a pumping test should last is difficult to answer as the period of pumping depends on the type of aquifer and the degree of accuracy desired in establishing its physical properties. Economizing on the pumping period is not recommended as the costs of running the pump a few extra hours are low compared with the total costs of the test. Moreover, better and more reliable data are obtained if pumping continues until the cone of depression has stabilized and does not seem to be expanding further as pumping continues. At the beginning of the test, the cone develops quickly as the pumped water is initially derived from the aquifer storage immediately around the well. But, as pumping continues, the cone expands and deepens more slowly as, with each additional meter of horizontal expansion, a larger volume of stored water becomes available. This may often lead inexperienced observers to conclude that the cone has stabilized, or in other words that steady state has been reached. Inaccurate measurements of the drawdowns in the piezometers — drawdowns that are becoming smaller and smaller as pumping continue — can also lead to this wrong conclusion. In reality, the depression cone will continue to expand until the recharge of the aquifer, if any, equals the discharge.

The unsteady-state flow, also known as non-equilibrium flow, is time dependent, that is, the water level as observed in piezometers, changes with time. During a pumping test, the unsteady-state flow condition occurs from the moment pumping starts till the steady state is reached. Theoretically, in an infinite, horizontal, completely confined aquifer of constant thickness that is pumped at a constant rate, there will always be an unsteady state, as the aquifer is not recharged by an outside source. In practice, well flow is considered to be in unsteady state as long as the changes of the water level in the piezometers are measurable, or as long as the hydraulic gradient changes in a measurable way.

The steady-state flow, also known as equilibrium flow, is independent of time, that is, the water level, as observed in piezometers, does not change with time. It occurs, for instance, when there is equilibrium between the discharge of a pumped well and the recharge of the pumped aquifer by an outside source. Such outside sources may be recharge from surface water of nearby rivers, canals, or lakes, or recharge from groundwater of an unconfined aquifer with constant water table overlying an aquitard that covers a pumped leaky aquifer. As real steady-state conditions seldom occur, it is said in practice that a steady-state condition is reached when the changes of the water level as observed in piezometers are negligibly small, or when the hydraulic gradient has become constant.

To establish whether unsteady or steady-state conditions prevail, the changes in head during the pumping test should be plotted. Figure 10.11 shows possible shapes of time–drawdown plots and their interpretations.

In some wells, a steady state occurs a few hours after the start of pumping; in others, it does not occur until after a few days or weeks, whereas in yet other wells it never occurs, even though pumping continues for years. Kruseman and de Ridder (1994) suggest that, under average conditions, steady-state flow is generally reached in leaky aquifers after 15 to 20 h of pumping, and in a confined aquifer, after 24 h. In an unconfined aquifer, the cone of depression expands more slowly, so a longer period of pumping is required, say, three days.

Preliminary plotting of drawdown data during the test will often show what is happening and may indicate whether or not a test should be continued.

10.3.3 Processing the Data

All measurements of the water level, time, and discharge of the pump should preferably be noted on pre-printed forms or entered in a portable or handheld computer. After 3 h of pumping, sufficient time will become available in the field to draw the time–drawdown curves of each observation point. These

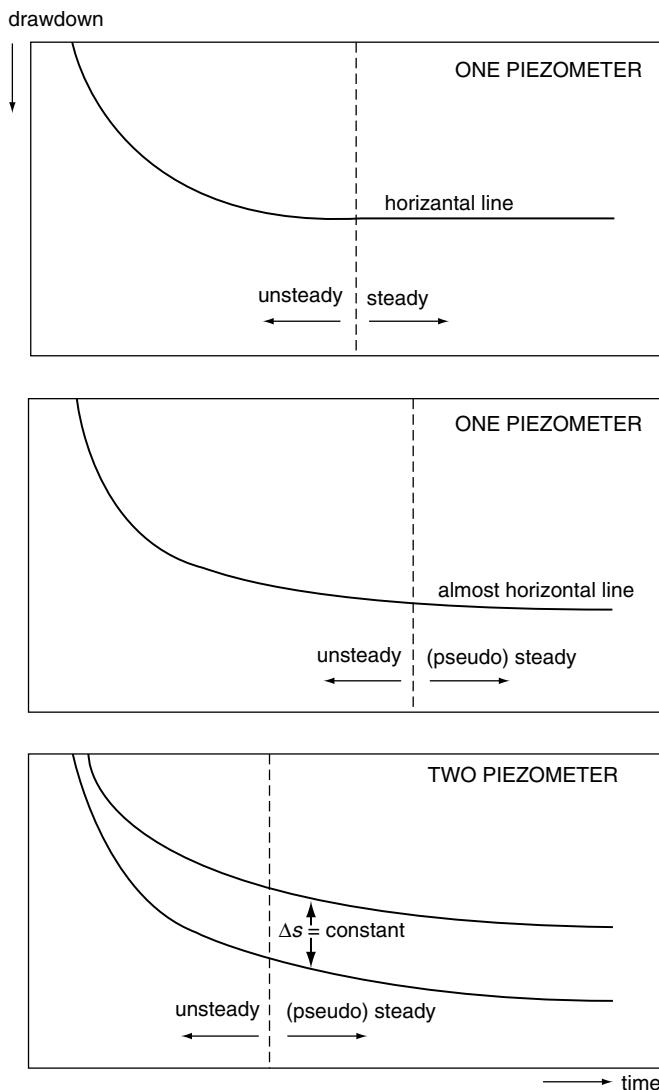

FIGURE 10.11 Time–drawdown plots showing the changes in drawdown during an aquifer test and their interpretations.

graphs will be helpful in checking whether the test is running well and in deciding on the time that the pump can be shut down when steady or pseudo-steady state flow has been reached.

As the well-flow equations require drawdown data instead of depth-to-water table data, the latter should therefore be converted to drawdown data, in other words, the initial depth to the water table must be subtracted from the depth-to-water table data during the test. It may be necessary to correct the observed drawdowns for external influences, that is, influences independent of the test (trend correction). If, during the post-recovery period, the same constant water level is observed as during the pre-testing period, it can be assumed that no external forces influenced the hydraulic head in the aquifer during the test. If, however, the water level is subject to unidirectional or rhythmic changes due to tidal influences for example, the observed drawdowns will have to be corrected before being used in the analysis. Such phenomena are likely to occur during pumping tests of long duration.

When the evaluation of the test data has been completed, a report on the results should be written. A copy of the report should be kept on file for further reference and later studies. Samples of the different

layers penetrated by the borings should be stored too, as they may be needed for other studies in a later phase of investigations. The basic field measurements of the test should be put on file as well. The conclusions drawn from the test may become obsolete in the light of new insights, but the hard facts, carefully collected in the field, remain facts and can always be reevaluated.

10.3.4 Interpretation of the Data

Calculating physical properties would be relatively easy if the aquifer system (i.e., aquifer plus well) were precisely known. This is generally not the case, so interpreting aquifer tests is primarily a matter of identifying an unknown system. System identification relies on models, the characteristics of which are assumed to represent the characteristics of the real aquifer system. In Section 10.2, well-flow equations were presented based on idealized theoretical models: homogeneous and isotropic aquifers of seemingly infinite extent, no well bore storage inside the pumped well, and the like.

To identify an aquifer system, one must compare its drawdown behavior with that of the various theoretical models. The model that compares best with the real system is then selected for the calculation of the physical properties. System identification includes the construction of diagnostics plots. In the literature, both log-log plots and semi-log plots of the drawdown vs. the time are used for this purpose. In the following sections, only the semi-log plots are used for identification and analysis purposes, as (1) they have more diagnostic value than log-log plots due to the occurrence of straight-line segments, and (2) they can also be used to analyze the field data of single-well tests. The characteristic shapes of the curves can help in selecting the appropriate model.

The choice of theoretical model is a crucial step in the interpretation of aquifer tests. If the wrong model is chosen, the physical properties for the real aquifer will not be correct. A troublesome fact is that theoretical solutions to well-flow problems are usually not unique. Some models, developed for different aquifer systems, yield similar responses to a given stress exerted on them. This makes system identification and model selection a difficult affair.

10.4 Time-Drawdown Analyses

All the analysis methods have in common that they are based on graphical solution procedures. For the pumping period, time-drawdown plots when plotted on semi-log paper will show characteristic shapes according to the governing equations as was illustrated in Figures 10.2, 10.4, 10.6, and 10.8. For the recovery period, time-ratio-residual-drawdown plots when plotted on semi-log paper will give characteristic shapes as was illustrated in Figure 10.9.

For the three main types of aquifers, the analysis procedures are now discussed together with sample calculations. These analysis procedures can be applied both to aquifer-test data as well as single-well test data. With the latter, the value of the specific yield or storativity can, in principle, not be determined.

10.4.1 Aquifer Test in a Confined Aquifer

The physical properties of a confined aquifer can be found by developing the time-drawdown relationship based on Equation 10.3. If the pumping time is long enough, a plot of the drawdown s observed at a particular distance r from the pumped well vs. the logarithm of time t , will appear as a straight line. If the slope of the straight-line segment is expressed as the drawdown difference ($\Delta s = s_1 - s_2$) per log cycle of time ($\log t_2/t_1 = 1$), rearranging Equation 10.3 gives

$$T = \frac{2.3Q}{4\pi \Delta s} \quad (10.17)$$

TABLE 10.2 Time–Drawdown Values Observed in a Piezometer at 90 m Distance from the Pumped Well of an Aquifer Test

Time (min)	Drawdown (cm)	Time (min)	Drawdown (cm)	Time (min)	Drawdown (cm)
1	2.5	30	20.0	150	35.0
2	3.9	40	22.6	360	42.6
4	6.1	50	24.7	550	44.0
6	8.0	60	26.4	720	44.5
9	10.6	90	30.4		
20	16.8	120	33.0		

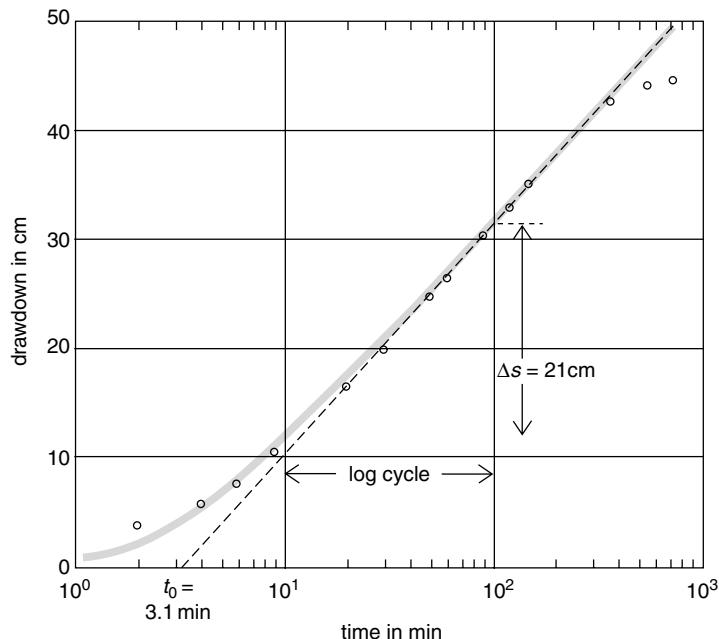

FIGURE 10.12 Time–drawdown plot of field data of an aquifer test in a confined aquifer.

If this line is extended until it intercepts the time-axis where $s = 0$, the interception point has the coordinates $s = 0$ and $t = t_0$. Substituting these values into Equation 10.3, after rearrangement, gives

$$S = \frac{2.25 T t_0}{r^2} \quad (10.18)$$

This procedure will now be illustrated with field data. An aquifer test was made in a confined aquifer. The well was pumped at a constant rate of $528 \text{ m}^3/\text{d}$ during 12 h. Table 10.2 shows the drawdowns of a piezometer at 90 m distance from the pumped well at various times. Figure 10.12 shows the time–drawdown plot on semi-log paper. From visual inspection, the data plot exhibits a straight line in the time range from 20 to 360 min. Through these points a best fitting straight line was drawn; Figure 10.12 shows that its slope Δs is $21 \text{ cm} = 0.21 \text{ m}$ per log cycle of time. Substitution of the appropriate values into Equation 10.17 gives

$$T = \frac{2.3 \times 528}{4 \times 3.14 \times 0.21} = 460 \text{ m}^2/\text{d}$$

From Figure 10.12 it can be seen that the extrapolated straight line intersects the x -axis where $s = 0$ at $t_0 = 3.1 \text{ min} = 2.2 \times 10^{-3} \text{ d}$. Substitution of the appropriate values into Equation 10.18 yields

$$S = \frac{2.25 \times 460 \times 2.2 \times 10^{-3}}{90^2} = 2.8 \times 10^{-4}$$

Finally, the selected data points to draw the best fitting straight line in Figure 10.12 should have corresponding $1/u$ values larger than 10 which is a practical condition for the applicability of the Jacob method. Rearranging Equation 10.2 and substituting $1/u > 10$, this condition gives

$$t > \frac{10r^2 S}{4T} = \frac{10 \times 90^2 \times 2.8 \times 10^{-4}}{4 \times 460} = 1.2 \times 10^{-2} \text{ d} = 18 \text{ min}$$

So, theoretically, all the observed drawdown values with t values larger than 18 min have $1/u$ values larger than 10 and can thus be expected to lie on a straight line. As the straight line was initially drawn through the plotted points in the time range from 20 to 360 min the above condition was already fulfilled. For an explanation for the fact that the last two drawdown values do not fall on the straight line, the reader is referred to Section 10.7.

The well was not observed during the recovery period, so no second estimate for the physical properties could be made based on the time–residual-drawdown relationship. Also no other piezometers were drilled, so the analysis of this aquifer test yielded only one value of the transmissivity and one value of the storativity and thus the consistency of these parameter values could not be checked.

To check the consistency of the analysis results in another way, the following procedure was followed. For all the data points, their u and corresponding $W(u)$ values were calculated and substituted into Equation 10.1 together with the appropriate values for Q and T . These theoretical drawdown values based on the Theis equation were plotted as a shaded line in Figure 10.12. It clearly shows that there is a good match between these theoretical drawdown values and those observed in the field. The above physical properties can thus be regarded to be representative for the aquifer under consideration. With the software package SATEM (Boonstra and Kselik, 2001), these theoretical drawdown values are always plotted in the data plot to check the consistency of the analysis results.

Finally, it can be noted that the more strict criterion, that is, that the data points should have $1/u$ values larger than 100, would have resulted in no analysis at all; in that case, only the last three data points in Figure 10.12 ($t > 180 \text{ min}$) would have been eligible to draw a best fitting straight line. This test clearly demonstrates that the limiting condition of large $1/u$ values to be able to apply the Jacob method, should be treated judiciously.

10.4.2 Aquifer Test in an Unconfined Aquifer

Figure 10.4 shows that even with a delayed yield effect, the time–drawdown curve will eventually exhibit a straight-line segment under a slope for late-time conditions. So, if the pumping time is sufficiently long, the physical properties of an unconfined aquifer can thus also be found by using Equation 10.17 and Equation 10.18, provided that the drawdown are corrected according to Equation 10.5. This procedure will now be illustrated with field data. An aquifer test was made in a 470-m thick, unconfined aquifer. The well only penetrating the aquifer to a depth of 60 m with a screen length of 40 m, was pumped at a constant rate of $6350 \text{ m}^3/\text{d}$ during 100 h. Table 10.3 shows the drawdowns observed in a piezometer at a distance of 91.5 m from the pumped well as function of time. The depth of this piezometer was 46 m with the last two meters screened.

The first step is to determine whether the observed drawdown values are small compared to the aquifer's thickness. The last observed drawdown value in Table 10.3 is less than 5% of the aquifer thickness. So, the uncorrected drawdown values can thus be used in the analysis. Figure 10.13 shows the time–drawdown plot on semi-log paper. From visual inspection, the data plot exhibits a straight line in the time range from

TABLE 10.3 Time–Drawdown Values Observed in a Piezometer at 91.5 m Distance from the Pumped Well of an Aquifer Test

Time (min)	Drawdown (cm)	Time (min)	Drawdown (cm)	Time (min)	Drawdown (cm)
1	1.0	40	18.0	600	25.9
2	1.0	50	18.6	750	26.5
3	2.1	60	19.2	1000	27.4
4	3.4	75	20.1	1250	28.7
6	6.1	100	20.7	1500	29.3
8	8.8	125	21.3	1750	29.9
10	11.0	150	21.6	2000	30.5

21	15.2	300	23.8	5000	36.9
25	15.8	400	24.4	6000	36.9
30	16.8	500	25.3		

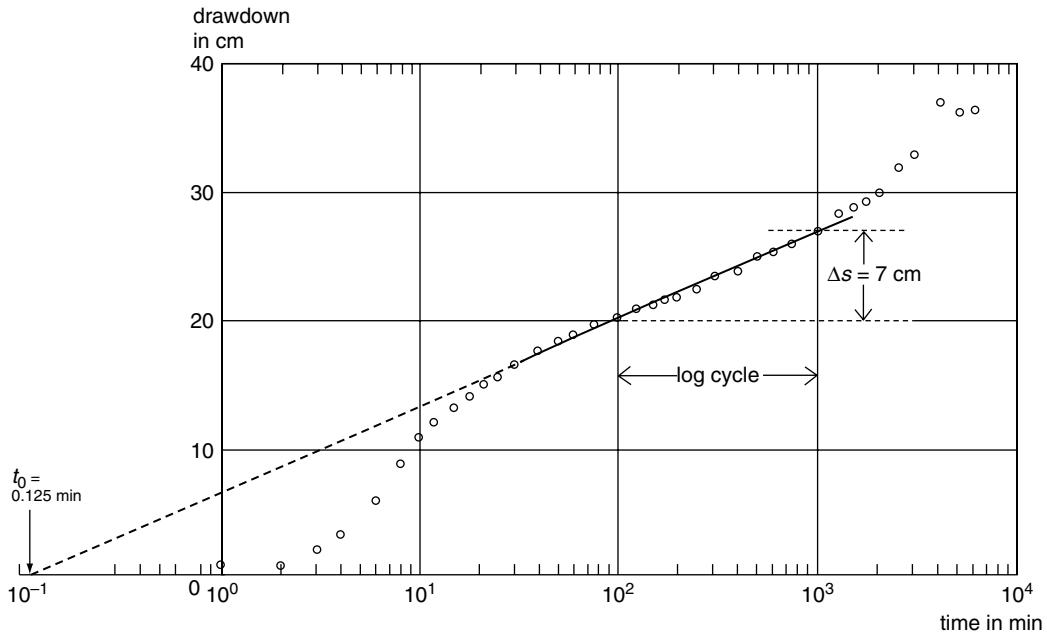

FIGURE 10.13 Time–drawdown plot of field data of an aquifer test in an unconfined aquifer with partially penetrating pumped well.

30 to 1000 min. Through these points a best fitting straight line was drawn; Figure 10.13 shows that its slope Δs is $7 \text{ cm} = 0.07 \text{ m}$ per log cycle of time. Substitution of the appropriate values into Equation 10.17 gives

$$T = \frac{2.3 \times 6350}{4 \times 3.14 \times 0.07} = 16,603 \text{ m}^2/\text{d}$$

Equation 10.18 cannot be used to estimate the specific yield due to the fact that there is a partially penetrating pumped well. Substituting the values $s = 0$ and $t = t_0$ into Equation 10.12, the specific yield

TABLE 10.4 Values of Components in Summation Series of Equation 10.11

n	K_0	sin	sin	cos	Component	Summation
1	0.7629	0.3904	0.1333	0.9551	0.1874	0.1874
2	0.3095	0.7188	0.2642	0.8244	0.0580	0.2454
3	0.1401	0.9332	0.3904	0.6197	0.0157	0.2611
4	0.0665	0.9994	0.5096	0.3594	0.0029	0.2640
5	0.0326	0.9071	0.6197	0.0668	0.0001	0.2641

value can then be obtained by

$$S_y = \frac{2.25 T t_o}{r^2} e^{f_s} \quad (10.19)$$

From Figure 10.13 it can be seen that the extrapolated straight line intersects the x -axis where $s = 0$ at $t_o = 0.125 \text{ min} = 8.7 \times 10^{-5} \text{ d}$. Before the value of S_y can be calculated, the value of f_s needs to be determined. Table 10.4 shows the different components of the first five values in the summation series of Equation 10.11 with $b = 60 \text{ m}$, $d = 20 \text{ m}$, $b' = 46 \text{ m}$, $d' = 44 \text{ m}$, and $D = 470 \text{ m}$. Substituting the appropriate values into Equation 10.11 gives

$$f_s = \frac{4 \times 470}{3.14(60 - 20)} \times 0.2641 = 14.96 \times 0.2641 = 3.95$$

Substitution of the appropriate values into Equation 10.19 then yields

$$S_y = \frac{2.25 \times 16,603 \times 8.7 \times 10^{-5}}{91.5^2} e^{3.95} = 3.9 \times 10^{-4} \times 51.9 = 0.02$$

Finally, the limiting condition to use Equation 10.12 for evaluating the physical properties of the tested unconfined aquifer should be checked:

$$t > \frac{D^2 S_y}{2T} = \frac{470^2 \times 0.02}{2 \times 16,603} = 0.133 \text{ d} = 192 \text{ min}$$

So, theoretically, all the observed drawdown values with t values larger than 192 min, can be expected to lie on a straight line. As the straight line was initially drawn through the plotted points in the time range from 30 to 1,000 min, the above condition was thus violated. When another straight line is drawn through the points in the time range from 200 to 1,000 min, its slope will be somewhat steeper. A repetition of the above calculations then yields a transmissivity value of $15,828 \text{ m}^2/\text{d}$ and a specific yield value of 0.016. These values do not differ significantly from the first ones.

For this aquifer test, two other piezometers were drilled at distances of 15.2 and 30.5 m from the pumped well (Boonstra, 1992). The time–drawdown analyses from these piezometers gave two other estimates of the physical properties: transmissivities of 16,691 and $14,104 \text{ m}^2/\text{d}$ and specific yield values of 0.011 and 0.013, respectively. This illustrates well the fact that with aquifer tests with more than one piezometer, a comparison between the various estimates of the physical properties can be made. When the various estimates are consistent in their values as with this test, more reliability can be given to the analyses results. It should be noted that the range in transmissivity values is usually smaller than the range in specific yield values due to the nature of the analysis procedure. This phenomenon also pertains to the aquifer-test results in confined and leaky aquifers.

10.4.3 Aquifer Test in a Leaky Aquifer

The physical properties of a leaky aquifer can be found by developing the time–drawdown relationship based on Equation 10.6. Figure 10.6 shows that the Hantush well function exhibits an inflection point and for large values of $1/u$ a horizontal straight-line segment indicating steady-state flow. On these phenomena the inflection-point method was based. Hantush (1956) showed that for the inflection point (s_p , t_p) the following relationships hold:

1. The drawdown value s_p is given by

$$s_p = 0.5s_m \quad (10.20)$$

2. The u_p value is given by

$$u_p = \frac{r^2 S}{4Tt_p} = \frac{r}{2L} \quad (10.21)$$

3. The slope of the curve at the inflection point Δs_p per log cycle of time is given by

$$\Delta s_p = \frac{2.3Q}{4\pi T} e^{-r/L} \quad (10.22)$$

4. At the inflection point, the relation between the drawdown and the slope of the curve is given by

$$2.3 \frac{s_p}{\Delta s_p} = e^{r/L} K_o(r/L) \quad (10.23)$$

This procedure will now be illustrated with field data. An aquifer test was made in a leaky aquifer. The well was pumped at a constant rate of $545 \text{ m}^3/\text{d}$ during 48 h. One of the piezometers was located 20 m away from the pumped well. Table 10.5 shows the observed drawdowns as function of time. Figure 10.14 shows that steady-state conditions did occur at the end of the pumping test

TABLE 10.5 Time–Drawdown Values Observed in a Piezometer at 20 m Distance from the Pumped Well of an Aquifer Test

Time (min)	Drawdown (m)	Time (min)	Drawdown (m)	Time (min)	Drawdown (m)
1	0.265	60	1.615	720	2.320
2	0.347	70	1.675	840	2.337
3	0.490	80	1.725	960	2.355
4	0.584	90	1.767	1080	2.377
5	0.635	120	1.895	1200	2.373
6	0.707	150	1.977	1320	2.385
7	0.793	180	2.020	1440	2.400
8	0.839	210	2.075	1620	2.410
9	0.882	240	2.113	1800	2.420
10	0.930	300	2.170	1980	2.440
15	1.079	360	2.210	2160	2.440
20	1.187	420	2.245	2340	2.450
25	1.275	480	2.270	2520	2.450
30	1.345	540	2.281	2700	2.440
40	1.457	600	2.298	2880	2.440
50	1.554	660	2.310		

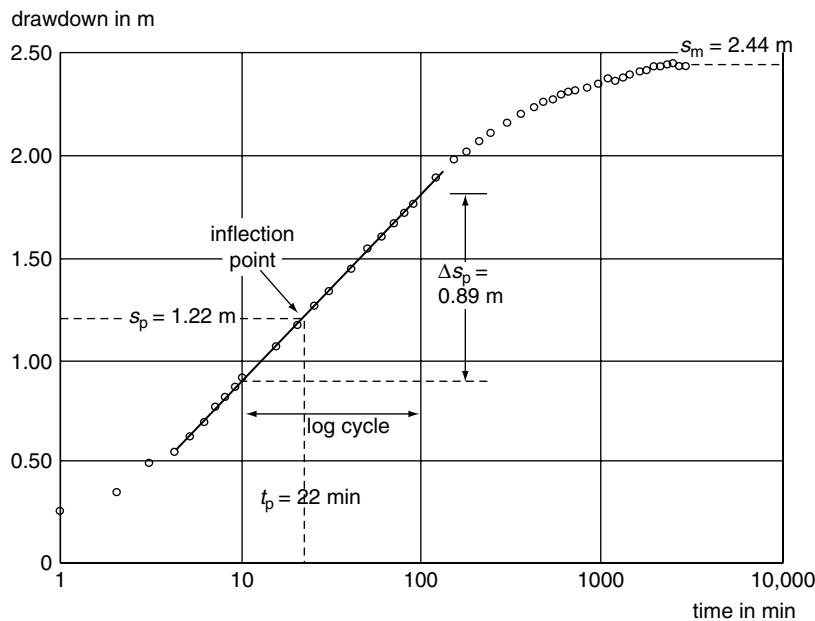

FIGURE 10.14 Time–drawdown plot of field data of an aquifer test in a leaky aquifer.

($s_m = 2.44 \text{ m}$). According to Equation 10.20 the s_p value is then 1.22 m . Locating the inflection point in Figure 10.14 using this s_p value, gives a t_p value of $22 \text{ min} = 1.5 \times 10^{-2} \text{ d}$.

The slope of the curve at this inflection point is 0.89 m per log cycle of time. Substitution of the appropriate values into Equation 10.23 yields

$$e^{r/L} K_o(r/L) = 2.30 \frac{s_p}{\Delta s_p} = 2.3 \frac{1.22}{0.89} = 3.15$$

A table with r/L , $K_o(r/L)$ and $e^{r/L} K_o(r/L)$ values is provided in Appendix 10.1. The r/L value is then 0.0575 . Substitution of the r value yields $L = 20/0.0575 = 348 \text{ m}$. Rearranging Equation 10.22 and substituting the appropriate values yields

$$T = \frac{2.3Q}{4\pi \Delta s_p} e^{-r/L} = \frac{2.3 \times 545}{4 \times 3.14 \times 0.89} e^{-0.0575} = 106 \text{ m}^2/\text{d}$$

The c value is then $L^2/T = 348^2/106 = 1142 \text{ d}$. Rearranging Equation 10.21 and substituting the appropriate values yields

$$S = \frac{4Tt_p}{r^2} \frac{r}{2L} = \frac{4 \times 106 \times 1.5 \times 10^{-2}}{20^2} \times \frac{20}{2 \times 348} = 4.6 \times 10^{-4}$$

It should be noted that the accuracy of the calculated physical properties depends to a large extent on the accuracy of the value of the (extrapolated) steady-state drawdown s_m . The calculations should therefore be checked by substituting the different values into Equation 10.6; calculations of s should be made for the observed values of t . If the values of t are not too small, the values of s should fall on the observed data curve. If the calculated data deviate from the observed data, the (extrapolated) value of s_m should be adjusted. Sometimes, the observed data curve can be drawn somewhat steeper or flatter through the plotted points, and so Δs_p can be adjusted too. With the new values of s and Δs_p , the calculation is then repeated.

TABLE 10.6 Time–Drawdown Values of a Single-Well Test

Time (min)	Drawdown (m)	Time (min)	Drawdown (m)	Time (min)	Drawdown (m)
15	4.161	50	4.486	240	4.808
20	4.283	56	4.471	300	4.776
25	4.257	60	4.474	360	4.885
30	4.357	80	4.534	420	4.960
36	4.358	105	4.618	480	4.906
40	4.399	120	4.672	540	4.972
46	4.456	180	4.748	600	5.016

With the software package SATEM (Boonstra and Kselik, 2001), the above time-consuming work can be avoided. This program follows the same procedure as described above. In addition, it displays the drawdowns calculated with Equation 10.6 on the monitor, together with the data observed in the field. This makes it easy to check whether the correct (extrapolated) steady-state drawdown s_m has been selected.

10.4.4 Single-Well Tests

With single-well tests, basically the same procedures can be applied as with aquifer tests. The r value now represents the effective radius of the single well. This is difficult to determine under field conditions; as a “best” estimate, the outer radius of the well screen is often used.

A complicating factor is the phenomenon that due to nonlinear well losses the water levels inside the well can be considerably lower than those directly outside the well screen. This implies that drawdown data from the pumped well can, in general, only be used for the analysis when corrected for these nonlinear well losses using the results of so-called step-drawdown tests (see Chapter 11).

The procedure with single-well tests will now be illustrated with field data from an unconfined aquifer. The well was pumped at a constant rate of $3853 \text{ m}^3/\text{d}$ for 10 h. The outer radius of the well screen was 0.20 m. Table 10.6 shows the observed drawdowns as a function of time. At the same site, a step-drawdown test was also made. From the analysis of this test, the nonlinear well loss was calculated as 1.93 m (see Chapter 11 under the heading “Jacob’s Method”).

The first step is to determine whether the observed drawdown values are small compared with the aquifer’s thickness. The depth of the pumped borehole was 271 m. Substituting this value and the last observed drawdown value corrected for nonlinear well loss into Equation 10.5 gives a maximum correction value of $(5.016 - 1.93)^2 / (2 \times 271) = 0.02 \text{ m}$. So, no corrections on the observed drawdowns are needed with respect to Equation 10.5.

Figure 10.15 shows the time–drawdown plot of the observed drawdowns in the pumped well corrected for nonlinear well loss on semi-log paper. From visual inspection, the data plot exhibits a straight line over the whole time range. Through all the points a best fitting straight line was drawn; Figure 10.15 shows that its slope Δs is 0.50 m per log cycle of time. Substitution of the appropriate values into Equation 10.17 gives

$$T = \frac{2.3 \times 3853}{4 \times 3.14 \times 0.50} = 1410 \text{ m}^2/\text{d}$$

From Figure 10.15 it can be seen that the intersection of the straight line with the x -axis where $s = 0$ cannot be determined directly. When such a situation occurs, the following procedure can be used. The Δs value was calculated as 0.50 m. Figure 10.15 shows that for a drawdown of 2.50 m — being 5 times the Δs value — the corresponding time is 44 min. The t_0 value is then equal to $44 \times 10^{-5} \text{ min} = 3.1 \times 10^{-7} \text{ d}$. Substitution of the appropriate values into Equation 10.18 yields

$$S_y = \frac{2.25 \times 1410 \times 3.1 \times 10^{-7}}{0.20^2} = 0.025$$

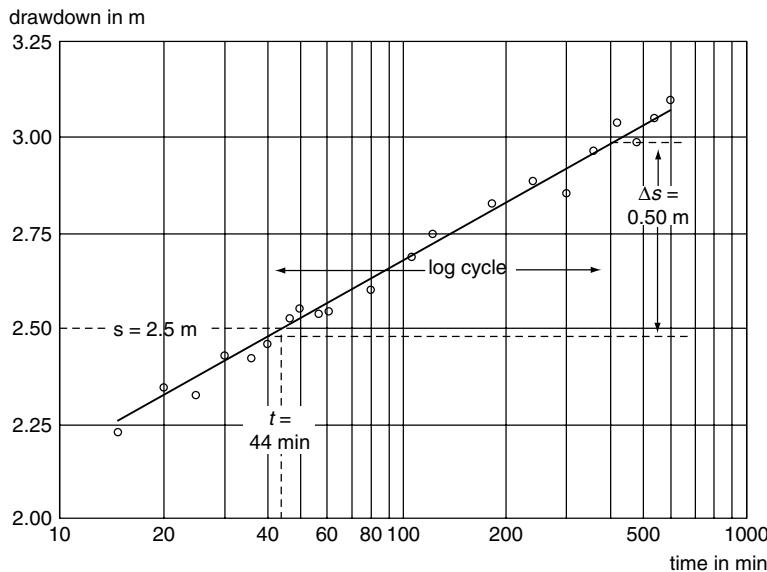

FIGURE 10.15 Time–drawdown plot of field data of a single-well test in an unconfined aquifer.

Finally, the selected data points to draw the best fitting straight line in Figure 10.15 should have corresponding $1/u$ values larger than 10 which is a practical condition for the applicability of the Jacob method. Rearranging Equation 10.2 and substituting $1/u > 10$, this condition gives

$$t > \frac{10r^2S_y}{4T} = \frac{10 \times 0.2^2 \times 0.025}{4 \times 1410} = 1.8 \times 10^{-6} d = 2.6 \times 10^{-3} \text{ min}$$

So, theoretically, all the observed drawdown values with t values larger than 2.6×10^{-3} min, can be expected to lie on a straight line. In other words, all the observed drawdown data as plotted in Figure 10.15 can be used to determine the slope of the straight line. It should be noted that the condition $1/u > 10$ is usually fulfilled in single-well tests because of the small r value.

With the above procedure, we can also use the uncorrected drawdown data and still get representative transmissivity values, as the slope of the straight-line segment in the time–drawdown plot on semi-log paper is not affected by the constant value of the nonlinear well loss. Specific yield values based on the corrected data, should, however, be treated with caution, as they are highly sensitive to the value of the effective radius of the pumped well.

For this single-well test, field measurements were also made during the recovery period. Table 10.7 shows the observed residual drawdowns as a function of time. Figure 10.16 shows the plot of residual drawdown vs. time on semi-log paper. From visual inspection, the data plot exhibits a straight line in the time-ratio range from 2 to 40. Through these points a best fitting straight line was drawn; Figure 10.16 shows that its slope $\Delta s'$ is 0.56 m per log cycle of time ratio. Rearranging Equation 10.15 and assuming that $S'_y = S_y$ gives

$$T = \frac{2.3Q}{4\pi \Delta s'} = \frac{2.3 \times 3853}{4 \times 3.14 \times 0.56} = 1260 \text{ m}^2/\text{d}$$

From Figure 10.16 it can be seen that the straight line intersects the axis where $s'(r, t/t') = 0$, at $(t/t')_0 = 1.39$. Substituting the appropriate values into Equation 10.15 yields

$$S'_y = \frac{S_y}{1.39} = 0.7S_y$$

TABLE 10.7 Time-Residual Drawdown Values of a Single-Well Test

Time (min)	Residual Drawdown (m)	Time (min)	Residual Drawdown (m)	Time min)	Residual Drawdown (m)

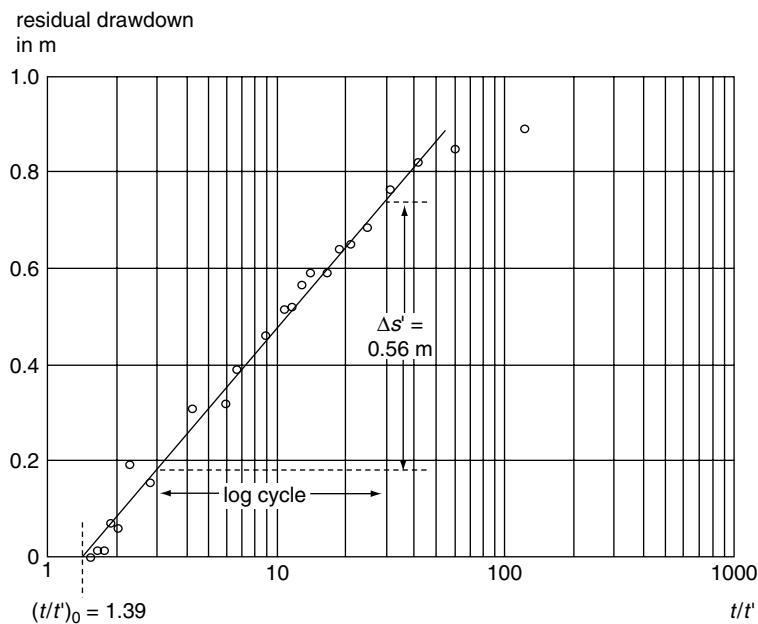

FIGURE 10.16 Time–ratio–residual-drawdown plot of field data of a single-well test in an unconfined aquifer.

The above implies that the specific yield value during recovery is less than during pumping. This phenomenon is often encountered because of air entrapment when the pores are again filled with water.

The above transmissivity value corresponds well with that found from the time–drawdown analysis. The application of time–drawdown and time–recovery analyses thus enables us to check the calculated transmissivity value. When the two values are close to each other, it implies that the data are consistent, that is, that the results of the test are reliable.

10.5 Distance–Drawdown Analyses

These analysis methods have also in common that they are based on graphical solution procedures. For all three main types of aquifers, plots of steady-state drawdowns of piezometers vs. the logarithms of the distances of these piezometers from the pumped well will show characteristic shapes; these diagnostic plots are from hereon referred to as distance–drawdown plots. Steady-state drawdowns of at least two piezometers are required for this type of analysis. The presented distance–drawdown analyses can only

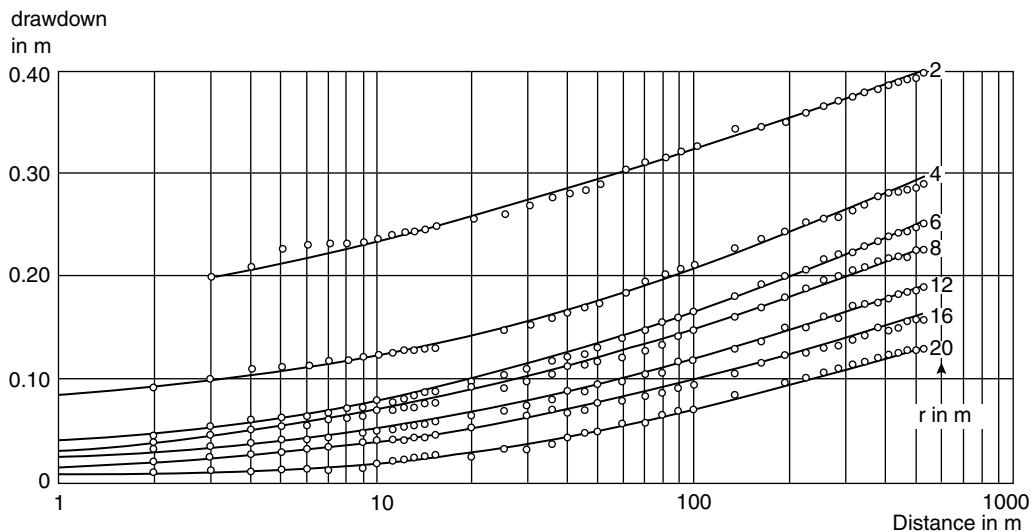

FIGURE 10.17 Time–drawdown curves of seven piezometers showing field data of an aquifer test in an unconfined aquifer.

be applied to aquifer tests with fully-penetrating pumped wells. The advantage of distance–drawdown analyses is that an independent estimate of the aquifer’s transmissivity can be made, in addition to the estimates obtained from the time–drawdown analyses of each piezometer separately. For leaky aquifers, an independent estimate of the aquitard’s hydraulic resistance can be made as well.

10.5.1 Confined and Unconfined Aquifers

Theoretically, in confined and unconfined aquifers that are pumped at a constant rate, there will always be an unsteady state, as these aquifers are not recharged by an outside source. Instead of steady state, the concept of pseudo-steady state is used for these types of aquifers. It is said that the aquifer is in pseudo-steady state when the hydraulic gradient has become constant, that is, when the time–drawdown curves are running parallel (see Figure 10.11).

The physical properties of a confined or unconfined aquifer can be found by developing the distance–drawdown relationship based on Equation 10.4. From this equation it can be seen that the corresponding distance–drawdown plot will show a straight line. If the slope of this straight line is expressed as the drawdown difference ($\Delta s = s_1 - s_2$) per log cycle of distance ($\log r_2/r_1 = 1$), rearranging Equation 10.4 gives

$$T = \frac{2.3Q}{2\pi \Delta s} \quad (10.24)$$

This procedure will now be illustrated with field data. An aquifer test was made in a shallow unconfined aquifer; prior to pumping, the aquifer’s saturated thickness was only 6.5 m. The well was pumped at a constant rate of $167 \text{ m}^3/\text{d}$ for 520 min. The water table was observed in seven piezometers. Figure 10.17 shows the time–drawdown graphs of these seven wells; the plotted drawdowns were already corrected using Equation 10.5. As can be seen from this figure, the curves run almost parallel in the last few hours of the test. Table 10.8 shows the drawdown values in the seven piezometers at the end of the test; these were assumed to represent the pseudo-steady-state drawdowns. Figure 10.18 shows the distance–drawdown plot on semi-log paper. From visual inspection, the data plot exhibits a straight line in the distance range from 4 to 20 m. Through these points a best fitting straight line was drawn; Figure 10.18 shows that its slope Δs is 0.22 m per log cycle of distance. Substitution of the appropriate values into Equation 10.24

TABLE 10.8 Pseudo-Steady-State Drawdown
Values of an Aquifer Test

Distance to Pumped Well (m)	Pseudo-Steady-State Drawdown	
	Uncorrected (m)	Corrected (m)
2	0.407	0.394
4	0.294	0.287
6	0.252	0.247
8	0.228	0.224
12	0.193	0.190
16	0.161	0.159
20	0.131	0.130

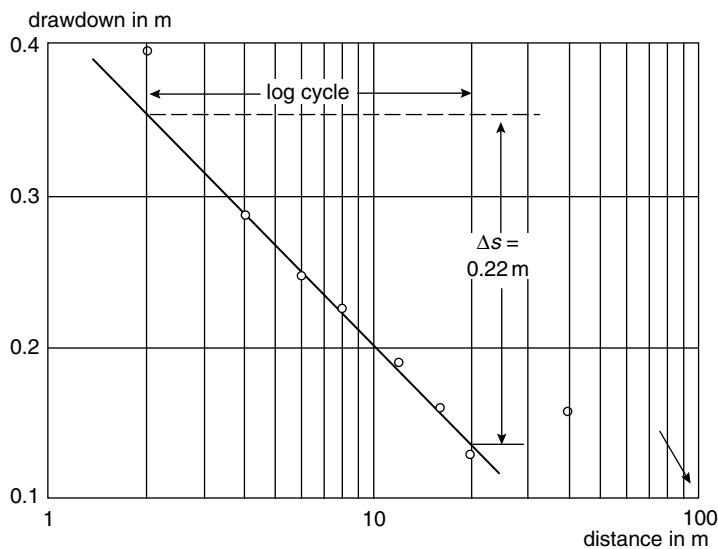

FIGURE 10.18 Distance-drawdown plot of field data of an aquifer test in an unconfined aquifer.

gives

$$T = \frac{2.3 \times 167}{2 \times 3.14 \times 0.22} = 278 \text{ m}^2/\text{d}$$

The fact that the drawdown of the piezometer at 2 m distance is not lying on the straight line, can be explained by an additional head loss that usually occurs near the well because of the relatively strong curvature of the water table. It should be noted that, as the aquifer is very thin, the piezometers were drilled at relatively short distances from the pumped well. The above transmissivity value corresponds well with those found from the time–drawdown analyses based on the individual piezometers; the latter ranged from 210 to 260 m^2/d .

10.5.2 Leaky Aquifers

The physical properties of a leaky aquifer can be found by developing the distance–drawdown relationship based on Equation 10.8. The transmissivity of a leaky aquifer can also be found from Equation 10.24 (Boonstra and de Ridder, 1994). If the straight line is extended until it intercepts the distance-axis where

TABLE 10.9 Extrapolated Steady-State Drawdown Values of an Aquifer Test

Distance from Pumped Well (m)	Steady-State Drawdown (m)
10	0.282
30	0.235
60	0.170
90	0.147
120	0.132
400	0.059

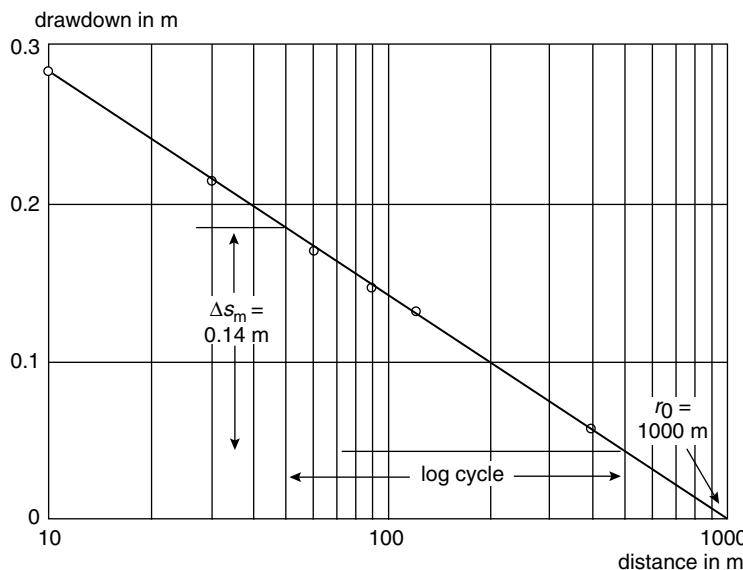

FIGURE 10.19 Distance-drawdown plot of field data of an aquifer test in a leaky aquifer.

$s_m = 0$, the interception point has the coordinates $s_m = 0$ and $r = r_0$. Substituting these values into Equation 10.8 gives

$$\log \frac{1.12L}{r_0} = 0 \quad \text{or} \quad \frac{1.12L}{r_0} = 1 \quad \text{or} \quad L = \frac{r_0}{1.12} \quad (10.25)$$

This procedure will now be illustrated with field data. An aquifer test was made in a leaky aquifer with a thickness of 10 m. The well was pumped at a constant rate of $761 \text{ m}^3/\text{d}$ for 480 min. Table 10.9 shows the extrapolated steady-state drawdowns in the six piezometers. Figure 10.19 shows the distance-drawdown plot on semi-log paper. From visual inspection, the data plot exhibits a straight line over the whole distance range. Through all the points a best fitting straight line was drawn; Figure 10.19 shows that its slope Δs_m is 0.14 m per log cycle of distance. Substitution of the appropriate values into Equation 10.24 gives

$$T = \frac{2.3 \times 761}{2 \times 3.14 \times 0.14} = 1990 \text{ m}^2/\text{d}$$

From Figure 10.19 it can be seen that the extrapolated straight line intersects the x -axis where $s_m = 0$ at $r_o = 1000$ m. Substitution of this value into Equation 10.25 gives

$$L = \frac{r_0}{1.12} = \frac{1000}{1.12} = 890 \text{ m}$$

The c value can now be calculated as $c = L^2/T = 890^2/1990 = 398$ d. Finally, the limiting conditions should be checked. Substituting the above L value into the condition $L > 3D$ gives $D < 296$ m, so this condition is fulfilled. Substituting the appropriate values into the condition $r/L < 0.2$ gives $r < 178$ m. According to this condition, the drawdown value of the piezometer at a distance of 400 m should be eliminated from the analysis. Figure 10.19, however, shows that this point, too, lies on the straight line, so in this case this condition is not a limiting factor. The above transmissivity and hydraulic resistance values correspond well with those found from the time–drawdown analyses based on the individual piezometers; the latter ranged from 1730 to 1980 m^2/d for the aquifer's transmissivity and from 350 to 510 d for the aquitard's hydraulic resistance.

10.6 Interpretation of Heterogeneous Aquifers

The assumptions shown in Section 10.2 are not likely to be found in a real field situation. Especially the assumption that the aquifer is an isotropic homogeneous medium is often far from the truth. This may not always result in “bad” aquifer properties, because the well tests described before will integrate the heterogeneity of the aquifer over large areas. The heterogeneity of an aquifer is thus related to scale, and water flow may still be described well with the obtained aquifer properties. However, for some applications, it is more important to pay attention to the heterogeneity of aquifers, especially with respect to describing the behavior of contaminants.

As it is currently not possible to describe aquifer heterogeneity with certainty, the art of groundwater hydrology can be combined with statistical methods based on geological observations at the groundwater wells that have been installed in the past. This method has been described in detail by Carle et al. (1998). Using geostatistics, one can develop a set of scenarios that is likely to describe the aquifer geology. Through groundwater modelling (described in Chapter 23) and comparison with the observed hydrological data, separate aquifer properties for the defined hydrogeological units can then be estimated. It is important to note that the resulting properties are estimates, and that the description of the geological units are a representation of the statistical likeliness of occurrence that equal the statistical occurrence of the hydrogeological properties at the locations of the installed wells.

Methods exist to improve on the estimation of the hydrological properties. A variety of aquifer representations based on the same statistical inputs can be developed. The groundwater model can then be run multiple times, and a statistical distribution of the results can be created (Monte-Carlo analysis). This will result in an average value of the properties for each hydrogeological unit, and include a standard deviation for each property. As the hydrological properties of the actual aquifer system will vary spatially, a distributed value for the hydrological properties is likely to describe the actual situation better than a single value.

The equations shown in this chapter can all be run using a distribution of input parameters and will result in a distribution of the output. However, this is time intensive and may not necessarily result in a better understanding of the aquifer system. For groundwater resources development, sufficient other properties have uncertainties (as in thickness or extent of the pumped aquifer) that a closer representation of the actual aquifer properties will not improve groundwater management practices. However, for certain applications, especially contaminant transport a better understanding of the distribution of geological material and its property distribution may be needed.

Actual contaminant transport will be different in an aquifer when it is considered heterogeneous than when it is considered homogeneous. This is related to the fact that the bulk water flow, as used in theories assuming a homogenous aquifer system, are different than the aquifer properties that an actual water

or contaminant particle will encounter. Contaminant flow in a heterogeneous aquifer system will have a different flow path than the assumed bulk water flow (LaBolle et al., 2000). When the actual behavior of contaminants in a heterogeneous aquifer system can be estimated, groundwater remediation activities can be more optimally implemented.

10.7 Concluding Remarks

The diagnostic plots of time–drawdown data based on the well-flow equations are theoretical curves. The time–drawdown curves based on field data will often deviate from these theoretical shapes. These deviations can stem from the fact that one or more of the general assumptions and conditions listed in Section 10.2 are not met in the field, or that the method selected is not the correct one for the test site. Some of the common departures from the theoretical curves will now be discussed.

All real aquifers are limited by geological or hydrological boundaries. If, however, at the end of the pumping period, no such boundaries have been met within the cone of depression, it is said that the aquifer has a seemingly infinite areal extent. When the cone of depression intersects an impervious boundary (e.g., a fault or an impermeable valley wall), it can expand no farther in that direction. The cone must expand and deepen more rapidly at the fault or valley wall to maintain the yield of the well. This will result in time–drawdown plots in which the last part of the late-time drawdown data will deviate from a straight line under a slope. This part of the plot should be disregarded when the slope of the straight-line segment is being determined. The same phenomenon can occur when, in one of the directions, the sediments become finer and the hydraulic conductivity decreases. Well interference where two wells are close to each other, will also result in a similar phenomenon (see Chapter 11).

An opposite effect is encountered when the cone of depression intersects an open water body. If the open water body is hydraulically connected with the aquifer, the aquifer is recharged at an increasing rate as the cone of depression spreads with time. This results in a flattening of the slope of the time–drawdown curve at later times, which resembles the recharge that occurs in a leaky aquifer. The same phenomenon occurs when, in one of the directions, the hydraulic conductivity or the aquifer thickness increases. The above cases will result in time–drawdown plots in which the last part of the late-time drawdown data will deviate from a straight line under a slope. This part of the plot should be disregarded when the slope of the straight-line segment is being determined.

It will be clear that there are various reasons why time–drawdown data depart from the theoretical curves. It will also be clear that different phenomena can cause approximately the same anomalies. So, if one is to make a correct analysis, one must have a proper knowledge of the geology of the test site. As, unfortunately, this knowledge is often fragmentary, determining physical properties is more an art than science. This is one of the main reasons why it is strongly recommended to continue to monitor the water table behavior during the recovery period. This allows a second estimate of the aquifer’s transmissivity to be made, which can then be compared with the one found during the pumping period. Even with single-well tests, this second estimate is possible. With computer software, even a third estimate of the transmissivity and a second estimate for the specific yield or storativity are then possible (Boonstra and Kselik, 2001).

Finally, a few remarks on the difference between aquifer tests and single-well tests. The results of aquifer tests are more reliable and more accurate than those of single-well tests. Another advantage is that aquifer tests allow estimates to be made of both the aquifer’s transmissivity and its specific yield or storativity, which is not possible with single-well tests. Further, if an aquifer test uses more than one piezometer, separate estimates of the physical properties can be made for each well, allowing the various values to be compared. Moreover, one can make yet another estimate of the physical properties by using not only the time–drawdown relationship, but also the distance–drawdown relationships.

Glossary

Aquiclude: water-bearing layer in which both the horizontal and vertical flow components are so small that they can be neglected. In an aquiclude the groundwater flow is assumed to be zero.

Aquifer: water-bearing layer in which the vertical flow component with respect to the horizontal-flow component is so small that it can be neglected. In an aquifer the groundwater flow is assumed to be predominantly horizontal.

Aquitard: water-bearing layer in which the horizontal-flow component with respect to the vertical flow component is so small that it can be neglected. In an aquitard the groundwater flow is assumed to be predominantly vertical.

Drawdown: change in observed water level as function of pumping time with respect to original water level prior to pumping.

Homogeneous: an aquifer or aquitard is called homogeneous when its hydraulic conductivity is the same throughout such a water-bearing layer; its value is thus independent of the location.

Isotropic: an aquifer or aquitard is called isotropic when its hydraulic conductivity is the same in all directions at a particular location in such a water-bearing layer; its value is thus independent of the orientation.

Piezometer: small-diameter pipe placed in the subsoil so that there is no leakage around the pipe and all water enters the pipe through its open bottom. A piezometer indicates only the hydrostatic pressure of the groundwater at the specific point in the subsoil at its open lower end. To prevent clogging, piezometers are sometimes equipped with a short screen of a few decimeters length.

Residual drawdown: change in observed water level as function of recovery time with respect to original water level prior to pumping.

Further Information

Kruseman and de Ridder (1994) provide an excellent, well-illustrated handbook to well-flow equations that cover a wider range of conditions than here presented, that is, bounded, sloping, and consolidated fractured aquifers and their application to field data.

Boonstra and Kselik (2001) present a software package that facilitates the analysis of aquifer-test data of (un)confined and leaky aquifers, including partially penetrating wells, based on time–drawdown, distance–drawdown, and time–ratio–residual–drawdown relationships.

11.1 Introduction

Wells are drilled either for exploration or exploitation purposes. With exploration wells, the objective is to collect information on the geology of the underlying aquifer. Apart from describing the various geological layers encountered (well logs), the physical properties are commonly assessed by conducting aquifer tests. These aquifer tests are commonly preceded by step-drawdown tests to determine the proper discharge rate. Proper in this respect means that good measurable drawdowns are produced in the piezometers, and that the drawdown in the pumped well does not reach the top of the well screen during the pumping period.

For exploitation or production wells, the objective can be summarized as pumping the required amount of water at the lowest cost considering investment, operation, and maintenance. Exploitation wells are drilled for water supply for municipal, industrial, and irrigation purposes, and for watertable control for drainage purposes. In the latter two cases, the exploitation wells are usually placed in the so-called well fields; well fields are also required when the required pumping capacity for municipal and industrial purposes cannot be met by a single exploitation well.

In the design of exploitation wells, two main aspects can be distinguished: the maximum expected drawdown in the well and the production capacity of the underlying aquifer system. The maximum expected drawdown determines the length of the pump casing section and is mainly composed of aquifer losses and well losses. To these aquifer losses, interference effects and partially penetrating effects should be added, when applicable. The production capacity of the underlying aquifer system determines the minimum length of the screen section that mainly depends on maximum screen velocities and screen type. To this end, well-field equations and step-drawdown tests are presented to relate aquifer losses to discharge rate and recharge rate of the aquifer, and to determine well losses and production capacity of exploration wells that will be used later on as exploitation wells. Step-drawdown tests are also required to analyze well performance of exploitation wells with time for maintenance and rehabilitation purposes.

11.2 Well-Field Equations

Chapter 10 described the flow to single wells pumping in extensive aquifers. It is usually assumed that the aquifer is not recharged during the relatively short pumping period of aquifer tests. For exploitation wells this assumption is not realistic as they are operated on a more or less continuous basis over a long time span. Most aquifer systems receive continuous or intermittent recharge from percolating rainfall and losses from surface water systems. When recharge is intermittent because of seasonal effects, the aquifer may perform without recharge for periods of several months or even longer. There is clear evidence that after such a period watertables will completely recover once the aquifer is recharged again by rainfall.

In this section, we assume that the aquifer is replenished at a constant rate, R , expressed as a volume per unit surface per unit of time ($\text{m}^3/\text{m}^2 \text{ d}$). The well-flow equations that will be presented are based on a steady-state situation. The flow is said to be in a steady state as soon as the recharge and the discharge balance each other. In such a situation, beyond a certain distance from the well, there will be no drawdown induced by pumping. This distance is called the radius of influence of the well, r_e . When the wells in a well field are placed in a triangular pattern, their individual radii of influence hardly overlap (Figure 11.1). The simplifying assumption is then made that the discharge and the drawdown of each well will not be affected by those of neighboring wells. In other words, the theory of a single well can be used.

In a well field, there is a direct relationship between the discharge rate of the well, the recharge rate of the aquifer by percolation, and the area affected by pumping. The decline of the water level due to

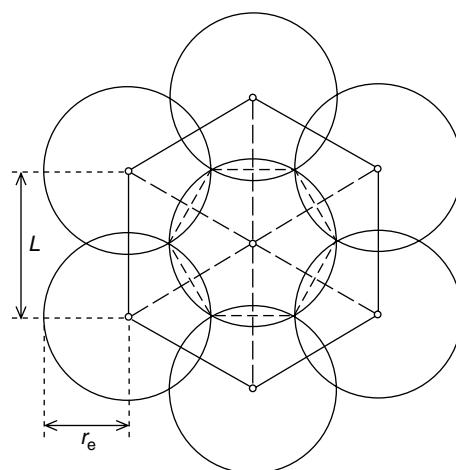

FIGURE 11.1 Layout of a well field where the wells are located in a pattern of equilateral triangles ($L = r_e\sqrt{3}$).

pumping is determined by the discharge rate of the well and the permeability and thickness of the aquifer. The discharge rate and the drawdown in the well are important factors in calculating the pumping costs of well fields. In an unconfined aquifer, the steady-state flow through an arbitrary cylinder at a distance r from the well is given by

$$Q_r = \pi(r_e^2 - r^2)R \quad (11.1)$$

where Q_r is the volumetric flow rate in m^3/d at a distance r from the well, r_e is the radius of influence of the well in meters, and R is the recharge rate of the aquifer per unit surface area in m/d . According to Darcy's law, Q_r equals the product of the cylindrical area of flow and the flow velocity. Hence, the discharge at distance r from the well can also be expressed by

$$Q_r = 2\pi rhK \frac{\partial h}{\partial r} \quad (11.2)$$

where h is the hydraulic head in meters, K is the hydraulic conductivity of the aquifer in m/d , and $\partial h/\partial r$ is the hydraulic gradient in the aquifer at distance r . As, in steady state, the discharge of the well, Q , equals the vertical recharge of the area within the radius of influence, the following relationship can be used

$$Q = \pi r_e^2 R \quad (11.3)$$

Combining Equation 11.1 and Equation 11.3 yields

$$Q_r = Q - \pi r^2 R \quad (11.4)$$

or, combining Equation 11.2 and Equation 11.4 and separating r and h gives

$$\left(\frac{Q}{r} - \pi r R \right) \partial r = 2\pi K h \partial h \quad (11.5)$$

Integration between the limits $r = r_w$, $h = h_w$, and $r = r_e$, $h = h_e$ yields

$$Q \ln \left(\frac{r_e}{r_w} \right) - \frac{1}{2} \pi R (r_e^2 - r_w^2) = \pi K (h_e^2 - h_w^2) \quad (11.6)$$

The quantity $1/2\pi R r_w^2$ is very small in comparison with $1/2\pi R r_e^2$ and can be neglected. If, moreover, the drawdown in the well is small in comparison with the original hydraulic head, the right-hand side of Equation 11.6 can be expressed as (Peterson et al., 1952)

$$\pi K (h_e + h_w)(h_e - h_w) \approx \pi K 2D(h_e - h_w) = 2\pi K D \Delta h_r \quad (11.7)$$

where D is the saturated thickness of the aquifer before pumping in meters and Δh_r is the drawdown due to radial flow toward the pumped well in meters. As, according to Equation 11.3,

$$r_e^2 = \frac{Q}{\pi R} \quad (11.8)$$

Equation 11.6 can be written as

$$\Delta h_r = \frac{Q}{2\pi K D} \left[2.3 \log \left(\frac{r_e}{r_w} \right) - \frac{1}{2} \right] \quad (11.9)$$

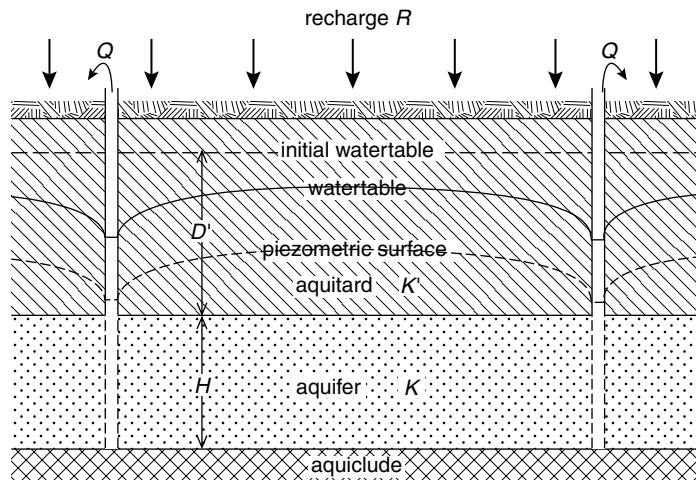

FIGURE 11.2 Schematic cross-section of wells located in a leaky aquifer.

If $r_e/r_w > 100$, and if we accept an error of 10%, the term $-1/2$ can be neglected and Equation 11.9 reduces to

$$\Delta h_r = \frac{2.3Q}{2\pi T} \log \frac{r_e}{r_w} \quad (11.10)$$

where $T = KD$ is the transmissivity of the aquifer in m^2/d . Equation 11.10 can be used to calculate the drawdown in a single well or, when no interference between the wells is assumed, the drawdown in a well field. From Figure 11.1, it can be seen that the distance between the wells (L) should then be equal to $r_e\sqrt{3}$.

Figure 11.2 shows a leaky aquifer whose overlying layer, the aquitard, is replenished by percolating rain or excess irrigation water at a constant rate R . Depending on the recharge rate and the hydraulic resistance of the aquitard, a difference in head between the free watertable in the aquitard and the piezometric level of the aquifer will develop. Under steady-state conditions, the same recharge rate will replenish the underlying aquifer. So, Equation 11.10 can also be used to calculate the head loss in a well or well field for leaky aquifers.

The application of Equation 11.10 will now be illustrated with an example calculation. In Chapter 10, data were presented for a single-well test. The analysis of this test yielded a transmissivity value of some $1400 \text{ m}^2/\text{d}$. Suppose that from a water-balance analysis, the long-term average net recharge to the aquifer was estimated as $550 \text{ mm/yr} (=1.5 \text{ mm/d})$. To calculate the drawdown in a well with a constant discharge of $200 \text{ m}^3/\text{h}$, the radius of influence needs to be calculated. Using Equation 11.3, the radius of influence will be

$$r_e = \sqrt{\frac{200 \times 24}{3.14 \times 0.0015}} = 1010 \text{ m}$$

Substituting this value into Equation 11.10 with an outer well screen radius (r_w) of 0.2 m gives

$$\Delta h_r = \frac{2.3 \times 200 \times 24}{2 \times 3.14 \times 1400} \log \frac{1010}{0.2} = 4.65 \text{ m}$$

So, the steady-state drawdown in a single well due to radial flow amounts to 4.65 m . A similar drawdown can be expected when wells are placed in a well field with a triangular pattern. The distance between the wells in Figure 11.1 should then be $L = 1010 \times 1.73 = 1747 \text{ m}$; it is then assumed that there will be no mutual interference between the various wells. If the wells are located at shorter distances or in a

TABLE 11.1 Comparison between Pumping Capacities, Drawdown due to Aquifer Losses, and Distances between Wells (Triangular Pattern) for a Net Recharge of 1.5 mm/d

Pumping capacity (m ³ /h)	Radius of Influence (m)	Aquifer Losses (m)	Distance Between Wells (m)	Area Per Well (ha)
100	714	2.23	1236	160
200	1010	4.65	1747	320
300	1236	7.14	2141	480

rectangular pattern, the drawdown in the wells will increase due to well interference; this phenomenon will be numerically illustrated in Section 11.5.

In well-field design for drainage purposes, there is a trade-off between the capacity and the number of wells required as is shown in Table 11.1. If larger pumps are installed, fewer pumps will be required that generally results in lower investment costs. On the other hand, larger capacity pumps may result in considerably higher drawdowns and thus higher energy costs. Determining pump capacities on a purely economic basis could lead to very high pumping rates. There are, however, several practical constraints to these high pump capacities for drainage purposes. A well with a very high pump capacity may serve a very large area that exceeds the spacing determined by other factors. If such a well were to be out of order for a prolonged period, the neighboring wells would be overburdened, and proper drainage of the area would be impossible. Moreover, if the water is also used for irrigation, pump capacities are often limited by the requirements of the farmers.

11.2.1 Partial Penetration

Equation 11.10 was derived under the assumption that the well fully penetrates the pumped aquifer. Some aquifers are so thick, however, that installing a fully penetrating well would not be justified. In these cases, the aquifer has to be pumped by a partially penetrating well. This partial penetration causes the flow velocity in the immediate vicinity of the well to be higher than it would otherwise be, leading to an extra loss of head. According to Hantush (1964), the effect of partial penetration in an unconfined aquifer is similar to that in a confined aquifer, as the drawdown is usually small in relation to the saturated thickness of the aquifer. To calculate the effect of partial penetration, the following equation can be used

$$\Delta h_p = \frac{Q}{4\pi T} F \quad (11.11)$$

and

$$F = 2 \frac{D}{p} \left[\left(1 - \frac{p}{D} \right) \ln \left(\frac{2p}{r_w} \right) - \frac{p}{D} \ln \frac{2D}{p} - 0.423 \frac{p}{D} + \ln \frac{2D+p}{2D-p} \right] \quad (11.12)$$

where Δh_p is the additional head loss due to partial penetration effects in meters, Q is the well discharge in m³/d, T is the transmissivity of the aquifer in m²/d, D is the thickness of the aquifer in meters, and p is penetration depth of the well into the aquifer in meters, assuming screening over the full depth of the well. So, when the well only partially penetrates the aquifer, the additional head loss calculated from Equation 11.11 should be added to the drawdown calculated by Equation 11.10.

11.3 Aquifer and Well Losses

The drawdown in a pumped well consists of two components: the aquifer losses and the well losses (Figure 11.3). Aquifer losses are the head losses that occur in the aquifer where the flow is laminar. They

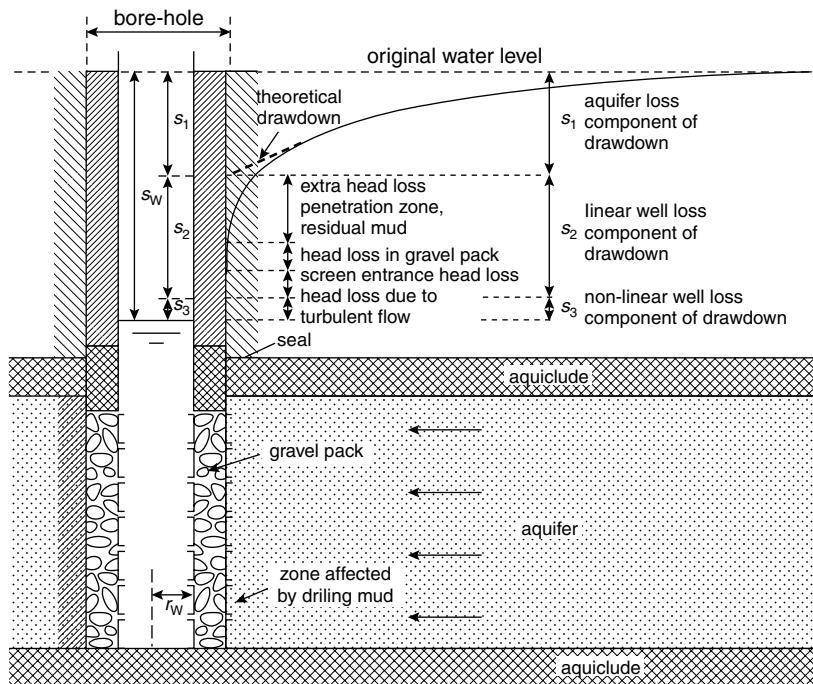

FIGURE 11.3 Various components of head losses in a pumped well.

are time dependent and vary linearly with the well discharge. The drawdown s_1 corresponding to this linear aquifer loss can be expressed as

$$s_1 = B_1(r_w, t) Q \quad (11.13)$$

where B_1 is the linear aquifer loss coefficient in d/m^2 . This coefficient can be calculated from the well-flow equations presented in Chapter 10. For confined aquifers for example, it can be expressed using Equation 10.1 and Equation 10.2 in Chapter 10 as

$$B_1(r_w, t) = \frac{W(u)}{4\pi T}$$

where $u = (r_w^2 S)/(4Tt)$. From the results of aquifer-test analyses, the values for transmissivity T and storativity S can be used to calculate B_1 values as function of r_w and t .

Well losses are divided into linear and nonlinear head losses. Linear well losses are caused by the damaging of the aquifer during drilling and completion of the well. They comprise, for example, head losses due to the compaction of the aquifer material during drilling; head losses due to plugging of the aquifer with drilling mud, that reduce the permeability near the bore hole; head losses in the gravel pack; and head losses in the screen. The drawdown s_2 corresponding to this linear well loss can be expressed as

$$s_2 = B_2 Q \quad (11.14)$$

where B_2 is the linear well loss coefficient in d/m^2 .

Among the nonlinear well losses are the friction losses that occur inside the well screen and in the suction pipe where the flow is turbulent, and head losses that occur in the zone adjacent to the well where the flow is usually also turbulent. All these losses responsible for the drawdown inside the well being much

greater than one would expect on theoretical grounds. The drawdown s_3 corresponding to this nonlinear well loss can be expressed as

$$s_3 = CQ^P \quad (11.15)$$

where C is the nonlinear well loss coefficient in $\text{d}^P/\text{m}^{3P-1}$, and P is an exponent. The general equation describing the drawdown in a pumped well as function of aquifer/well losses and discharge rate thus reads

$$s_w = (B_1 + B_2)Q + CQ^P = BQ + CQ^P \quad (11.16)$$

where $s_w = s_1 + s_2 + s_3$. Jacob (1947) used a constant value of 2 for the exponent P . According to Lennox (1966) the value of P can vary between 1.5 and 3.5; from personal experience, its value may be even higher in fractured rock aquifers. The value of $P = 2$ as proposed by Jacob, is however still widely accepted. Values of the three parameters B , C , and P in Equation 11.16 can be found from the analysis of so-called step-drawdown tests.

11.3.1 Well Efficiency

The relationship between drawdown and discharge can be expressed as the *specific capacity* of a well, Q/s_w , which describes the productivity of both the aquifer and the well. The specific capacity is not a constant but decreases as pumping continues and also decreases with increasing Q . The well efficiency, E_w , is defined as the ratio of the aquifer head loss to the total head losses; it reads when expressed as a percentage,

$$E_w = \left\{ \frac{B_1 Q}{BQ + CQ^P} \right\} \times 100\% \quad (11.17)$$

The well efficiency according to Equation 11.17 can be assessed when both the results of a step-drawdown and those of an aquifer test are available. The former are needed for the values of B , C , and P and the latter for the value of B_1 .

In practice, only the results of a step-drawdown tests are usually available. The substitution of the B , C , and P values into Equation 11.17 would overestimate the well efficiency, as $B > B_1$. For these cases, Driscoll (1986) introduced another parameter, L_p , being the ratio of the laminar head loss to the total head losses; it reads when expressed as a percentage,

$$L_p = \left\{ \frac{BQ}{BQ + CQ^P} \right\} \times 100\% \quad (11.18)$$

It should be noted that Equation 11.18 is sometimes erroneously used to calculate the well efficiency.

11.4 Step-Drawdown Tests

A step-drawdown test is a single-well test in which the well is pumped at a low constant-discharge rate until the drawdown within the well stabilizes. The pumping rate is then increased to a higher constant-discharge rate and the well is pumped until the drawdown stabilizes once more (Figure 11.4). This process is repeated through at least three steps, which should all be of equal duration, say a few hours each.

In step-drawdown analyses, the so-called diagnostic plots are used. Values of s_w/Q vs. Q are therefore plotted on arithmetic paper where s_w represents the drawdown at the end of each step. Various

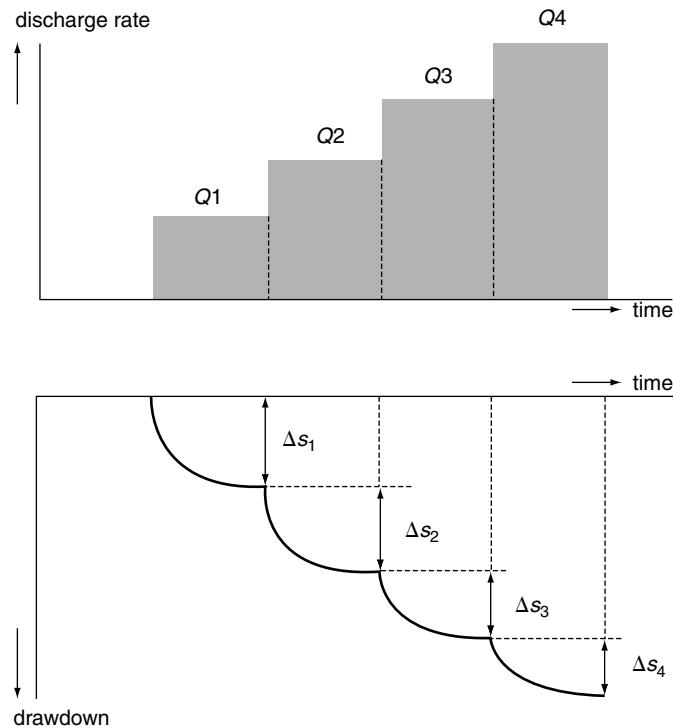

FIGURE 11.4 Principles of a step–drawdown test.

configurations of diagnostic plots are then possible:

1. The points fall on a horizontal line. This implies that $s_w/Q = B$. Equation 11.16 reduces to

$$s_w = BQ \quad (11.19)$$

Hence, there are no nonlinear well losses. This situation is only encountered with very low pumping rates. The well will act differently if the pumping rates are increased.

2. The points fall on a straight line under a slope. This means that $s_w/Q = B + CQ$. Equation 11.16 then reduces to

$$s_w = BQ + CQ^2 \quad (11.20)$$

Equation 11.20 is known as the Jacob's equation. Based on this equation, Jacob (1947) developed an analysis method to calculate the values of B and C .

3. The points fall on a curved line, that is, $P \neq 2$ in Equation 11.16. When a concave curve can be drawn through the points, it implies that $P > 2$ and for a convex curve that $P < 2$. For these cases, Rorabaugh (1953) developed an analysis method to calculate the values of B , C , and P . Both analysis methods may be applied to confined, unconfined, and leaky aquifers.

11.4.1 Jacob's Method

The values of B and C can be directly found from the diagnostic plot of s_w/Q vs. Q itself; it will yield a straight line whose slope is equal to C ; the value of B can be found by extending the straight line till it intercepts the $Q = 0$ axis.

TABLE 11.2 Time–Drawdown Values Observed in the Pumped Well of a Step–Drawdown Test

Time in Each Step (min)	Step 1 $Q: 2765$ m^3/d (m)	Step 2 $Q: 3364$ m^3/d (m)	Step 3 $Q: 3853$ m^3/d (m)	Step 4 $Q: 4306$ m^3/d (m)

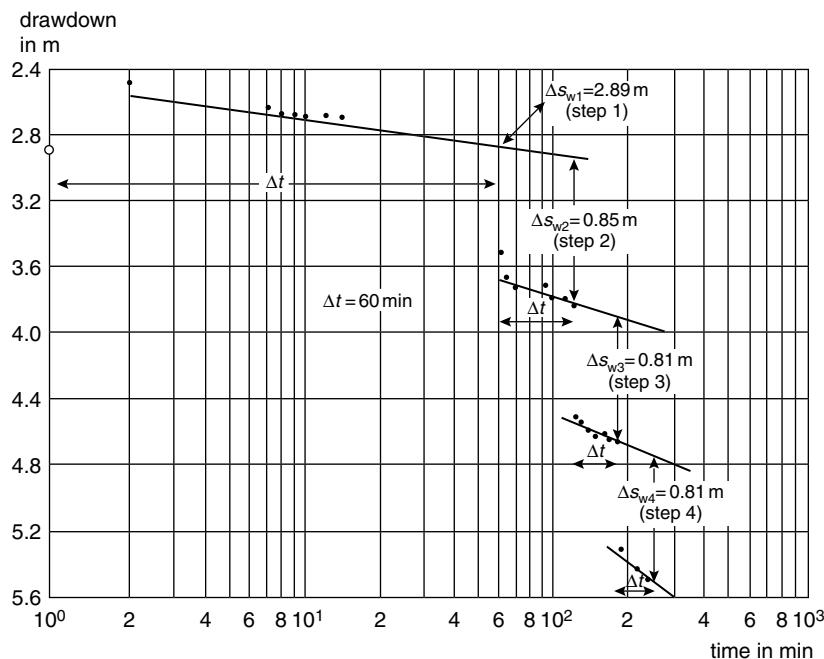

FIGURE 11.5 Time–drawdown plot of field data of a step–drawdown test in an unconfined aquifer.

This procedure will now be illustrated with field data. A step–drawdown test was carried out in an unconfined aquifer. The well was pumped with a step-wise increased discharge rate with a duration of each step of 60 min. Table 11.2 shows the observed drawdowns as function of time. Figure 11.5 shows the time–drawdown plot on semi-log paper; from this figure it can be observed that the drawdowns were not yet stabilized at the end of each step. This implies that the observed drawdown values at the

end of each step need to be corrected. This can be done using the following procedure as developed by Hantush-Bierschenk (1964):

1. Extrapolate the curve through the plotted data of each step to the end of the next step.
2. Determine the increments of drawdowns $\Delta s_{w(i)}$ for each step by taking the difference between the observed drawdown at a fixed interval Δt , taken from the beginning of each step, and the corresponding drawdown on the extrapolated curve of the preceding step.
3. Determine the values of $s_{w(n)}$ corresponding to the discharge Q_n from $s_{w(n)} = \Delta s_{w(1)} + \Delta s_{w(2)} + \dots + \Delta s_{w(n)}$.

From Figure 11.5 the drawdown differences for each step were determined using a time interval $\Delta t = 60$ min. Based on these values, the specific drawdown values s_w/Q at the end of each step were calculated (see Table 11.3). Figure 11.6 shows the resulting diagnostic plot of s_w/Q vs. Q ; the data plot clearly exhibits a straight line. This implies that $P = 2$ (Equation 11.20), so the Jacob's method can be applied. Through the points a best fitting straight line was drawn; its slope was calculated as $0.16 \times 10^{-3}/1276 = 1.25 \times 10^{-7} d^2/m^5$. The interception point of the straight line with the $Q = 0$ axis can be calculated as follows: $1.133 \times 10^{-3} - 3500 \times 1.25 \times 10^{-7} = 7.0 \times 10^{-4} d/m^2$. Hence, the drawdown equation of this well can be written as

$$s_w = 7.0 \times 10^{-4} Q + 1.3 \times 10^{-7} \times Q^2 \quad (11.21)$$

This step-drawdown test was followed by a single-well test. For that test, the discharge rate of the third step was adopted, being $3853 \text{ m}^3/\text{d}$. According to Equation 11.15 the nonlinear well loss s_3 can then be calculated as

$$s_3 = CQ^P = 1.3 \times 10^{-7} \times 3853^2 = 1.93 \text{ m}$$

This non-linear well loss was subtracted from the drawdowns observed in the pumped well (see Chapter 10 under the heading “Single-Well Tests”). The analysis of these corrected drawdowns resulted in a transmissivity of $1410 \text{ m}^2/\text{d}$ and a specific yield of 0.025 for the tested aquifer. Based on these values, the theoretical drawdown according to the Theis equation (Equation [10.1] in Chapter 10) at $t = 60 \text{ min}$ can be calculated being 2.06 m. The linear aquifer loss coefficient B_1 is then according to Equation 11.13

$$B_1 = \frac{s_1}{Q} = \frac{2.06}{3853} = 5.35 \times 10^{-4} \text{ d/m}^2$$

and the linear well loss coefficient B_2 is

$$B_2 = B - B_1 = 7.0 \times 10^{-4} - 5.35 \times 10^{-4} = 1.65 \times 10^{-4} \text{ d/m}^2$$

The well efficiency for the discharge rate of $3853 \text{ m}^3/\text{d}$ can then be calculated as 45% according to Equation 11.17. If Equation 11.18 would have been used as being representative of the well efficiency, it would have resulted in a value of 58%, that is, in an overestimation of the true well efficiency.

11.4.2 Rorabaugh's Method

The values of B , C , and P cannot be directly found from the diagnostic plot of s_w/Q vs. Q itself, when $P \neq 2$. Equation 11.16 then reads

$$\frac{s_w}{Q} = B + CQ^{P-1} \quad (11.22)$$

Rearranging Equation 11.22 and taking the logarithms, Equation 11.22 can also be written as

$$\log \left[\frac{s_w}{Q} - B \right] = \log C + (P - 1) \log Q \quad (11.23)$$

Equation 11.23 implies that a plot of $(s_w/Q - B)$ vs. Q on log-log paper would yield a straight line under a slope. The slope of this straight line is equal to $P - 1$, while the value of C can be found by extending the straight line till it intercepts the $Q = 1$ axis.

This procedure will now be illustrated with field data from a step-drawdown test. Table 11.4 shows the drawdowns observed at the end of each step (Sheahan, 1971). Figure 11.7 shows the resulting diagnostic

Step	$B_1 = 0$ (d/m ²)	$B_2 = 0.8 \times 10^{-3}$ (d/m ²)	$B_3 = 1 \times 10^{-3}$ (d/m ²)	$B_4 = 1.1 \times 10^{-3}$ (d/m ²)
1	1.2×10^{-3}	0.4×10^{-3}	0.2×10^{-3}	0.1×10^{-3}
2	1.6×10^{-3}	0.8×10^{-3}	0.6×10^{-3}	0.5×10^{-3}
3	2.6×10^{-3}	1.8×10^{-3}	1.6×10^{-3}	1.5×10^{-3}
4	4.4×10^{-3}	3.6×10^{-3}	3.4×10^{-3}	3.3×10^{-3}

plot of s_w/Q vs. Q ; this plot clearly shows that the points do not lie on a straight line. This implies that $P \neq 2$, so the Jacob's method cannot be applied. For different values of B (see Table 11.5), the values of $(s_w/Q - B)$ vs. Q were plotted on log-log paper. Figure 11.8 shows that for a B value of 1×10^{-3} d/m² the plotted points, almost exhibit a straight line. Through these points a best fitting straight line was drawn; its slope was calculated as

$$\frac{\Delta[s_w/Q - B_3]}{\Delta Q} = \frac{\log(0.2 \times 10^{-3}/3.4 \times 10^{-3})}{\log(2180/9811)} = 1.88$$

As the slope of this line equals $(P-1)$, it follows that $P = 2.88$. The interception point of the straight line with the $Q = 1$ axis can be calculated as follows. Figure 11.8 shows that the value of $(s_w/Q - B)$ for

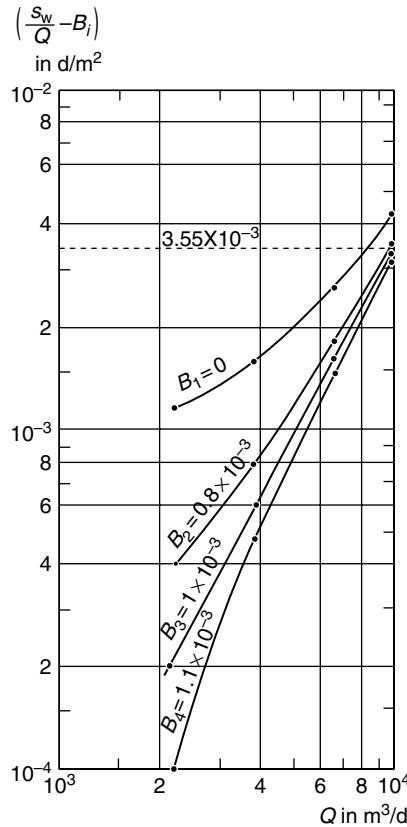

FIGURE 11.8 Log-log plot of $(s_w/Q - B)$ vs. Q to determine the parameters B , C , and P according to the Rorabaugh's method.

$Q = 10^4 \text{ m}^3/\text{d}$ is $3.55 \times 10^{-3} \text{ d/m}^2$. Hence, the intersection of the line with the $Q = 1$ axis is four log cycles to the left. This corresponds with $4 \times 1.88 = 7.52$ log cycles below the point $(s_w/Q - B) = 3.55 \times 10^{-3} \text{ d/m}^2$.

The intersection point $(s_w/Q - B)$ is then calculated as follows: $\log(s_w/Q - B) = \log(3.55 \times 10^{-3}) - 7.52 = -2.45 - 7.52 = -9.97$, thus $(s_w/Q - B) = 1.1 \times 10^{-10} = C$. Hence, the drawdown equation of this well can be written as

$$s_w = 1.0 \times 10^{-3}Q + 1.1 \times 10^{-10}Q^{2.88}$$

Based on the above relationship, the optimum discharge rate can be determined, when this well would be converted to an exploitation well.

11.5 Well Design

Exploitation wells are drilled either for water supply for municipal, industrial, and irrigation purposes or for water table control for drainage purposes. The principle objectives of a properly designed well are (1) pumping of water at the lowest cost; (2) pumping of water that is free of sand and silt; (3) minimum operation and maintenance costs; and (4) a long and economic lifetime. For water supply wells, good quality water with proper protection from contamination is an important additional objective.

Hydrogeologic information required for a proper design includes: stratigraphical information concerning the aquifer and overlying sediments, aquifer-test analyses of the physical properties of the

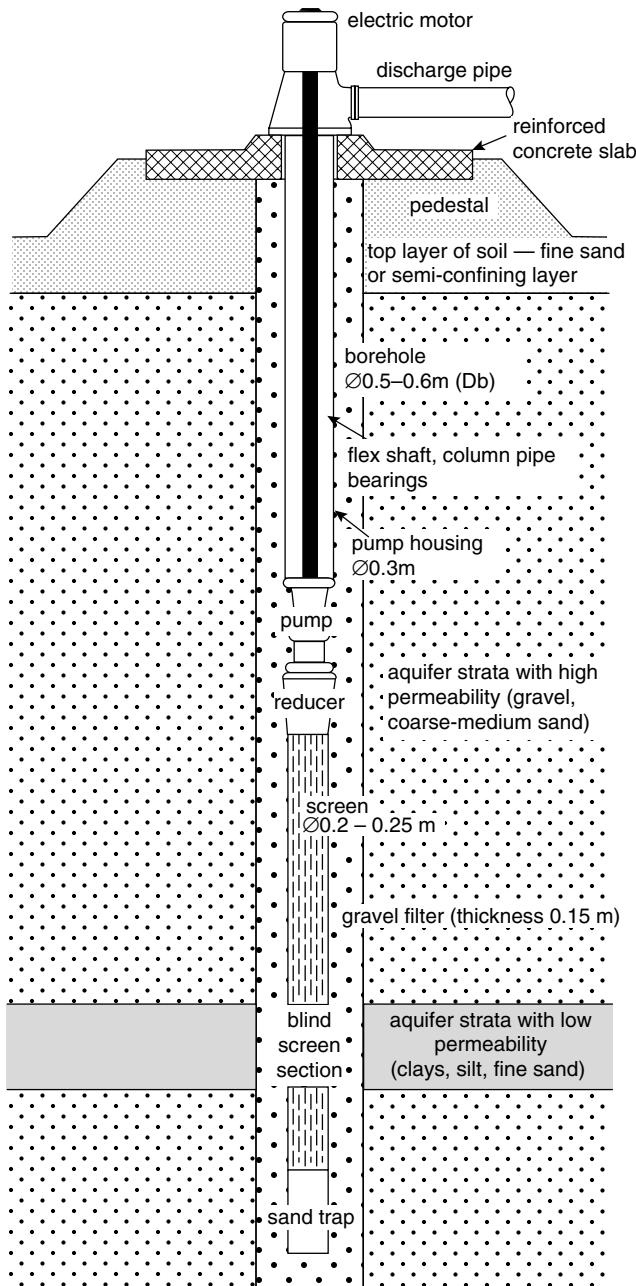

FIGURE 11.9 Typical well design.

aquifer, water-balance analyses of the sustainable yield, grain-size analyses of unconsolidated aquifer materials, and groundwater quality.

Well design is the process of specifying the physical materials and dimensions for a well. A good well design depends on many factors, some of which are discussed below. More detailed information on technical well design can be found in reference books such as those of Driscoll (1986) and Huisman (1975). Figure 11.9 shows the various well sections of a typical well design. The purpose and design of these well sections, and their position in the well, will be discussed below.

11.5.1 Casing Section

The pump housing is the upper section of blind casing that supports the well against collapse, and in which the pump is installed. The length of the pump housing should be chosen so that the pump remains below the water level in the well, for the selected discharge rate, under all conditions, and over the total lifetime of the well. A pump housing is always required when submersible pumps are used. No special pump housing is required in the case of a shallow water table with little drawdown where suction pumps can be used; both pump and engine are then installed at the surface beside the well. The diameter of the pump housing should be large enough to accommodate the pump with enough clearance for installation and efficient operation. It is recommended that the pump housing be two pipe sizes larger than the nominal diameter of the pump; the diameter of the pump depends on the selected discharge rate and the pump type.

The production casing is the lower section of the blind pipe between the bottom of the pump housing and the top of the aquifer. The production casing is not required in unconfined aquifers at shallow depth where the pump housing reaches sufficiently deep into the top section of the aquifer. The length of the production casing depends on the thickness of the aquitard overlying the pumped aquifer. To minimize the head losses in the production casing itself, the upward velocity of the pumped water should be less than 1.5 m/sec. Based on this criterion, Table 11.6 shows casing sizes recommended for various pumping rates; for the pipe sizes and pumping rates shown in this table, the head losses will be small. Moreover, the diameter of the production casing should be smaller than the diameter of the pump housing and should be larger or equal to the diameter of the underlying screen section.

11.5.2 Calculation Example Length of Pump Housing

In this calculation example, the results of the calculations presented under the heading “Well-Field Equations” and the results of the step-drawdown test presented under the heading “Jacob’s Method” will be combined with the results of the aquifer test presented under the heading “Single-Well Tests” in Chapter 10.

The actual length of the pump housing is primarily determined by the required depth of the pump. The location of the pump depends on the expected depth to which the water level inside the well will drop for

the selected design discharge rate. The procedure to determine the maximum expected water-level depth inside the pumped well is as follows.

The first step is to determine the aquifer losses. The aquifer losses are the head losses due to the laminar flow of water to the well and are determined by the hydraulic conductivity and thickness of the aquifer. Equation 11.10 can be used to estimate these losses when the wells are located in a triangular well field. Based on a constant recharge of 1.5 mm/d, a transmissivity of the aquifer of $1400 \text{ m}^2/\text{d}$ and an outer radius of the well screen of 0.2 m, the resulting aquifer losses were presented in Table 11.1 assuming that there will be no interference effects of neighboring wells. When the recharge is intermittent rather than continuous because of seasonal effects, the aquifer may perform without recharge for periods of several months or even longer. The aquifer losses should then be calculated using the equations presented in Chapter 10. Based on a specific yield of the aquifer of 0.025 together with the above transmissivity and well screen data, Equation 10.3 of Chapter 10 yields the following aquifer loss when it is assumed that the aquifer is not replenished during half a year

$$\Delta h_r = \frac{2.3 \times 200 \times 24}{4 \times 3.14 \times 1400} \log \frac{2.25 \times 1400 \times 182}{0.20^2 \times 0.025} = 5.50 \text{ m}$$

The effect of well interference should now be considered. For a discharge rate of $200 \text{ m}^3/\text{h}$, the well spacing was calculated as 1747 m (Table 11.1). The effect of well interference from one neighboring well can then be calculated as

$$\Delta h_r = \frac{2.3 \times 200 \times 24}{4 \times 3.14 \times 1400} \log \frac{2.25 \times 1400 \times 182}{1747^2 \times 0.025} = 0.55 \text{ m}$$

When the well field consists of seven wells as indicated in Figure 11.1, the aquifer loss of the center well can be calculated as $5.50 + 6 \times 0.55 = 8.8 \text{ m}$. Table 11.7 shows these aquifer losses for discharge rates and distances between the wells according to Table 11.1. With partially penetrating tubewells, the additional head loss according to Equation 11.11 should be added to these aquifer losses.

The second step is to determine the well losses from the results of the step-drawdown test. Based on the values of C and P in Equation 11.21, Equation 11.15 gives the following nonlinear loss component

$$s_3 = CQ^P = 1.3 \times 10^{-7} \times (200 \times 24)^2 = 3.00 \text{ m}$$

Table 11.7 shows the contribution of the nonlinear well losses to the total head losses as function of the discharge rate. Such calculations of the nonlinear well loss based on the results of a step-drawdown test can only be applied to wells with designs similar to that of the tested well. For wells with different designs, Huisman (1975) presented methods involving rather complicated calculations to estimate their expected well losses.

The third step is to assess the maximum depth to the water table; this information can be found from analyzing groundwater hydrographs showing the seasonal fluctuations of the water table throughout the years. Suppose that this maximum water table depth is 8 m below land surface. The required minimum length of the pump housing for the center well of the well field as shown in Figure 11.1 would be

TABLE 11.7 Various Components of the Total Head Loss Based on Data of Table 11.1 After Half a Year without Recharge

Pumping Rate (m^3/h)	Aquifer Loss Components (m)		Non-linear Well Loss (m)	Total Head Loss (m)
	Single Well	Well Interference		
100	2.75	2.22	0.75	5.72
200	5.50	3.30	3.00	11.80
300	8.24	3.96	6.74	18.94

$11.80 + 8.00 = 19.80$ m for a discharge rate of $200 \text{ m}^3/\text{h}$. Usually an additional length of several meters is added for safety. So, the total length of the pump housing can be taken as 23 m for this well.

When wells will be used for drainage purposes, the required design depth to the water table should be used instead of the maximum expected depth to the water table. In leaky aquifers, the difference in head between the free water table in the overlying aquitard and the piezometric head of the pump should then also be added; this head loss depends on the hydraulic resistance of the aquitard and the *drainable surplus*. Representative values of the former can be found from aquifer-test analyses, while values of the latter can be found from water-balance analyses.

11.5.3 Screen Section

Important properties of the screen are that it prevents sand and fine material from entering the well during pumping, has a large percentage of open area to minimize the head loss and entrance velocity, supports the wall of the well against collapse, and is resistant to chemical and physical corrosion by the pumped water.

Polyvinyl chloride (PVC) and fiberglass screens are lighter and more resistant to corrosion by chemically aggressive water, but have a lower collapse strength than steel screens and casings. In practice, PVC and fiberglass-reinforced screens and casings will be technically and economically attractive for wells in alluvial aquifers, where wells are placed at moderate depths of up to 400 m. Steel screens are required in deep wells drilled in hard rock aquifers. Stainless steel screens combine both strength and resistance to corrosion and chemically aggressive water, but are more expensive.

The selection of the screen slot size depends on the type of aquifer and the use of a gravel pack. The screen slot size must be selected so as to ensure that most of the finer materials in the formation around the borehole are transported to the screen and removed from the well by bailing and pumping during the well-development period immediately after the borehole has been constructed and the screen and casing have been installed.

In wells without an artificial gravel pack, well development creates a zone of graded formation materials extending about 0.5 m outward from the screen. Driscoll (1986) and Huisman (1975), among others, give detailed procedures for selecting the correct slot size. They report that with good quality water and the correct slot opening, 60% of the material will pass through the screen and 40% will be retained. With corrosive water the 50%-retained size should be chosen, as even a small enlargement of the slot openings due to corrosion could cause sand to be pumped.

The screen length should be chosen so as to ensure that the actual screen entrance velocity is in accordance with the prescribed entrance velocities as listed in Table 11.8. From these screen entrance velocities, the minimum length of the well screen can be calculated from

$$Q = 86400 v_e l_{\min} A_0 \quad (11.24)$$

where Q is the discharge rate of the well in m^3/d , v_e is the screen entrance velocity in m/sec , l_{\min} is the minimum screen length in meters, and A_0 is the effective open area per meter screen length in m^2/m . In determining the effective open area per meter screen length, it is often assumed that 50% of the actual open area is clogged by gravel particles (Huisman, 1975). The actual open area per meter screen length depends on the type and diameter of the selected screen type. Conventional slotted screens have open areas not exceeding 10% in order not to weaken the column strength, whereas more expensive continuous slot screens of stainless steel or modern PVC screens have an open area of 30 to 50%. So, the minimum total screen length is determined by the maximum screen entrance velocity and the actual screen type.

The optimum length of the screen may differ from its minimum length. Determining the optimum screen length is rather complex; it depends on (1) all the cost factors that determine the costs of pumping the required discharge or draining 1 ha; (2) the total thickness of the aquifer. In very thick aquifers, the deeper penetration of the well will result in a smaller drawdown that reduces the pumping costs but increases the investment costs in the borehole; and (3) the selected pumping rate.

Source: From U.S. Environmental Protection Agency, 1975. *Manual of Water Well Construction Practices*. EPA-570/9-75-001. Office of water supply, Washington, DC. 156 p. With permission.

The total length of the required screen section is found by adding to the actual screen length, as outlined above, the total length of sections of blind (imperforated) pipe used to case off unproductive layers in the aquifer. The total length of blind pipe depends on the distribution of hydraulic conductivity in the aquifer (i.e., the distribution of layers of higher and lower hydraulic conductivity). This stratification can be determined from the driller's log, geophysical log, and sieve analysis.

11.5.4 Calculation Example Well Screen

In this calculation example, the same data will be used as for the calculation of the length of the pump housing. The productive layers as delineated from the well logs had a total thickness of 56 m. The corresponding hydraulic conductivity of the aquifer is then 25 m/d. From Table 11.8, the screen entrance velocity should then not exceed 0.015 m/sec. For a well screen with an open area of 20% and a diameter of 0.25 m, the effective open area per meter screen length can be calculated as, bearing in mind a clogging percentage of 50%

$$A_0 = 3.14 \times 0.25 \times 0.5 \times 0.20 = 0.08 \text{ m}^2/\text{m}$$

Substituting the above values into Equation 11.24 for a pumping capacity of $200 \text{ m}^3/\text{h} = 4800 \text{ m}^3/\text{d}$ yields the following minimum screen length

$$l_{\min} = \frac{4800}{86400 \times 0.015 \times 0.08} = 47 \text{ m}$$

Table 11.9 shows how this minimum screen length varies for different screen diameters (0.15, 0.20, and 0.25 m), and for different types of screens: cheap well screens with an open area of 10%, medium-priced well screens with an open area of 20%, and expensive, modern, continuously slotted well screens with an open area of up to 40%. The total available thickness of the productive layers was 56 m, so according to Table 11.9, only the expensive well screens for all the listed diameters and the medium-priced well screen with a diameter of 0.25 m can be used for a well with a discharge rate of $200 \text{ m}^3/\text{h}$.

For this discharge rate ($=4800 \text{ m}^3/\text{d}$), the diameter of the production casing connecting the pump housing with the well screen, should be 0.25 m according to Table 11.6. As its diameter should be larger or equal to the diameter of the underlying screen section, the above selected well screens can all be applied.

TABLE 11.9 Minimum Screen Lengths for Different Types of Screens and Pump Discharges

11.5.5 Gravel Pack

The effect of gravel-packed wells is to ensure that the zone around the well screen is made more permeable by removing some formation material and replacing it with specially graded material. This relatively narrow zone separates the screen from the formation material and increases the effective hydraulic diameter of the well. A gravel pack is chosen to retain most of the formation material; a well screen opening is then selected to retain about 90% of the gravel pack after development. Gravel-pack material should ideally be clean, rounded, siliceous sands or gravels; carbonate material, shale particles, or soluble material such as gypsum should not exceed 5% of the total. Gravel-pack material should be well sorted to assure good porosity and hydraulic conductivity of these materials around the screen. The application of a gravel pack is recommended in the following formations:

1. Fine sandy alluvium and aeolian sand aquifers. In these formations, gravel packing should be considered so that larger slot openings can be used to increase the hydraulic efficiency of the well. In general, if a slot opening based on natural development is smaller than 0.25 mm, gravel packing may be more desirable as the screen's transmitting capacity may not be great enough to supply the desired yield.
2. Alternating formations of fine, medium, and coarse sediment. In these formations, it is often difficult to determine precisely the position and thickness of each individual layer and to design a multiple-slot screen corresponding to the stratification.
3. Poorly cemented sandstone aquifers. These formations may continuously lose fine material resulting in a sand-pumping well. Another reason for gravel packing a sandstone aquifer is that the formation material usually provides little or no lateral support for the screen.

The gravel pack is designed on the basis of sieve analyses of aquifer samples. If aquifer samples from different depths show considerable variation in gradation, the gravel-pack design should be based to be stable against the finer-grade samples. Numerous investigators and agencies have experimented to develop formulae or criteria that will result in a stable gravel-pack gradation. According to Anderson (1995), the following criteria have generally been found satisfactory in actual practice:

1. Aquifer material with a *uniformity coefficient* less than 2.5: Use uniform gravel-pack material with a uniformity coefficient less than 2.5 and with the D_{50} of the gravel pack 4 to 6 times the D_{50} of the aquifer (Figure 11.10). If uniform gravel pack is not available, use a gravel pack with uniformity coefficient between 2.5 and 5 and with the D_{50} of the gravel pack not more than 9 times the D_{50} of the aquifer.
2. Aquifer material with uniformity coefficient between 2.5 and 5: Use uniform gravel-pack material with uniformity coefficient less than 2.5 and with the D_{50} of the gravel pack not more than 9 times the D_{50} of the aquifer. If uniform gravel pack is not available, use a gravel pack with uniformity

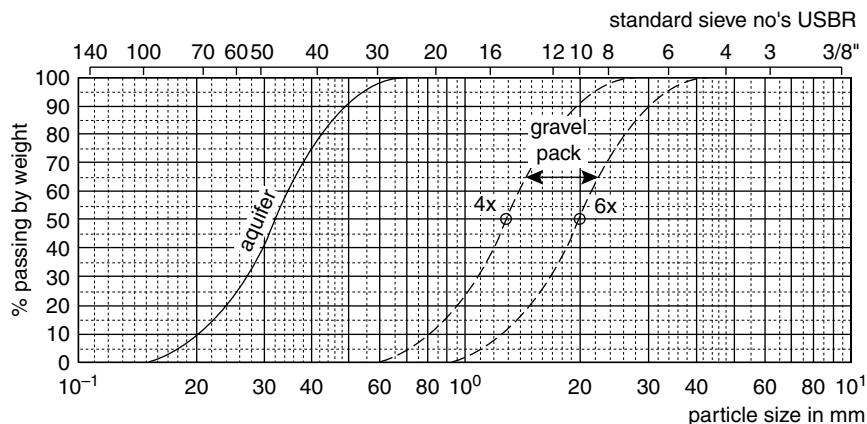

FIGURE 11.10 Aquifer and filter pack gradation.

coefficient between 2.5 and 5 and with the D_{50} of the gravel pack not more than 12 times the D_{50} of the aquifer.

3. Aquifer material with uniformity coefficient greater than 5: Multiply D_{30} of the aquifer by 6 and 9 and locate these points on the sieve analysis graph. Draw two parallel lines through these points having a uniformity coefficient of 2.5 or less, and specify gravel-pack material that will fall between these lines.

Although smaller thicknesses already fulfill the objective of a gravel pack, the thickness of a gravel pack should at least be 76 mm to ensure that a continuous layer of filter material will surround the entire screen. Under most conditions, the upper limit of gravel-pack thickness should be about 200 mm as the energy created by the development procedure must be able to penetrate the pack to repair the damage done by drilling, break down any residual drilling fluid on the borehole wall, and remove finer particles near the borehole.

11.5.6 Sand Trap

The sand trap is the section of blind pipe at the bottom of the screen section. Its function is to store sand and silt entering the well during pumping; this will occur even if the well has been properly developed. The length of the sand trap is usually of the order of a few meters (2–6 m). The diameter of the sand trap is usually the same as that of the screen section.

11.5.7 Pump

Centrifugal pumps are by far the most important class of pumps. Originally designed as a pump to be located at or near land surface for suction lift or booster service, it soon was adapted to installation under water in wells, first by long shafts extensions in large caissons (vertical turbine), and later in compact form as the familiar deep-well (submersible) turbine pump. A typical line-shaft pumping unit comprises a driver (power unit), discharge head, column (discharge) pipe and shaft, and one or more stages of *impellers* in a bowl assembly. The driver is commonly a vertical hollow-shaft electric motor, while the shaft is centered in the column pipe. A typical submersible pumping unit comprises a submersible electric motor directly coupled to the bowl assembly and a column (discharge) pipe.

The major factors determining the selection of a pump are the required discharge rate, the required head to be delivered by the pump, and the pump efficiency; the total dynamic head is made up of (1) the water-level depth inside the pumped well, as discussed earlier in this section; (2) the above ground lift; and (3) head losses due to friction and turbulence in the discharge pipelines. The required brake horsepower

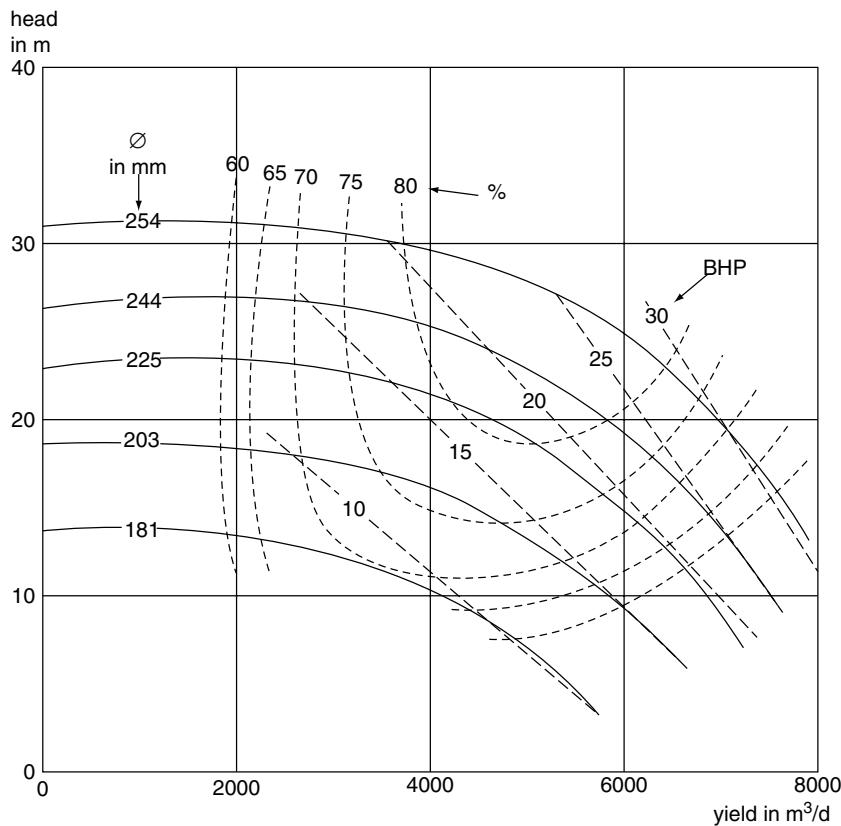

FIGURE 11.11 Representative performance curve for a vertical turbine pump operating at 1800 rpm.

at the pump shaft is defined as

$$P_s = \frac{\rho g Q H}{\eta} \quad (11.25)$$

where P_s is the power to be delivered to the shaft of the pump in Watts, Q is the pump discharge in m^3/sec , H is the total dynamic head delivered by the pump in meters, ρ is the density of water in kg/m^3 , g is the acceleration due to gravity in m/sec^2 , and η is the dimensionless pump efficiency.

Most pump manufacturers provide performance curves for each individual impeller design and for various rotation speeds. Generally, these curves are drawn for a single stage (pumping unit). These curves typically include (1) a head-capacity curve relating the total dynamic head to the discharge rate, (2) a curve relating efficiency to discharge rate, and (3) a curve relating brake horsepower requirement to discharge rate. From the performance curves, a particular impeller is chosen that can provide the desired yield for the total dynamic head at reasonable efficiency. The performance curve shown in Figure 11.11 indicates that a single-stage turbine pump with a 254 mm impeller operates at a peak efficiency of about 80% within a total head of 23 to 30 m and delivers from 6400 to 3700 m^3/d , respectively. If the required head fluctuates within this range, the pump operates efficiently and the power required varies by 7 brake horsepower.

In selecting a turbine pump, it is usually desirable to pick an impeller type that has a steep rather than flat head-capacity curve. This is particularly if the pumping lift will change significantly during the seasons of the year, or if the pumping lift is expected to increase over future years. With a steep curve, a moderate increase in pumping lift will not result in a large decrease in the discharge rate, whereas with a flat curve, even a slight increase in pumping lift can reduce the discharge by 50% or more. With steep head-capacity

curves, the peak efficiency might be lower, but the average pumping conditions would occur at a higher efficiency.

11.5.8 Design Optimization

The design of a well is rather straightforward when the water transmitting properties of the aquifer system are limited with respect to the required discharge rate. The well will be drilled to the bottom of the aquifer and all the productive layers of the aquifer will be screened using screens with the largest possible slots and open area. When the required pumping capacity is not restricted by the water transmitting properties of the aquifer system, that is, with highly productive, thick aquifers, and modest pumping requirements, the design becomes more complex, especially when well fields are considered as is usually the situation with wells for irrigation and drainage purposes. Some of the optimizing options are then:

1. If larger pumps are installed, fewer pumps will be required, which generally results in lower investment costs; on the other hand, larger capacity pumps may result in considerably higher drawdowns and thus higher energy costs.
2. Water can be brought to the land surface by a well with a short screen or a long screen. A short screen involves low investment costs and high energy costs because of greater drawdowns in the wells, while a long screen entails relatively higher investment costs but lower energy costs.

The optimization procedure involves examining the different well configurations that satisfy the design criteria, and, for each of these, calculating the investment costs and the annual costs of operation and maintenance. The present value of these costs is determined by applying an annual rate for discounting costs and an interest rate. The configuration that yields the lowest present value is then selected. Boehmer and Boonstra (1994) provides a checklist on how the investment costs can be calculated for a well with a pre-fixed pumping capacity and located in a given well-field layout.

With increasing screen lengths, investment costs rise but the drawdown and the pumping costs fall. The cost per cubic meter of water first decreases, owing to the decreasing head losses caused by the decreasing partial penetration of the aquifer, and leads to lower pumping costs. Having reached a minimum, the price of water rises, as the decreasing energy costs in the borehole no longer compensate for the higher investment costs. The calculations are repeated for different screen diameters, screen types, pump engine, and types of energy. Figure 11.12 shows the relation between the cost of water, investment and reinvestment costs, energy costs, and operation and maintenance costs.

Finally, the design with the lowest costs per cubic meter drainage water is selected. Obviously, the more types of screens, engines, pumps, and energy available, the better the results of the optimization procedure will be. The number of calculations required to arrive at a final result is large and complex and can best be handled by an optimum well-field-design computer program as advised by Boehmer and Boonstra (1994).

11.5.9 Groundwater Remediation Wells

As mentioned above, well designs can be optimized for the cost of a single well, but also for a well field. In a well field, it is important to realize that over-designed wells will negatively affect other wells in the surroundings. Optimization can then be obtained on economics. However, if the objective is not only economics, the optimization will not necessarily result in the cheapest option.

In the past decades, attention has been shifting from water resources development to water resources management. This includes an increased interest in maintaining or improving groundwater quality. At some locations, especially where groundwater pollution is decreasing groundwater resources for drinking water, remediation wells are installed. The objective of these wells is to either intercept pollution plumes before they reach the drinking water wells, or, when installed near the source of the pollution, even to reverse the hydraulic gradients, so that pollution is prevented from further spreading, and returns to the

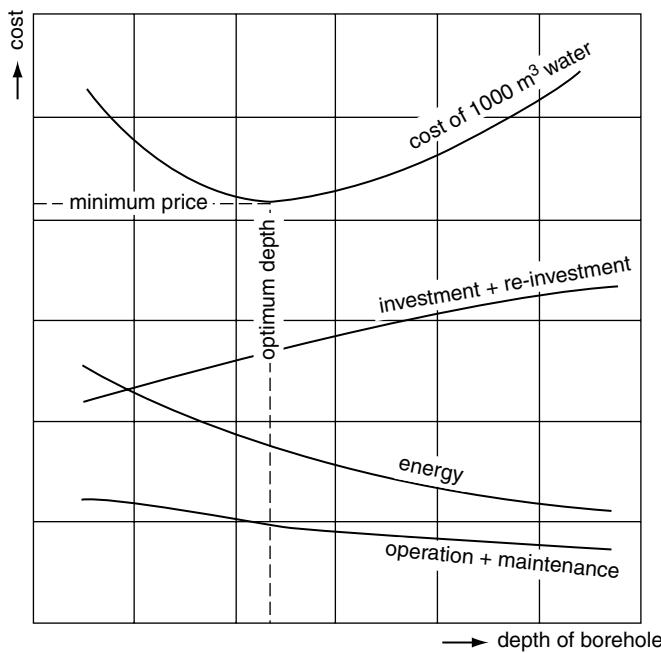

FIGURE 11.12 Costs of 1000 m^3 water as a function of borehole depth.

point of origin. A well field designed for this situation will preferably be designed to have sufficient overlap in the sphere of influence to protect human health.

Many design and construction parameters that are used for water development wells are also applicable to the remediation wells. Screening depth and length should be designed to intercept the maximum amount of pollution at the lowest possible costs. The well field should be designed to have maximum coverage over the pollution plume. Pump capacity should be selected in combination with the water treatment plant on the surface, to prevent higher flow rates than the capacity of the treatment plant. One special point of attention is that the gravel pack around the well is sealed at the bottom and the top of the screen. Especially in a multi-layer aquifer system, it is of major importance to prevent pollution to spread to other systems through the well.

Another special point of importance is the heterogeneity of the aquifer system. Although with current methods it is impossible to describe the heterogeneity accurately, it is possible to obtain a statistical likeliness of the geology (Carle and Fogg, 1996). Especially in groundwater remediation this is important, as small clusters of clay in a sandy aquifer could have a long retention time of pollutants.

11.5.10 Monitoring Wells

Another well type that is important in the management of groundwater is the monitoring well. Groundwater monitoring, preferably by the groundwater users themselves, may result in local groundwater management without the need of intervention from governing bodies (Steenbergen, 2003). Groundwater monitoring may be done using existing wells, which gives a good impression of the effects of groundwater pumping. However, if more detailed information is needed on either vertical or horizontal groundwater flows, additional monitoring wells could be installed.

Nested piezometers are often used to determine the vertical gradients in an aquifer system. Nested piezometers are a set of observation wells with varying depth, usually 3–4. As they are designed to measure the pressure at a defined depth in the aquifer system, it is important to design the well, and especially the screen depth. The screens should be installed at locations where a gradient could be expected, for example,

just above an aquitard, and just below. During the construction of the observation wells, the sealing is, like in the remediation wells, very important. As gradients in the aquifer system are expected (otherwise there would be no need to install nested piezometers), one should prevent the piezometers from being conduits for flow between different aquifers.

The spatial design of a well-monitoring field should also be based on the expected outcomes. When low regional lateral groundwater flow is expected, observation wells can be installed at large distances from each other. The area covered by monitoring wells should preferably be surrounded by obvious hydrological boundaries for the groundwater system, like rivers, large irrigation canals, or mountain ranges. Observation wells usually have a small diameter; it is advisable, however, to allow for a sufficient size so that portable submersible pumps can be lowered into the well. Observation wells can then also be used for groundwater sampling. Note that for groundwater sampling it is important to develop an observation well similar to a production well. Well development is described in the next paragraph.

11.6 Well Construction and Maintenance

Various well drilling methods have been developed as geologic conditions range from hard rock such as granite and dolomite to completely unconsolidated sediments such as alluvial sand and gravel. Particular drilling methods have become dominant in certain areas as they are the most effective in penetrating the local aquifers and thus offer cost advantages. In many cases, however, the drilling contractor may vary the usual drilling procedure depending on the depth and diameter of the well, type of formation to be penetrated, sanitation requirements, and principal use of the well. It is obvious, then, that no single drilling method is best for all geologic conditions and well installations. In most cases, the drilling contractor is best qualified to select the particular drilling procedure for a given set of construction parameters. Successful drilling is both an art developed from long experience and the application of good engineering practices.

Well construction usually comprises four of five distinct operations: drilling, installing the casing, placing a well screen and filter pack, if required, grouting to provide sanitary protection, and developing the well to insure sand-free operation at maximum yield. Well drilling and installation methods are so numerous that only some of the basic principles and their applications can be described in this section. More detailed information on well construction methods can be found in reference books such as those of Driscoll (1986) and Huisman (1975).

11.6.1 Construction Methods

In the various construction methods, a distinction can be made between shallow and deep wells. Shallow wells, generally less than 15 m in depth, are constructed by boring, driving, or jetting. These methods are now briefly described and their applications are given in Table 11.10. Bored wells are constructed with hand-operated or power-driven augers. The drive shaft is built up from rods; its upper part, the so-called kelly, has a square cross-section to receive the necessary torque from a rotary table. At the bottom, the auger is provided with a cutting face; for emptying the auger, the drive shaft should be dismantled and reassembled afterwards. A continuous-flight power auger has a spiral extending from the bottom of the hole to the surface. Cuttings are carried to the surface as on a screw conveyor, while sections of the auger may be added as depth increases. Driven wells are constructed by driving a pointed screen with attached pipe directly into the waterbearing formation. Water enters the well through a drive point at the lower end of the well. This consists of a screened cylindrical section protected during driving by a steel cone at the bottom. Driving can be done with a sledge, drop hammer, or air hammer. As driving proceeds and the well point sinks into the ground, succeeding sections of pipe are screwed on top of the screen. Jetted wells are constructed by the cutting action of a downward-directed stream of water. The high-velocity stream washes the earth away, while the casing, which is lowered into the deepening hole, conducts the water and

cuttings up and out of the well. The soil material is subsequently removed in a settling basin after which the water is picked up again by the jetting pump.

Most deep, high-capacity wells are constructed by cable-tool percussion drilling or by one of the several rotary methods. These methods are now briefly described and their applications are given in Table 11.10. Cable-tool drilling machines, also called percussion rigs, operate by repeatedly lifting and dropping a heavy string of drilling tools into the borehole. The drill bit breaks or crushes consolidated rock into small fragments, whereas the bit primarily loosens the material when drilling in unconsolidated formations. In both instances, the reciprocating action of the tools mixes the crushed or loosened particles with water to form a slurry at the bottom of the borehole. If little or no water is present in the penetrated formations, water is added to form a slurry. Slurry accumulation increases as drilling proceeds and eventually it reduces the impact of the tools. When the penetration rate becomes unacceptable, slurry is removed at intervals from the borehole by a sand pump or bailer. In water well drilling, the depth capability for cable rigs ranges from 100 to 1500 m.

The direct rotary drilling method was developed to increase drilling speeds and to reach greater depth in most formations. The borehole is drilled by rotating a bit, and cuttings are removed by continuous circulation of a drilling fluid as the bit penetrates the formation. The bit is attached to the lower end of a string of drill pipe, which transmit the rotating action from the rig to the bit (Figure 11.13). In the direct rotary system, drilling fluid is pumped down through the drill pipe and out through the ports or jets in the bit; the fluid then flows upward in the annular space between the hole and drill pipe, carrying the cuttings in suspension to the surface. The fluid is cleaned in a settling pit before it is recirculated; drilling fluids include air, clean water, and scientifically prepared mixtures of special-purpose materials.

In direct rotary drilling, the viscosity and uphole velocity of the drilling fluids are the controlling factors in removing cuttings effectively. Because of limitations in pump capacity and therefore effective cuttings removals, most direct rotary machines used to drill water wells are limited to boreholes with a maximum diameter of around 600 mm. This size may not be sufficient for high-capacity wells, especially those that are to be filter packed. Also, as hole-diameters increase past 600 mm, the rate of penetration by direct rotary machines becomes less satisfactory. To overcome the limitation on hole-diameter and drilling rate, reverse circulation machines were designed. The design of a reverse circulation rig is essentially the same as that of the direct rotary rig except most pieces of equipment are larger. For unconsolidated formations, the reverse circulation rig is probably the most rapid drilling equipment available. It requires a large volume of readily available water.

Rotary drillings can also be accomplished with compressed air instead of drilling mud. The technique is rapid and convenient for small-diameter holes in consolidated formations where a clay lining is unnecessary to support the wall against caving in. An important advantage of the air rotary method is its ability to drill through fissured rocks with little or no water.

TABLE 11.10 Well Construction Methods and Applications

Method	Materials	Depth (m)	Diameter (cm)	Yield (m^3/d)
Bored	unconsolidated	10–25	5–90	15–500
Driven	silt, sand	15	3–10	15–200
Jetted	silt, sand	15	4–8	15–150
Percussion	all	450	8–60	15–15,000
Direct rotary	all	450	8–45	15–15,000
Reverse rotary	unconsolidated	60	40–120	2500–20,000
Air rotary	consolidated	250	15–45	2500–15,000

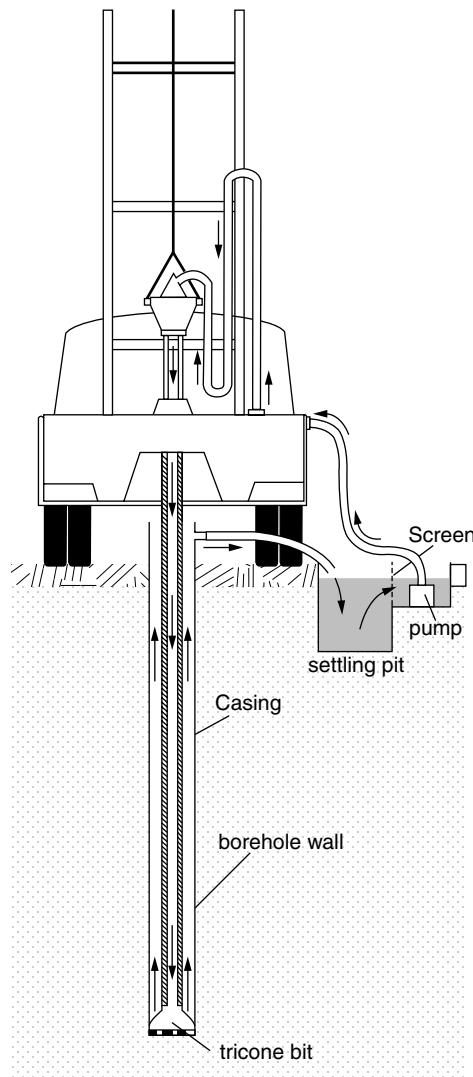

FIGURE 11.13 Schematic diagram of a direct rotary circulation system.

Finally, it should be noted that the depth, diameter, and yield of wells as presented in Table 11.10, are only indications of the order of magnitude of what can be expected. In reality, larger diameters and depth may be obtained, whereas the yield is primarily depending on the actual geology and availability of groundwater.

11.6.2 Well Development

The principal purpose of well development is to remove the fine materials adjacent to the well bore, to increase porosity and hydraulic conductivity of the aquifer and gravel pack, to remove any mud cake or compacted zone as a result from the actual drilling, and to minimize or eliminate sand pumping.

Upon completion of drilling, most wells require development to reach maximum efficiency. This is particularly true of wells producing from unconsolidated aquifer materials and those in which an artificial gravel pack has been placed around the well screens. In addition, many wells may require periodic redevelopment to restore production capacity that has been lost as a result of such factors as encrustation

of screens, clogging of screens by bacterial deposits, or migration of fine particles into a gravel pack. The following discussion summarizes some developments and procedures.

The simplest method of removing finer material from water-bearing formations is by overpumping, that is, pumping at a higher rate than the well will be pumped during exploitation. Overpumping, by itself, seldom produces an efficient well as most of the development action takes place in the most permeable zones closest to the top of the screen. The same applies to a certain extent to surging/backwashing. It consists of pumping a well at a high rate for a short period, shutting down the pump to allow water in the column to fall and backwash the screen, and then repeating the process until the discharge is clear. Although overpumping and backwashing techniques are widely used, and in certain situations may produce reasonable results, their overall effectiveness in high-capacity wells is rather limited when compared with other development methods.

Another method of development is to force water to flow into and out of the screen by operating a plunger up and down the casing, similar to a piston in a cylinder. The tool normally used is called a surge block. The block is usually made of discs of belting bolted between steel plates, or of wood. The outside diameter of the block should be only slightly less than the inside diameter of the screen. Before development, the well should be bailed to make sure that water will flow into it. Surging should start above the screen and move progressively downward to reduce the possibility of sand locking the surge block. The initial motion should be relatively gentle with long strokes and at a slow rate. After surging above the screen, the hole should be cleaned and surging starts at the lower end of the screen, gradually working upward until the entire screen has been developed. The process is then repeated with a faster stroke until little or no sand can be pulled into the well. Surging procedures produce good results for screen installations in zones having good porosity and hydraulic conductivity.

Many drillers use compressed air to develop wells in consolidated and unconsolidated formations. The practice of alternatively surging and pumping with air became feasible with the great number of rotary drilling rigs equipped with large air compressors. In air surging, air is injected into the well to lift the water to the surface. As it reaches the top of the casing, the air supply is shut off, allowing the aerated water column to fall. The effectiveness is often enhanced, particularly with long screens, by using a double-packer tool that confines the pumping to a short length of the screen. Equipment can also be designed to provide a stronger backwash effect in addition to the pumping. As with surge blocks the well should be periodically cleaned.

High-velocity jetting is a very effective way to develop sand and gravel aquifers and artificial gravel packs. In practice, jetting with water is almost always accompanied by simultaneous air-lift pumping so that clogging of the formation does not occur (Figure 11.14). A jetting tool is lowered on a drop pipe and water pumped down at high pressure to produce nozzle velocities of 30 m/sec or more, with a minimum desirable velocity of about 45 m/sec. Driscoll (1986) provides data for nozzles of several sizes at different operating pressures. The tool should have two to four nozzles, spaced equally around the circumference and directed horizontally toward the inside of the well screen. The nozzles should extend to within 25 mm from the inside of the screen. In operation, the jetting tool is lowered into the lower part of the screen, rotated slowly, and raised slowly throughout the length to be developed. The process is then repeated until development is complete.

Various acids and chemicals can be very effective in well development under certain conditions, both upon completion of drilling and for maintenance. Acid and chemicals can be used alone, or in combination with other methods such as surge blocks or water jetting. Acids can be very effective in limestone and dolomite aquifers by enlarging fractures adjacent to the well bore and thereby significantly reducing drawdown at a given pumping rate. Acids can also be effective in removing encrusting deposits on well screens (see section on maintenance). Acids frequently used in well development and rehabilitation are hydrochloric acid and sulfamic acids. The usual procedure is to introduce a volume of acid several times that of the section of screen to be treated, followed by frequent agitation, and then removed by pumping after 6 to 8 h. Chemicals frequently used in well development are polyphosphates and surfactants (wetting agents). The polyphosphates act to deflocculate and disperse clays and drilling muds. They are typically introduced as a solution of from 0.5 to 1.5 kg polyphosphate in 100 l of water in conjunction with surge

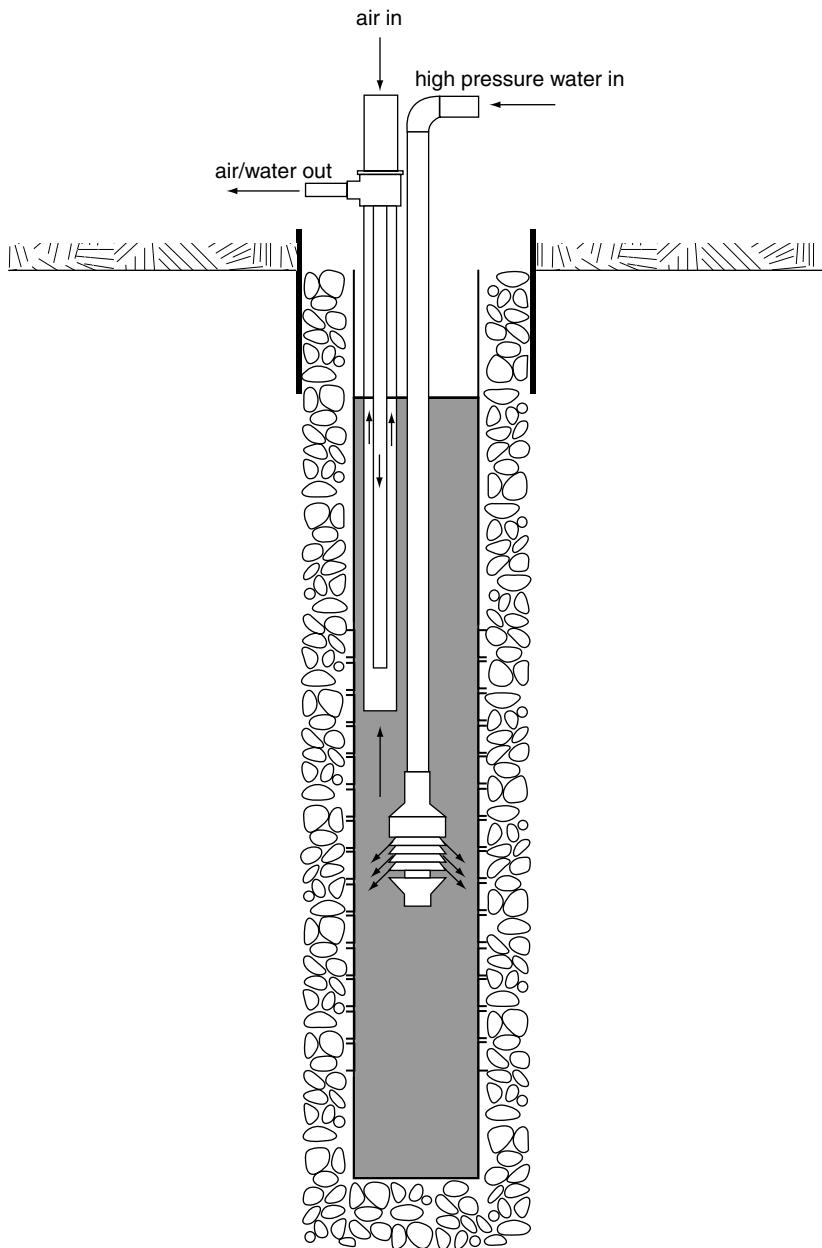

FIGURE 11.14 Schematic diagram of high-velocity jetting with air-lift pumping system.

block or water jetting development. The addition of wetting agents aids in allowing the polyphosphates to penetrate clays.

11.6.3 Maintenance

The performance of a well usually declines after some years of operation, resulting in higher drawdowns and higher pumping costs. The well is in need of rehabilitation when the specific capacity of the well becomes so small that the pumping costs increase or the discharge rate of the well can no longer be

maintained. Before that time, the well needs to be rehabilitated. An effective well-maintenance program begins with good records being kept of the well's construction, including good records of the geological conditions, the position and types of aquifers and aquiclude, water quality, and the specific capacity of the well, determined during well testing.

Every type of well requires its own maintenance program. To evaluate the performance of a well, Driscoll (1986) provides a checklist. A significant decrease in specific capacity or an increase in the pumping of sand indicates that the well needs rehabilitation or restoration to its original performance. In general, rehabilitation measures are most successful when the well performance has not deteriorated too badly, or the specific capacity has not decreased too much. If the specific capacity of the well has declined by 25% of its original value, it is time to carry out a rehabilitation program. To determine the right moment for well rehabilitation, periodic monitoring of well performance should be done in term of short standard tests. Complete well records can be kept at relatively minor expense, and these are indispensable in determining the causes of well failure and selecting the maintenance and rehabilitation program.

The major causes of a reduction in well performance are: (1) a reduced well yield due to chemical encrustation or clogging of the screen due to bacteriological activity; (2) plugging of the formation around the well screen by fine particles of clay and sand in the pores; (3) pumping of sand due to poor well design or corrosion of the well screen; and (4) collapse of the well screen due to chemical or electrolyte corrosion of metal well screens.

Chemical and biological encrustations are major causes of well failure. Water quality and flow velocity through the screen openings determine the occurrence of encrustation. Chemical encrustation is caused by the precipitation of carbonates, mainly calcium carbonate, or iron hydroxides, which block the screen openings. Carbonate precipitation is caused by the release of carbon dioxide from the water owing to a pressure decline in the water caused by the drawdown in the well. Iron dissolved in groundwater may precipitate from the water on the well screen as oxygen is introduced into the water when the well is pumped. Another reason for the precipitation of iron may be the presence of iron bacteria in the water. Chemical encrustation can best be removed by treating the well with a strong acid solution that chemically dissolves the encrusting materials so that they can be removed from the well by pumping. Hydrochloric acid and sulphuric acid can be used. Chlorine, a strong oxidizing agent, inhibits the growth of iron bacteria. The use of hypochlorite is a relatively safe and convenient alternative to chlorine gas. The occurrence of iron bacteria in wells can be prevented by disinfecting the well and the pump immediately after installation.

Physical plugging by clay and silt particles can best be prevented by proper well development after the well screen has been installed. The removal of fine particles from the formation immediately around the screen can best be achieved by washing and brushing the screen with dispersing compounds such as sodium tripolyphosphate and other types of polyphosphates.

Sand pumping causes the abrasion of pump bowls that leads to the failure of the pump. Sand pumping results from over-sized slots in screens, over-sized gravel pack, corrosion of the well screen, inadequate development of the well, or too high entrance velocities, causing the transport of sand from the formation toward the well. One of the above conditions, or a combination of them, results in sand from the formation entering the well. Remedy this problem may be uneconomic: it may be better to drill a new well. The best alternative, if possible, is to replace the screen or to place an inner screen inside the original well screen.

Corrosion of well screens can severely reduce the lifetime of a well. Chemical corrosion occurs especially when metal well screens are used in aggressive and saline water loaded with gasses like hydrogen sulphide, carbon dioxide, and oxygen. Corrosion can be prevented by applying nonmetal screens, or, when the water is not aggressive, only metal screens of stainless steel and low-carbon steel.

Finally, to pump water from a well in the most economic way, proper maintenance of pumps and engines is a prerequisite. Pump and engine manufacturers prescribe periodical maintenance of their products. Maintenance procedures depend on the pump type. They include the adjustment and replacement of impellers, bearings, stuffing boxes, and bowl assemblies. A complete analysis of pump and engine maintenance is beyond the scope of this chapter, so readers are referred to the maintenance procedures specified by manufacturers.

Glossary

- Drainable surplus:** the quantity of water that flows into a groundwater reservoir in excess of the quantity that flows out under natural conditions.
- Impeller:** devices that accelerate the water within the pump to build pressure.
- Specific capacity:** the yield of a well per unit drawdown, usually expressed as cubic meters per day per meter drawdown. It is a measure for the productivity of a well.
- Uniformity coefficient:** ratio of the 40% retained particle size of the sediment and the 90% retained size. The lower its value, the more uniform is the grading between these limits.

The objective of this chapter is to present the problem of sea water intrusion into a coastal aquifer, together with the conceptual and complete mathematical models that describe it. Examples are presented of how some typical sea water intrusion cases that are described by the models are solved by the computer code FEAS. A brief discussion is presented on the management of a coastal aquifer.

12.1 Introduction

Coastal aquifers constitute important sources of fresh water in many parts of the world, especially in arid and semiarid zones. Often, coastal areas are also heavily urbanized, a fact that makes the need for fresh water in such areas even more acute. However, the proximity and contact with the sea require special attention when planning the management of such aquifers. In fact, in many coastal aquifers, the intrusion of sea water has become one of the major constraints on groundwater management. As sea water intrusion progresses, the part of the aquifer close to the sea becomes saline, and pumping wells close to the coast start pumping saline water and have to be abandoned. Also, the area above the intruding sea water wedge is, usually, lost as a source of fresh water (by natural replenishment).

Since the famous works of Badon-Ghyben (1888) and Herzberg (1901), and the less known work of Du Commun (1828) (Konikow and Reilly, 1999), extensive research has been carried out, leading to the understanding of the mechanisms that govern sea water intrusion. The dominant factors are (1) the flow regime in the aquifer above the intruding sea water wedge, (2) the variable density, and (3) hydrodynamic

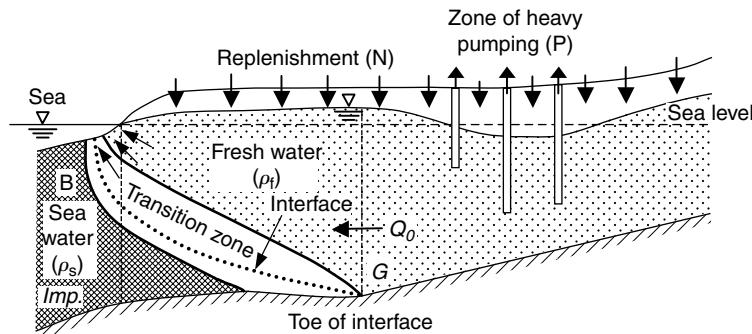

FIGURE 12.1 A typical cross section of sea water intrusion in a coastal aquifer. (After Bear, 1979, *Hydraulics of Groundwater*. McGraw-Hill, New York, p. 569. With permission.)

dispersion. Reviews of the phenomenon of sea water intrusion, and of the research that has been carried out on this subject, both theoretical work and field and laboratory investigations, may be found in many books and publications, and will not be repeated here (e.g., Bear, 1972, 1979; Reilly and Goodman, 1985; Bear and Verruijt, 1987; Bear et al., 1999; Cheng and Ouazar, 2004).

Briefly, under normal conditions in a coastal aquifer, excess fresh water (i.e., natural and artificial recharge minus pumping) is discharged into the sea. This means that close to the coast, a seaward hydraulic gradient exists in the aquifer. Due to the presence of sea water in the aquifer under the sea, a zone of contact is formed between the lighter fresh water flowing towards the sea, and the heavier sea water in the aquifer. A typical cross section, with natural replenishment, pumping, and a transition zone, is shown in Figure 12.1. The detailed shape of the transition zone, from fresh water to sea water, depends also on whether this zone is advancing inland or retreating. In all cases, the domain in the aquifer that is occupied by sea water has, usually, the form of an advancing or receding wedge. One should note that, like all figures that describe aquifers, these are also highly distorted figures, not drawn to scale.

Sea water and fresh water are often referred to as “miscible liquids,” although, actually, both constitute a *single* liquid phase — water, H_2O — with different concentrations of *total dissolved matter* (salt, TDM). For the sake of simplicity, we shall continue to refer to them as two liquids — fresh water and sea water. Hence, the passage from the portion of the aquifer that is occupied by the former to that occupied by the latter takes the form of a *transition zone*, rather than a *sharp interface*. Under certain circumstances, depending on the extent of sea water intrusion and on certain aquifer properties, this transition zone, which is primarily a result of *hydrodynamic dispersion* of the dissolved matter, may be rather wide. Under other conditions, it may be rather narrow, relative to the aquifer’s thickness, and the passage from the zone occupied by fresh water to that occupied by sea water may be *approximated* as a *sharp interface*. Often, the term “interface” is used for the iso-density surface that is midway between fresh water and sea water. In this article, the term “interface” will, sometimes, be used interchangeably with “transition zone.”

Under natural undisturbed conditions in a coastal aquifer, a state of equilibrium is maintained, with a steady-state sea water zone and a zone of flowing fresh water above it. The transition zone is also fed from below by sea water (Figure 12.1). When the discharge to the sea is reduced as a result of pumping fresh water from a coastal aquifer, water levels (or the piezometric heads in a confined aquifer) close to the sea are lowered and the transition zone rises. The sea water wedge and the transition zone advance landward, until a new equilibrium is reached. Wells that operate within the sea water wedge and the transition zone pump saline water and have to be abandoned. When pumping takes place in a well located above the transition zone, the latter *upcones* towards the well. Unless the well is at a sufficient distance above this zone and the rate of pumping is sufficiently small, the well will eventually pump saline water.

We should emphasize here that the geological structure and configuration of a coastal aquifer are usually much more complex than the schematic one shown in Figure 12.1. Often, especially close to the sea, the coastal aquifer is divided into a number of sub-aquifers by impervious or semi-pervious layers,

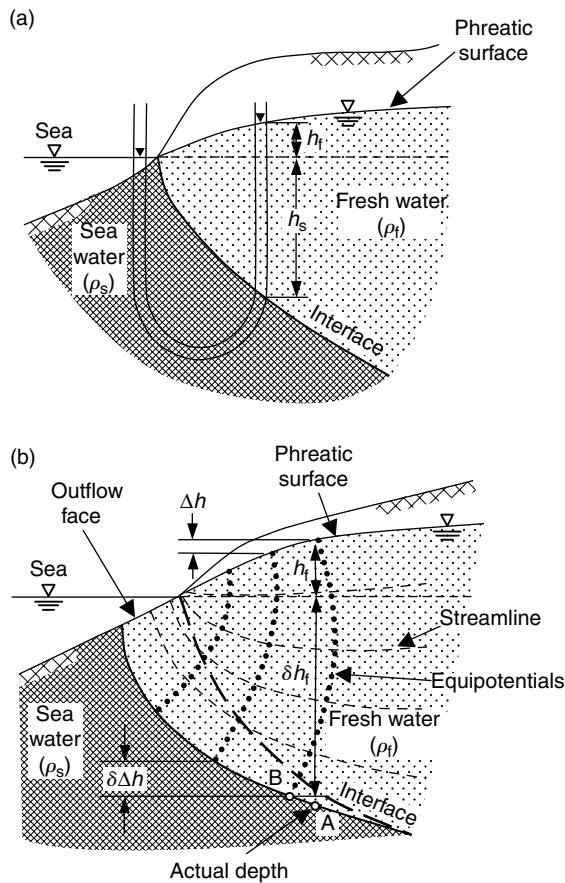

FIGURE 12.2 (a) The Ghyben–Herzberg approximation, and (b) the actual sharp interface.

with leakage taking place through the latter. The flow in such multilayered aquifers and the shape of the transition zone(s) are often much more complex than shown in Figure 12.1. An example of sea water intrusion in a multilayered coastal aquifer is demonstrated in Section 12.4.

As emphasized so far, a transition zone always exists between fresh water and sea water. Moreover, nowadays, we also have enough tools to handle three-dimensional (3D) transition zone models. Nevertheless, it is useful to use the “sharp interface approximation” of this zone to discuss certain basic features of sea water intrusion. Here, we shall present the concept of a sharp interface to introduce the relationship between seaward flow of fresh water and the extent of sea water intrusion. We shall do so by a simple steady-state analysis.

We start by introducing the famous Ghyben–Herzberg rule that describes the relationship between the fresh water flow to the sea and the extent of sea water intrusion, say, as expressed in terms of the length of the sea water wedge. Figure 12.2a shows a vertical cross section normal to the coast, with a sharp interface separating the two fluids as envisaged by the *Ghyben–Herzberg assumption*. Essentially, Ghyben and Herzberg assumed that under steady-state conditions, a static equilibrium exists, with stationary sea water and a hydrostatic pressure distribution in the seaward-flowing fresh water. This means that the flow is (essentially) horizontal and the equipotentials (i.e., surfaces of equal piezometric head) are vertical. This, in fact, is identical to the Dupuit assumption of essentially horizontal flow in aquifers. With the notation of Figure 12.2a, we have

$$h_s = \delta h_f \quad (12.1)$$

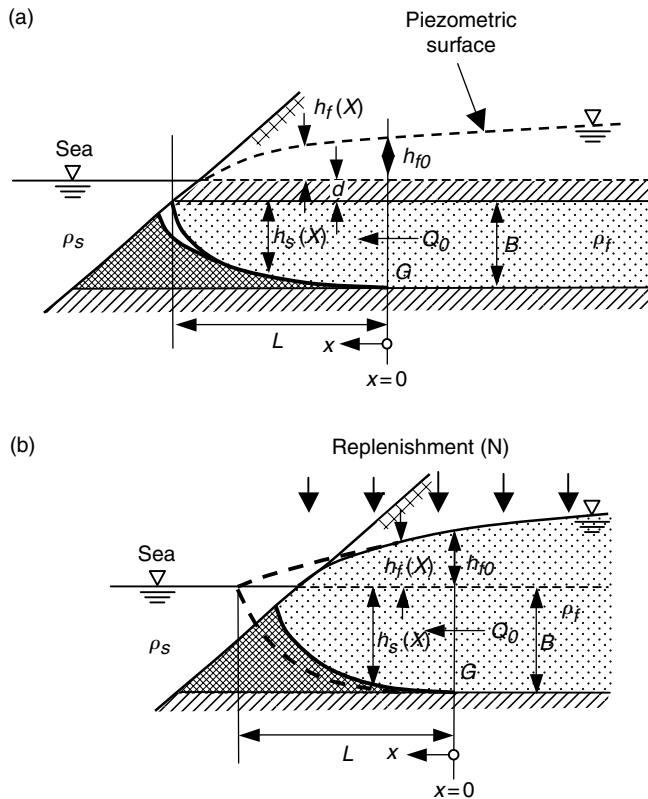

FIGURE 12.3 The interface (a) in a confined, and (b) in a phreatic coastal aquifer.

where

$$h_f = z + \frac{p}{\rho_f g}, \quad h_s = z + \frac{p}{\rho_s g}, \quad \delta = \frac{\rho_f}{\rho_s - \rho_f} \quad (12.2)$$

in which p is the pressure, h_f and h_s denote the fresh water and sea water piezometric heads, in the fresh water zone and in the sea water wedge, respectively; ρ_f and ρ_s denote the respective densities, assumed constant, z denotes the vertical coordinate (positive upward), and g denotes gravity acceleration. Note the discrepancy from the Ghysen–Herzberg interface shape as the interface approaches the coast. The discrepancy stems from the difference between the actual shape of the equipotentials and the vertical ones assumed by the Dupuit approximation. In a confined aquifer, h_s in Equation 12.1, is the depth of a point on the interface below sea level, while h_f is the fresh water piezometric head.

We now consider the simple case of essentially horizontal steady flow normal to the coast in a confined aquifer with the stationary interface shown in Figure 12.3a. For this case, the fresh water flow equation, a combination of the steady-state mass balance equation and the flux equation, is written:

$$\frac{\partial Q_f}{\partial x} \equiv \frac{\partial}{\partial x} \left(-K_f h_s \frac{\partial h_f}{\partial x} \right) = 0 \quad (12.3)$$

where Q_f is the discharge rate of fresh water to the sea, per unit length of coast, K_f is the hydraulic conductivity in fresh water ($=(\rho_f g k / \mu_f)$) k is the permeability and μ_f is the fresh water dynamic viscosity).

With the relationship between h_f and h_s :

$$h_s + d = \delta h_f \quad (12.4)$$

and the boundary conditions:

$$Q_f \equiv Q_0, \quad h_f = h_{f0}, \quad \text{and} \quad h_s = B, \quad \text{at } x = 0 \quad (12.5a)$$

$$h_s = 0, \quad \text{at } x = L \quad (12.5b)$$

we have the solution:

$$Q_0 x = \frac{K_f (B^2 - h_s^2)}{2\delta}, \quad Q_0 L = \frac{K_f B^2}{2\delta} \quad (12.6)$$

Equation 12.6, which describes a *parabola*, clearly shows the relationship between the length of sea water intrusion, L , and the discharge to the sea, Q_0 (as well as the piezometric head, h_{f0} , above the toe of the interface (G)).

For the phreatic aquifer shown in Figure 12.3b, the flow equation, under the same conditions, takes the form:

$$-\frac{\partial Q_f}{\partial x} + N = 0, \quad Q_f = -K_f(h_f + h_s) \frac{\partial h_f}{\partial x} \quad (12.7)$$

where N is the replenishment. With Equation 12.1 and the following boundary conditions:

$$Q_f = Q_0, \quad h_f = h_{f0}, \quad h_s = h_{s0} = \delta h_{f0}, \quad \text{at } x = 0 \quad (12.8a)$$

$$h_s = h_f = 0, \quad \text{at } x = L \quad (12.8b)$$

we have the solution:

$$h_{f0}^2 - h_f^2 = \frac{2Q_0 x + Nx^2}{K_f(1+\delta)} \quad (12.9a)$$

$$h_{f0}^2 = \frac{2Q_0 L + NL^2}{K_f(1+\delta)} \quad (12.9b)$$

$$Q_0 = \frac{K_f B^2}{2L} \frac{1+\delta}{\delta^2} - \frac{NL}{2} \quad (12.9c)$$

Again, we see here the relationship between the drainage of fresh water to the sea and the length of sea water intrusion. Reducing Q_0 means an increased L . By controlling h_{f0} at the toe G, say, by means of artificial recharge, the water table may be lowered landward, without any additional sea water intrusion.

Altogether, also in the general case of 3D flow with a transition zone, the extent of sea water intrusion, measured, say, by the length of the intruding wedge on the aquifer's bottom, is related to the rate of fresh water drained to the sea. As this rate is reduced (by pumping), the extent of sea water intrusion increases. This makes the problem of sea water intrusion into a coastal aquifer a *management problem*. In such a problem, we seek, for example, to determine the maximum annual net rate of pumping from the aquifer (i.e., pumping minus artificial recharge) such that a certain goal is achieved (e.g., maximize net benefits), without violating specified (legal, hydrologic, technical, etc.) constraints. Thus, in managing a coastal aquifer, the issue is not to stem sea water intrusion, but to determine the optimal extent of sea water intrusion. Usually, we wish to maximize pumping in order to achieve certain, say, economic, goals, without violating specified constraints. Models of flow, solute transport, and optimization are used in

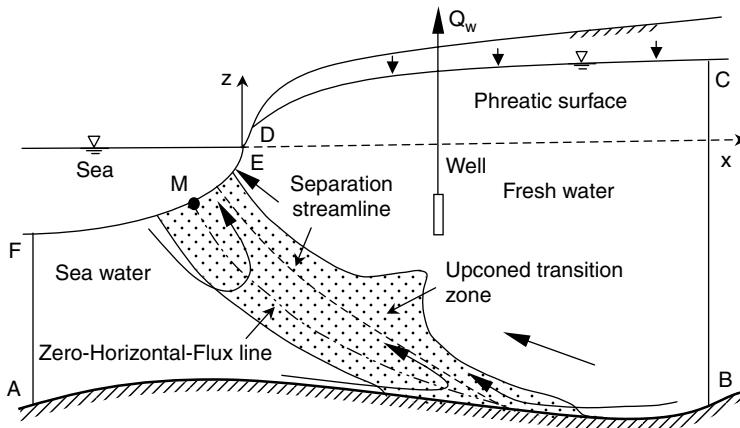

FIGURE 12.4 The transition zone with upconing in a simplified vertical cross section of a coastal aquifer, normal to the coast line.

planning aquifer management. An essential constraint to be satisfied, as part of the optimization model, is the mathematical flow and solute transport model, which takes into account the dependence of water density on salt concentration (= variable density flow).

In the past, the *sharp interface approximation* was introduced, primarily, to enable relatively easy solutions, both analytical and numerical, of certain simple sea water intrusion problems of practical interest. However, nowadays, with the availability of new improved numerical techniques, including methods for coping with the nonlinearities that are inherent in the transition zone model, and with fast and large memory computers (even PCs), numerical solutions of 3D models that take the transition zone into account should not pose special difficulties. There is also no reason to limit the models to (vertical) two-dimensional (2D) flow domains. Indeed, a number of models and computer codes that consider sea water intrusion as a solute transport problem have already been developed (e.g., Sorek and Pinder, 1999). In Section 12.4, we present a number of typical sea water intrusion cases solved by the computer code FEAS (Zhou, 1999; Bensabat et al., 2000; Bear et al., 2001; Zhou et al., 2001, 2005).

Plenty of information on sea water intrusion into coastal aquifers (e.g., the management problem, modeling with the sharp interface approximation, analytical solutions, modeling as a variable density flow and transport problem, numerical solutions, and discussions on specific numerical codes) can be found in Bear et al. (1999). A few comments on the management of a coastal aquifer will be presented in Section 12.5.

12.2 Mathematical Modeling of Sea Water Intrusion

As already mentioned in the introduction, *in reality*, the aquifer domain occupied by only sea water, and the aquifer domain occupied by only fresh water are separated by a *transition zone*. This is a consequence of the fact that the two “miscible” liquids are, actually, single liquid — water — with different concentrations of dissolved salts. The width of the transition zone is dictated by three phenomena (a) advection of fresh water towards the sea (or, under certain conditions, landward), (b) recirculation of sea water and mixed water, and (c) hydrodynamic dispersion (dispersion and molecular diffusion) in the transition zone. Across it, the salinity of the water varies from that of fresh water to that of sea water. The width of this zone grows as it is being displaced in response to changes in the flow regime and in the discharge of water to the sea. The transition zone is also fed by a flux of salt from the sea water zone.

Figure 12.4 shows a phreatic coastal aquifer with a transition zone between sea water and fresh water. The considered flow domain is ABCDEMFA. The detailed conceptual and mathematical models of flow and solute transport are presented in Chapters 4, 18, and 19 of this Handbook and will not be repeated

here. The new features here are that the flow and the solute transport models are *coupled* as the density of the liquid continuously varying in response to the changes in dissolved salt concentration, and that here we apply these models to the particular case of sea water intrusion in a coastal aquifer. We usually refer to such a model as “variable density flow and transport model.” In what follows, we shall present this model, assuming isothermal conditions.

The mathematical model describing sea water intrusion in a coastal aquifer consists of (a) mass balance equation for the water, (b) flux equation for the water of variable density (Darcy's law), (c) mass balance equation for the dissolved salts, and (d) flux equation for the dissolved salts. The first two equations are often combined as a single *flow equation* for the water. The last two equations may be combined to form a single mass balance equation for the dissolved salts, often referred to as the *advection-dispersion equation*, or *the transport equation*. In addition, the complete model includes (a) constitutive equations that relate the liquid's density and dynamic viscosity to the total dissolved salt concentration, and (b) initial and boundary conditions (Bear, 1999; Zhou, 1999; Zhou et al., 2005).

Although, in principle, the flow model can be written in terms of pressure, p , as a primary variable, a more (numerically) efficient model is obtained by expressing the flow model in terms of a *reference (fresh water) piezometric head*, $h_f(x, y, z, t)$, as defined in Equation 12.2, using ρ_f as a reference density (Frind, 1982). To generalize the discussion on variable density flow, we consider the Total Dissolved Solids (TDS) in the range where the volume of water may vary with concentration. To facilitate the discussion, we introduce a *normalized salt mass fraction*, $C(x, y, z, t)$, defined by

$$C = \frac{\omega - \omega_f}{\omega_s - \omega_f} \quad (12.10)$$

in which ω and ω_s denote the salt (or TDS) mass fraction (i.e., mass of the dissolved salt per unit mass of fluid) in water (=salt solution) and in sea water, respectively, and ω_f is the fresh water mass fraction, used as a reference mass fraction. Note that $c = \rho\omega$, in which c denotes the TDS concentration (=mass of TDS per unit volume of fluid).

The constitutive equation that expresses the relationship, $\rho = \rho(p, \omega)$, between the fluid density, the pressure, and the salt mass fraction, is

$$\rho = \rho_0 \exp[\beta'_p(p - p_0) + \beta'_\omega(\omega - \omega_0)] \quad (12.11)$$

where ρ_0 , p_0 , and ω_0 are reference values of density, pressure, and salt mass fraction, respectively, $\beta'_p = (1/\rho)\partial\rho/\partial p$ is the coefficient of water compressibility (at constant salt mass fraction), and $\beta'_\omega = (1/\rho)\partial\rho/\partial\omega$ is a coefficient that introduces the effect of change in salt mass fraction on the fluid's density (at constant pressure). Usually, we select $\omega_0 = \omega_f$ (i.e., equal to the mass fraction of fresh water). The reference pressure is such that for fresh water at $p = p_0$, the density is $\rho = \rho_f$, as the density of fresh water is selected as *a reference density*.

The linearized approximation of Equation 12.11 is

$$\rho = \rho_0[1 + \beta''_p(p - p_0) + \beta''_\omega(\omega - \omega_0)] \quad (12.12)$$

where $\beta''_p = (1/\rho_0)\partial\rho/\partial p$ and $\beta''_\omega = (1/\rho_0)\partial\rho/\partial\omega$. In what follows, we shall assume that for the range of pressures considered here, $\beta''_\omega|\Delta\omega| \gg \beta''_p|\Delta p|$, so that we may employ the approximation:

$$\rho = \rho_f(1 + \beta_c C), \quad \beta_c = \beta''_\omega(\omega_s - \omega_f) \quad (12.13)$$

where β_c may be referred to as a *density difference factor* (dimensionless). In spite of the above assumption, we do take into account the effect of pressure in the expression for the specific storativity appearing in the mass balance equation.

To introduce the effect of mass fraction on the fluid's dynamic viscosity, we may use the constitutive relationship for dynamic viscosity in the form (Lever and Jackson, 1985):

$$\mu = \mu_f \mu_r = \mu_f (1 + 1.85\omega - 4.1\omega^2 + 44.50\omega^3) \quad (12.14)$$

in which the viscosity, μ_f , corresponds to $\omega = 0$, and μ_r is defined by Equation 12.14.

The *specific discharge relative to the solid*, $q_r \equiv \phi(\mathbf{V} - \mathbf{V}_s) = \mathbf{q} - \phi\mathbf{V}_s$, is expressed by Darcy's law (Bear, 1972; Bear and Bachmat, 1990)

$$\mathbf{q}_r = \phi(\mathbf{V} - \mathbf{V}_s) = -\frac{\mathbf{k}}{\mu}(\nabla p + \rho g \nabla z) \quad (12.15)$$

in which \mathbf{V} and \mathbf{V}_s denote the velocity vectors of the water and of the solid matrix, respectively, ϕ denotes the porosity, the second rank tensor, \mathbf{k} , denotes the permeability, and \mathbf{q} denotes the specific discharge vector. We usually assume, also here, that $\mathbf{V}_s \approx 0$, $\mathbf{q}_r \approx \mathbf{q}$. In terms of h_f and C , Darcy's law can be rewritten in the form:

$$\mathbf{q} = -\frac{\mathbf{K}_f}{\mu_r}(\nabla h_f + \beta_c C \nabla z), \quad \mathbf{K}_f = \frac{\rho_f g \mathbf{k}}{\mu_f} \quad (12.16)$$

with \mathbf{K}_f denoting the reference hydraulic conductivity.

For a single fluid phase, for example, water, of variable density, Bear (1972, 1979) and Bear and Bachmat (1990), as many others, present the general mass balance equations in the form:

$$\frac{\partial \phi \rho}{\partial t} = -\nabla \cdot (\rho \mathbf{q} - \phi \mathbf{D} \nabla \rho) + (\rho_R Q_R - \rho Q_P) \quad (12.17)$$

in which Q_R and Q_P , denote, symbolically, the rates of injection of water into and withdrawal of water from the aquifer (dimension 1/T), ρ_R denotes the density of the injected water, t is the time, and \mathbf{D} , a second rank symmetric tensor, denotes the *coefficient of dispersion* (dimensions L²/T). When water is withdrawn and injected through (point) wells, the symbolic source and sink terms in Equation 12.17 may, symbolically, be written as:

$$\rho_R Q_R = \sum_n \rho_{Rn} Q_{Rn}(\mathbf{x}_n, t) \delta(\mathbf{x} - \mathbf{x}_n) \quad (12.18a)$$

$$\rho Q_P = \sum_m \rho_m Q_{Pm}(\mathbf{x}_m, t) \delta(\mathbf{x} - \mathbf{x}_m) \quad (12.18b)$$

in which Q_{Rn} and ρ_{Rn} are the injection rate, and the density of the water injected through a well at point \mathbf{x}_n , respectively, and Q_{Pm} and ρ_m are the pumping rate and density of the water pumped through a well at point \mathbf{x}_m , and δ denotes the *Kronecker delta*.

Note that Equation 12.17 includes a term, $\mathbf{J}^{*\rho}$, denoting the *dispersive flux of the total fluid mass*, which can be rewritten in the form:

$$\mathbf{J}^{*\rho} = -\mathbf{D} \cdot \nabla \rho = -\rho_f \beta_c \mathbf{D} \cdot \nabla C \quad (12.19)$$

In the case of a fluid of variable density, significant density gradients may develop. For example, it is possible that a rather narrow transition zone will develop, with a relatively large density gradient across it, therefore with flow that is more or less normal to such a gradient, significant lateral dispersion may take place. Bear and Bachmat (1990, p. 290) present and discuss a method, using appropriate Peclet numbers (that define the ratio between advective and dispersive fluxes), for examining the conditions under which the dispersive flux of the total mass may be neglected as being much smaller than the advective one. Note

that *there is no diffusive flux of the total dissolved mass*. In the case of sea water intrusion, we may encounter a rather narrow transition zone, with flow parallel to it. The appropriate Peclet number may be less than or not much larger than one, so that we cannot conclude, *a-priori*, that advection dominates over dispersion.

In view of the relationship $\rho = \rho(p, C)$, we make use of Equation 12.16 and Equation 12.19 to modify Equation 12.17, rewriting it in terms of the reference piezometric head, h_f , and the normalized mass fraction, C , in the form:

$$S_0 \frac{\partial h_f}{\partial t} + \phi \beta_c \frac{\rho}{\rho_f} \frac{\partial C}{\partial t} = \nabla \cdot \left[\frac{(1 + \beta_c C)}{\mu_r} \mathbf{K}_f \cdot (\nabla h_f + \beta_c C \nabla z) + \phi \beta_c \mathbf{D} \cdot \nabla C \right] + \frac{\rho_R}{\rho_f} Q_R - (1 + \beta_c C) Q_P \quad (12.20)$$

in which $S_0 = \rho g(\phi \beta_p + \alpha)$ denoting the *aquifer's elastic storativity*, with α denotes the aquifer's (vertical) compressibility. Other forms are also possible.

For a fluid of variable density, the general mass balance equation for the TDS in the water can be written in the form:

$$\frac{\partial \phi \rho \omega}{\partial t} = -\nabla \cdot (\rho \omega \mathbf{q} - \phi \rho \mathbf{D}_h \cdot \nabla \omega) + \rho_R \omega_R Q_R - \rho \omega Q_P \quad (12.21)$$

in which \mathbf{D}_h denotes the *coefficient of hydrodynamic dispersion* (a second rank symmetric tensor), $\mathbf{D}_h = \mathbf{D} + \mathbf{D}_{\text{diff}}^*$, and $\mathbf{D}_{\text{diff}}^*$ denotes the *coefficient of molecular diffusion in a porous medium*. In an *isotropic* porous medium, the *coefficient of dispersion*, D , is related to the fluid's velocity and to the *longitudinal and transversal dispersivities*, α_L and α_T (dimension L), respectively, by

$$D_{ij} = \alpha_T V \delta_{ij} + (\alpha_L - \alpha_T) \frac{V_i V_j}{V} \quad (12.22)$$

in which δ_{ij} denotes the *Kronecker delta*, and $V = |V|$.

The salt transport equation, Equation 12.21, can be written in terms of the normalized mass fraction, C , with $\omega_f = 0$ (Bear, 1999; Zhou et al., 2005):

$$\frac{\partial \phi \rho C}{\partial t} = -\nabla \cdot (\rho C \mathbf{q} - \phi \rho \mathbf{D}_h \cdot \nabla C) + \rho_R C_R Q_R - \rho C Q_P \quad (12.23)$$

Expanding the first-order derivatives in Equation 12.23 and making use of the mass balance equation for water, Equation 12.17, we can rewrite the transport equation in the form:

$$\phi \rho \frac{DC}{Dt} = \nabla \cdot (\phi \rho \mathbf{D}_h \cdot \nabla C) + \rho_R Q_R (C_R - C) \quad (12.24)$$

in which DC/Dt is the material derivative with respect to solute particles. Altogether, we have to solve the variable density flow equation, Equation 12.20, and the salt transport equation, Equation 12.24, simultaneously, for the two primary variables: $h_f(x, y, z, t)$ and $C(x, y, z, t)$, making use of Equations 12.13 and 12.14 to express ρ and μ , and Equation 12.16 to express \mathbf{V} or \mathbf{q} .

The initial conditions for the variable density flow and salt transport equations are

$$h_f(x, y, z, 0) = h_{f0}(x, y, z), \quad C(x, y, z, 0) = C_0(x, y, z) \quad (12.25)$$

where $h_{f0}(x, y, z)$ and $C_0(x, y, z)$ are known distributions.

The conditions on the boundary segments (shown in Figure 12.4) for the flow equation, Equation 12.20, neglecting the dispersive flux of the total fluid mass, are:

$$\begin{aligned}
 \text{On AB : } q_n &\equiv \mathbf{q} \cdot \mathbf{n} = 0, & & \text{(impervious bottom)} \\
 \text{On BC : } h_f &= h_{fp}, \text{ or } \mathbf{q} \cdot \mathbf{n} = q_{np}, & & \text{(land-side lateral boundary)} \\
 \text{On CD : } \rho q_n &= -\rho_N N n_z + \frac{(\phi\rho - \theta_{w0}\rho_N)}{|\nabla F|} \frac{\partial h_f}{\partial t}, & & \text{(phreatic surface)} \\
 \text{On DE : } h_f &= \varsigma \gamma_{DE}, & & \text{(seepage face)} \\
 \text{On EF : } h_f &= \beta_c H_{sea}, & & \text{(sea bottom)} \\
 \text{On FA : } h_f &= \beta_c H_{FA}, & & \text{(sea-side lateral boundary)} \tag{12.26}
 \end{aligned}$$

where h_{fp} is the prescribed reference head on a Dirichlet-type boundary, q_{np} is the prescribed fluid flux on a 2nd-type boundary, \mathbf{n} ($= \nabla F/|\nabla F|$, with $F(x, y, z, t) = 0$ representing the equation of a boundary surface) is the unit outward normal vector, with the components n_x, n_y, n_z in 3D, N is the rate of replenishment, ρ_N is the density of the replenishment, θ_{w0} is the irreducible water content assumed to prevail in the unsaturated zone, ς_{DE} is the elevation at a point on the seepage face above sea level, H_{sea} and H_{FA} are the depth of sea water at a point on the sea bottom and the sea-side lateral boundaries, respectively. If we wish to take into account the dispersive flux of the fluid's mass, we replace $\rho\mathbf{q}$ by $\rho\mathbf{q} - \phi\rho\beta_c\mathbf{D} \cdot \nabla C$.

The boundary conditions for the salt transport equation are:

$$\begin{aligned}
 q_n^d &\equiv -\mathbf{D}_h \cdot \nabla C = 0, & & \text{On AB and DE} \\
 C &= 0, & & \text{On BC} \\
 q_n^d &= -\left(\frac{\rho_N}{\rho} C - C_N\right)\left(N n_z + \frac{\phi_{w0}}{|\nabla F|} \frac{\partial h_f}{\partial t}\right), & & \text{On CD} \\
 C &= 1, & & \text{On FA} \tag{12.27a}
 \end{aligned}$$

where q_n^d is the hydrodynamic dispersive flux normal to a 2nd- or 3rd-type boundary, and C_N is the normalized mass fraction in the replenishment water.

On the sea bottom boundary, EF, we may have either only landward flow from the sea, in which case the condition there is the same as on FA, or we may have both an inflow portion, MF, and an outflow portion, EM, separated by a point with zero-normal fluid flux. For the inflow portion, we usually employ either a 3rd-type condition

$$q_n^d \equiv -\mathbf{D}_h \cdot \nabla C = (1 - C)q_n \tag{12.27b}$$

or a Dirichlet condition

$$C = 1 \tag{12.27c}$$

For the outflow portion, the assumption is often made that the fluid concentrations are identical (i.e., continuous) on both sides of this boundary. Since the fluid fluxes are also identical, the condition becomes a 2nd-type condition:

$$q_n^d \equiv -\mathbf{D}_h \cdot \nabla C = 0 \tag{12.27d}$$

The (moving) point M , between the inflow and outflow portions of the boundary, is unknown a priori. In a numerical solution, during each iteration, we check whether flow along the sea bottom is directed inward or outward, and then assign the appropriate boundary condition accordingly.

We note an *inconsistency* in the salt mass fraction specified on the sea bottom segment EM between the flow boundary condition (based on the assumption of hydrostatic pressure of sea water [$C = 1$] on the sea side of EM) and the transport boundary condition (based on the assumption of equality of mass fraction [$C < 1$]). As a consequence, a large error in the salt mass balance may occur in a numerical simulation, when such an inconsistency occurs in the specified flow and transport boundary conditions. To overcome this inconsistency, we may assume the presence of a *buffer zone* on the sea bottom, which contains out-flowing water. We then take the density of this fluid into account when determining the head condition on this boundary. Iterations may be required in a numerical solution. The thickness of this buffer zone is a calibration parameter.

Let us demonstrate the solution of this flow and transport model for three example cases of sea water intrusion in coastal aquifers.

12.3 Numerical Modeling and Computer Code

As discussed earlier, the density-dependent flow equation, Equation 12.20, and the salt transport equation, Equation 12.24, in the mathematical model presented in Section 12.2, are coupled and nonlinear. In most cases, the aquifer is also heterogeneous and anisotropic, with rather irregular boundaries. Obviously, no analytical solutions are possible for the two simultaneous equations. A numerical solution is needed, using a computer program. A number of computer codes have been developed and published in the literature (e.g., Bear et al., 1999), such as FEFLOW (Diersch, 1988), MOCDFENSE (Sanford and Konikow, 1985), SUTRA (Voss, 1984; Voss and Souza, 1987), SEAWAT (Langevin, 2003; Langevin et al., 2003), DSTRAM (Huyakorn et al., 1987), CODESA-3D (Galeati et al., 1992; Putt and Paniconi, 1995), and SWIFT (Ward et al., 1984; Ma et al., 1997). However, in this chapter, we'll solve the examples by first transforming the mathematical model into finite element numerical models, which are, in turn, solved by using the computer code called FEAS (a Finite Element Aquifer Simulator). The code has been successfully used for a number of practical modeling projects in the coastal aquifer in Israel (Zhou, 1999; Bensabat et al., 2000; Bear et al., 2001; Zhou et al., 2001, 2005).

12.3.1 The Numerical Model

In the numerical model, the Galerkin finite element method (FEM) is employed to discretize the density-dependent flow equation, Equation 12.20, and the salt transport equation, Equation 12.24, and their boundary conditions, and to compute the reference head and salt mass fraction fields (Huyakorn and Pinder, 1983). In addition, the Galerkin FEM is also used to discretize the flux equation, Equation 12.16, and to compute the specific discharge and velocity field (Zhou et al., 2001). The numerical model consists of the density-dependent flow model, the consistent velocity model, the salt transport model, and the *modified Picard iterative scheme*. The salt transport equation is solved within the Eulerian–Lagrangian framework in two successive steps. The advective (Lagrangian) mass fraction is first computed by using the *adaptive pathline-based particle tracking technique* (Zhou, 1999; Bensabat et al., 2000). The remaining dispersion equation is then solved by using the Galerkin FEM. This method can be applied to any transport problem with an arbitrary mesh Peclet number in the range from 0 to infinity. The Picard method is employed for linearizing the coupled nonlinear density-dependent flow and salt transport equations. The iterative sequential procedure consists of three steps: first the density-dependent flow equation is solved for the reference head field; then the consistent specific discharge scheme is used to solve for the velocity field; finally the salt transport equation is solved for the salt mass fraction field. In each step, the iterative process continues until a satisfactory convergence is reached.

To apply the Galerkin FEM, we represent the two primary variables (reference fresh water head and salt mass fraction) and the specific discharge vector, using the basis functions:

$$h_f = h_f(x, y, z, t) \approx N_j(x, y, z) h_{fj}(t) \quad (12.28a)$$

$$C = C(x, y, z, t) \approx N_j(x, y, z) C_j(t) \quad (12.28b)$$

$$q_i = q_i(x, y, z) \approx N_j(x, y, z) q_{ij} \quad (12.28c)$$

where the $N_J(x, y, z)$ are the global basis functions, J is the nodal numbering, $h_{fJ}(t)$, and $C_J(t)$ are the nodal values of reference head and mass fraction at the t time step, respectively, and q_{IJ} is the i th component of the J th nodal specific discharge vector. Note that repeated indices indicate nodal summation.

12.3.1.1 Flow Model

Application of the Galerkin criterion and Green's theorem to the flow equation, Equation 12.20, and using the flux boundary condition on the 2nd- and 3rd-type boundaries lead to

$$\begin{aligned} \int_{\Omega} \frac{\partial N_I}{\partial x_i} K_{ij} \frac{\partial N_j}{\partial x_j} h_{fj} d\Omega + \int_{\Omega} N_I N_j S_0 \frac{dh_{fj}}{dt} d\Omega &= - \int_B N_I \frac{\rho}{\rho_f} q_n dB \\ + \int_{\Omega} N_I \frac{\rho_R Q_R - \rho Q_P}{\rho_f} d\Omega - \int_{\Omega} \frac{\partial N_I}{\partial x_i} K_{ij} \beta_c C \frac{\partial z}{\partial x_j} d\Omega - \int_{\Omega} N_I \frac{\phi \beta_c \rho}{\rho_f} \frac{\partial C}{\partial t} d\Omega \end{aligned} \quad (12.29)$$

where B is the boundary of the considered domain Ω , q_n is the outward normal flux on the boundary, and $K_{ij} = \rho g k_{ij}/\mu$, which depends on the fluid's density. We assume that the dispersive flux of the total fluid mass is negligible in the flow equation, Equation 12.20, in comparison with the advective flux. Equation 12.29 can be written in the matrix–vector form:

$$[A_{IJ}] \{h_{fJ}\} + [B_{IJ}] \left\{ \frac{dh_{fJ}}{dt} \right\} = \{F_I\} \quad (12.30a)$$

where $[A_{IJ}]$, $[B_{IJ}]$, and F_I are the stiffness (or flux) matrix, the fluid's mass storage matrix, $\{h_{fJ}\}$ is the reference head solution vector, and the right-hand side load vector, respectively, given by

$$[A_{IJ}] = \sum_e A_{IJ}^e = \sum_e \int_{\Omega^e} K_{ij}^e \frac{\partial N_I^e}{\partial x_i} \frac{\partial N_j^e}{\partial x_j} d\Omega \quad (12.30b)$$

$$[B_{IJ}] = \sum_e B_{IJ}^e = \sum_e \int_{\Omega^e} S_0^e N_I^e N_J^e d\Omega \quad (12.30c)$$

$$\{F_I\} = \{F_I^B\} + \{F_I^S\} + \{F_I^G\} + \{F_I^C\} \quad (12.30d)$$

$$\{F_I^B\} = \sum_e F_I^{Be} = - \sum_e \left(\int_{B^e} N_I^e \frac{\rho}{\rho_f} q_n dB \right) \quad (12.30e)$$

$$\{F_I^S\} = \sum_e F_I^{Se} = \sum_e \int_{\Omega^e} N_I^e \left(\frac{\rho_R}{\rho_f} Q_R - \frac{\rho}{\rho_f} Q_P \right) d\Omega \quad (12.30f)$$

$$\{F_I^G\} = \sum_e F_I^{Ge} = - \sum_e \int_{\Omega^e} \frac{\partial N_I^e}{\partial x_i} K_{ij}^e \beta_c N_J^e \frac{\partial z}{\partial x_j} d\Omega C_J \quad (12.30g)$$

$$\{F_I^C\} = \sum_e F_I^{Ce} = - \sum_e \int_{\Omega^e} N_I^e \phi \beta_c \frac{\rho}{\rho_f} N_J^e d\Omega \frac{dC_J}{dt} \quad (12.30h)$$

where Ω^e is the element domain with boundary B^e , the superscript e represents the elemental values, and \sum_e represents the global assembly of the elemental matrices and vectors over the total number of elements, $\{F_I^B\}$ is the global right-hand vector contributed from the conditions on all boundaries except Dirichlet ones, $\{F_I^S\}$ is the global vector for the sources/sinks injected/pumped by wells, $\{F_I^G\}$ is due to the body force produced by the difference of salt mass fraction in the vertical direction, and $\{F_I^C\}$ is the

term representing the fluid's mass change caused by changes in mass fraction. In the numerical model, the incorporation of $\{F_I^B\}$ and $\{F_I^S\}$ into the global system is separated from the global assembly of element systems.

For each element, we employ the backward difference time integration scheme. Thus, the resulting system of element matrix equations takes the form:

$$[AB_{IJ}^e]\{h_{fJ}^{t+1}\} = \{F_I^{e*}\} \quad (12.31a)$$

with

$$[AB_{IJ}^e] = [A_{IJ}^e] + \frac{1}{\Delta t}[B_{IJ}^e] \quad (12.31b)$$

$$\{F_I^{e*}\} = \{F_I^{Ge}\}^{t+1} + \{F_I^{Ce}\}^{t+1} + \frac{1}{\Delta t}[B_{IJ}^e]\{h_{fJ}^t\} \quad (12.31c)$$

After global assembly of element matrix systems and treatment of boundary conditions and well's sources/sinks, we have a set of nonlinear algebraic equations for the density-dependent flow

$$[AB_{IJ}]\{h_{fJ}^{t+1}\} = \{F_I^*\} \quad (12.32a)$$

with

$$[AB_{IJ}] = \sum_e [AB_{IJ}^e] \quad (12.32b)$$

$$\{F_I^*\} = \sum_e \{F_I^{e*}\} + \{F_I^S\} + \{F_I^B\} \quad (12.32c)$$

This system is nonlinear due to (1) the effects of varying fluid's density (and dynamic viscosity) on the hydraulic conductivity, K_{ij}^e , and on the specific storativity, S_0^e , and (2) the presence of two additional coupling terms: $\{F_I^G\}$ and $\{F_I^C\}$. In a phreatic aquifer, the nonlinearity also comes from the moving phreatic surface. The resulting system of algebraic equations is symmetric positive definite, and an incomplete Cholesky conjugate gradient algorithm (ICCG) (Ajiz and Jennings, 1984; Barrett et al., 1994) is used to solve the linear algebraic equations.

12.3.1.2 Transport Model

The Eulerian–Lagrangian method is used for the simulation of salt transport. This method is based on the decomposition of the mass fraction field into two components: advection and dispersion. The advection (Lagrangian) mass fraction is computed using the *adaptive pathline-based particle tracking technique* (Zhou, 1999; Bensabat et al., 2000). The remaining dispersion problem is solved by the Galerkin FEM.

By performing the Galerkin FEM procedure on the transport equation, Equation 12.24, in the Eulerian–Lagrangian framework, we obtain a system of ordinary differential equations for salt transport:

$$[T_{IJ}]\{c_J\} + [E_{IJ}] \left\{ \frac{DC_J}{Dt} \right\} = \{G_I\} \quad (12.33a)$$

where DC_J/Dt is the material derivative with respect to the velocity of solute particles, $[T_{IJ}]$, $[E_{IJ}]$, and $\{G_I\}$ are the dispersive transport matrix, the solute mass storage matrix, and the transport right-hand side

vector, respectively, given by:

$$[T_{IJ}] = \sum_e T_{IJ}^e = \sum_e \int_{\Omega^e} \frac{\partial N_I^e}{\partial x_i} \phi \rho D_{hij} \frac{\partial N_J^e}{\partial x_j} d\Omega \quad (12.33b)$$

$$[E_{IJ}] = \sum_e E_{IJ}^e = \sum_e \int_{\Omega^e} \phi \rho N_I^e N_J^e d\Omega \quad (12.33c)$$

$$\{G_I\} = \sum_e G_I^e = \sum_e \left(\int_{\Omega^e} N_I^e \rho_R Q_R (C_R - N_J^e C_J) d\Omega + \int_{B^e} N_I^e \phi \rho D_{hij} \frac{\partial C}{\partial x_j} n_i dB \right) \quad (12.33d)$$

The global right hand vector, $\{G_I\}$, results from well's sources/sinks and boundary conditions, assuming that there are no volumetric or areal sources/sinks within the solution domain.

For each element, we have the material derivative in Equation (12.33a) rewritten as

$$\frac{DC_J}{Dt} = \frac{C_J^{t+1} - C_J^L}{\Delta t} \quad (12.34)$$

where C_J^L is the Lagrangian concentration, obtained by the adaptive backward particle tracking technique and mass fraction interpolation (Bensabat et al., 2000). Using the backward difference time integration scheme, we obtain a system of element matrix:

$$[TE_{IJ}^e] \{C_J^{t+1}\} = \{G_I^*\} \quad (12.35a)$$

with

$$[TE_{IJ}^e] = [T_{IJ}^e] + \frac{1}{\Delta t} [E_{IJ}^e] \quad (12.35b)$$

$$\{G_I^*\} = \frac{1}{\Delta t} [E_{IJ}^e] \{C_J^L\} \quad (12.35c)$$

The contribution from the boundary conditions and well's sources/sinks is incorporated into the global matrix and vector in the same way as for the flow problem. After global assembly of elemental systems, the treatment of boundary conditions and well's sources/sinks, we have a set of nonlinear algebraic equations

$$[TE_{IJ}] \{C_J^{t+1}\} = \{G_I^*\} \quad (12.36a)$$

with

$$[TE_{IJ}] = \sum_e [TE_{IJ}^e] \quad (12.36b)$$

$$\{G_I^*\} = \sum_e \{G_I^*\} + \{G_I\} \quad (12.36c)$$

The coefficient matrix $[TE_{IJ}]$ is a function of salt mass fraction (or fluid's density) and flow velocity, and the right-hand vector $\{G_I^*\}$ depends on flow velocity.

12.3.1.3 Calculation of Specific Discharge

In the calculation of specific discharge, or velocity, for a density-dependent flow problem, the gradient of the reference head, $\partial h_f / \partial x_j$, and the gravity term, $\beta_c C (\partial z / \partial x_j)$, in the vertical direction in Darcy's law, Equation 12.16, must have the same order of approximation within an element. This means that a

consistent approximation is obtained by using one-order higher basis functions for the reference head than that for the fluid density (salt mass fraction) in the vertical direction. When both the reference head and the salt mass fraction are approximated by linear interpolation functions in the vertical direction, spurious vertical velocities are produced (Voss and Souza, 1987; Herbert et al., 1988). To avoid the spurious vertical velocity, we use the element-averaged salt mass fraction in the flux equation, Equation 12.16.

By applying the standard Galerkin FEM to the water flux equation, Equation 12.16, we obtain the linear algebraic equations:

$$[P_{IJ}] \cdot \{q_{ij}\} = \{R_{il}^h\} + \{R_{il}^c\} \quad (12.37a)$$

with

$$[P_{IJ}] = \sum_e P_{IJ}^e = \sum_e \int_{\Omega^e} N_I^e N_J^e d\Omega \quad (12.37b)$$

$$\{R_{il}^h\} = \sum_e R_{il}^{he} = - \sum_e \int_{\Omega^e} N_I^e \frac{K_{fij}^e}{\mu_r} \frac{\partial N_J^e}{\partial x_j} d\Omega \{h_{fj}\} \quad (12.37c)$$

$$\{R_{il}^c\} = \sum_e R_{il}^{ce} = - \sum_e \int_{\Omega^e} N_I^e \frac{K_{fij}^e}{\mu_r} \beta_c C_e \frac{\partial z}{\partial x_j} d\Omega \quad (12.37d)$$

where $[P_{IJ}]$ is the global coefficient matrix, $\{q_{ij}\}$ is the nodal unknown vector of the i th component of \mathbf{q} , $\{R_{il}^h\}$ is the right-hand side load (flux) vector, contributed by the reference head gradient, $\{R_{il}^c\}$ is the load vector, contributed by the body-force term, C_e is the element-averaged salt concentration, and $K_{fij} (\equiv \rho_f g k_{ij} / \mu_f)$ is the reference hydraulic conductivity at reference density, ρ_f , and reference viscosity, μ_f .

12.3.2 The FEAS Code

The numerical model described above can be solved by the FEAS code, which was developed for simulating sea water intrusion in 2D and 3D coastal aquifers. FEAS, written in C++, is a code family for aquifer simulations based on the finite element techniques. The FEAS code has been verified using a number of benchmark problems, such as the Henry problem, the Elder problem, and the Hydrocoin problem, and has been applied to sea water intrusion in coastal aquifers and upconing problems (Zhou, 1999; Bear et al., 2001; Zhou et al., 2005).

We shall demonstrate the solution of this flow and transport model for three cases of sea water intrusion in 3D coastal aquifers.

12.4 Examples of Sea Water Intrusion

12.4.1 Example A: Sea Water Intrusion — A Typical Case

This example involves the simulation of a sea water wedge under natural equilibrium conditions and sea water intrusion under pumping conditions in a phreatic aquifer. The aquifer strip is 11,000 m long (perpendicular to the coast) and 1,000 m wide, with a sloping sea bottom of 5%. The depth of the aquifer bottom (with a slope of 0.8%) varies from 20 m below sea level at the land-side boundary, to 100 m at the coast, and further to 108 m depth at the vertical sea-side boundary. The aquifer's top is the ground surface above the phreatic aquifer. Under natural equilibrium conditions, a fresh water flux of 0.015 m/day enters the aquifer, and the fresh water natural replenishment is at a rate of 0.1 m/yr. The aquifer is homogeneous, with a hydraulic conductivity of 30 m/day and a porosity of 0.2. The longitudinal dispersivity is 10 m and the transversal dispersivity is 1 m. Three wells, located at 5,000, 7,000, and 9,000 m from the coast, respectively, pump, when active, a total of one-third of the total natural replenishment. Note that in all figures representing a cross section normal to the coast, the figures show only part of the total investigated aquifer.

In addition to the above boundary conditions, the aquifer bottom is assumed to be impervious to both flow and transport. The vertical, sea-side boundary and the sea bottom are assumed to be at hydrostatic pressure imposed by the sea water. For transport, the mass fraction of fresh water is specified at the land-side boundary, and the mass fraction of sea water is specified at the vertical, sea-side boundary. At the sea bottom, a mixed-type boundary condition is specified. This type of condition can be automatically switched from the 1st-type condition (Equation 12.27c) to the 2nd-type condition of zero dispersive flux (Equation 12.27d), depending on the direction of the normal groundwater flux. Initially, fresh water on the inland side and sea water on the sea side of the coast (with a vertical sharp interface) is used for the sea water wedge case under natural equilibrium conditions, whose steady-state solution is considered as initial conditions for the sea water intrusion case under pumping. The FEAS code is used to simulate the transient coupled density-dependent flow and salt transport until a steady-state condition is obtained for each case.

Figure 12.5a shows the groundwater flow field, with reference head contours and streamlines originating at both the sea water and fresh water zones. Also shown is the salt mass fraction field (in a vertical cross section) under natural equilibrium conditions. With the total fresh water discharged to the sea, the sea water wedge is formed in a region within approximately 610 m from the coast. The fresh water zone receives fresh water recharged from the land-side boundary and from natural replenishment, producing a seaward fresh water flow over the sea water wedge. In the sea water wedge, a recirculating sea water flow develops. Sea water fills the wedge primarily from the sea bottom, and is swept away back to the sea within the transition zone. As demonstrated by the streamlines, the fresh water and sea water flow originating from their respective zones are separated sharply by a “*separation streamline*,” which is the envelope of all streamlines originating at the sea. The point of the separation streamline at the aquifer bottom is referred to as its “toe,” a term usually used in a sharp interface model. At the toe of the separation streamline, the contrast of horizontal hydraulic gradient between the seaward fresh water flow and the landward sea water flow is balanced, and the entire system is at an equilibrium condition. Unlike the sharp separation of sea water and fresh water flow, a wide transition zone exists between the sea water zone and the fresh water zone, because of hydrodynamic dispersion. Within the transition zone salt mass fraction varies between sea water and fresh water. The shape and width of the transition zone depend on both the flow field and the velocity-dependent dispersion. Note that the 50% salt mass fraction is not close to the separation streamline, which may be considered as the sharp interface in the case of no dispersion.

As shown in Figure 12.5b, by pumping fresh water far away from the near-coast region affected by sea water, the elevations of the phreatic surface are lowered. The lowered fresh water hydraulic head in the sea water wedge disturbs the natural equilibrium conditions, inducing further sea water movement into the coastal aquifer. The sea water intrusion starts from the toe of the separation streamline at the aquifer bottom, where the reference head on the sea side of the sea water wedge is higher than the reference head on the inland side lowered by pumping. The landward gradient of reference head leads to advective intrusion of sea water. Once the sea water advances landward, the sea water intruded in the expanded wedge moves upward along the advancing separation streamline. The upward sea water movement results in higher salt mass fraction in the overlying zone, above the already intruded zone. Meanwhile, dispersion also induces an increase in salt mass fraction in this zone. Both of advection and dispersion facilitate the widening of the intruding sea water wedge in the vertical direction. The higher salt mass fraction and wider transition zone gradually increases the reference head in the expanded intruding wedge. Meanwhile, the intruding wedge also changes the reference head of the fresh water zone in contact with it by reducing the cross-sectional area for fresh water flow to the sea, and by reducing the reference head immediately inland of the sea water wedge. As a result, a further landward movement of sea water occurs. The speed of sea water intrusion is fast immediately after the initiation of the disturbance caused by pumping. With the intruding sea water wedge becoming wider and extending landward, the landward gradient of the reference head on the sea side of the wedge becomes smaller, and the sea water intrusion is slower. A new equilibrium is finally reached by the contrast in the reduced landward fresh water flow and the recirculating sea water flow. As shown in Figure 12.5, the sea water wedge changes from 610 to 860 m from

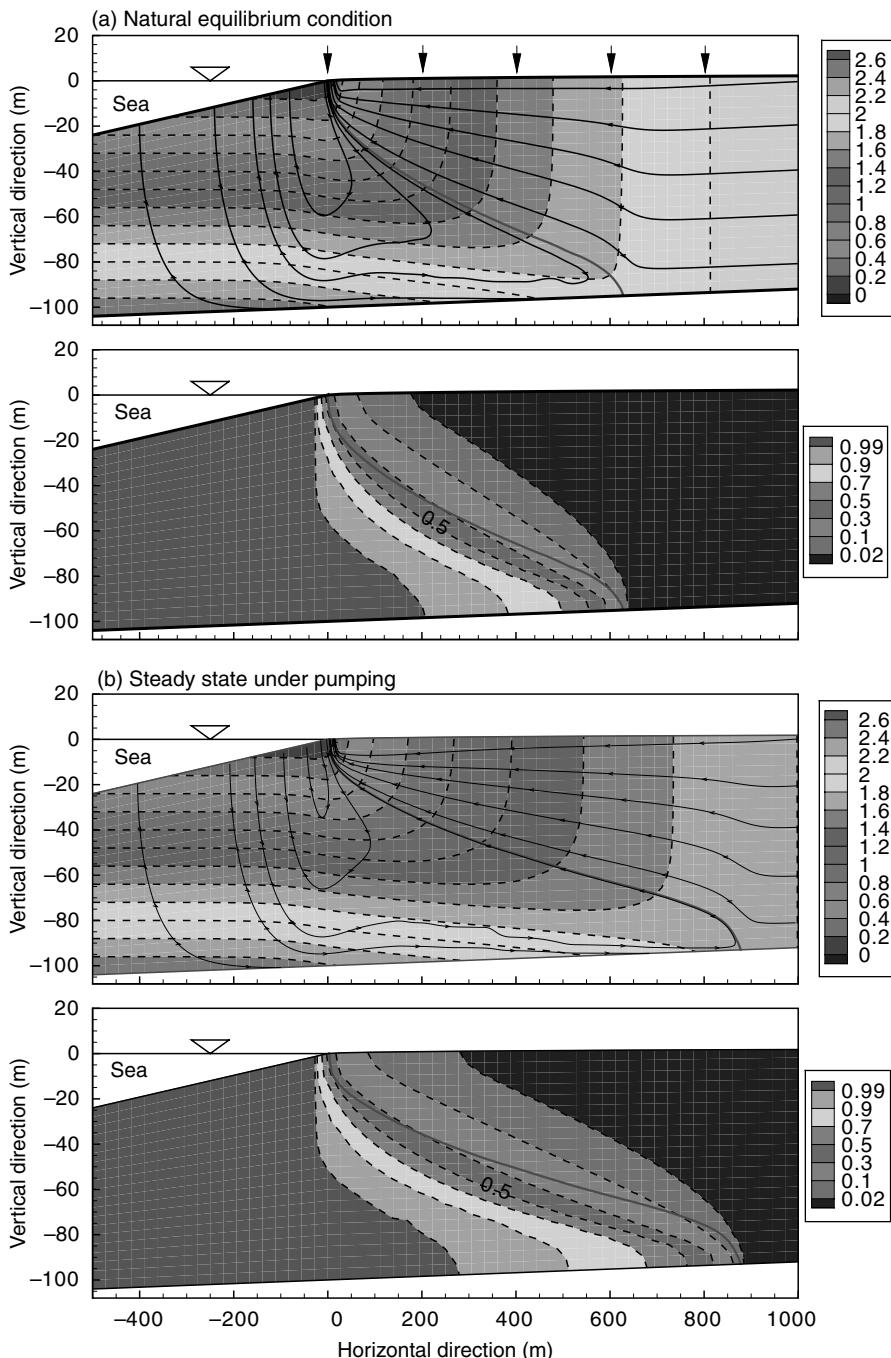

FIGURE 12.5 (See color insert following page 23-52) Numerical model results for (a) a sea water wedge under natural equilibrium conditions (no pumping) and (b) steady-state sea water intrusion under pumping conditions (three pumping wells). In each case, the figure shows the reference head distribution and streamlines in the top figure, and salt mass fraction in the bottom figure, as well as the separation streamline (in red solid line).

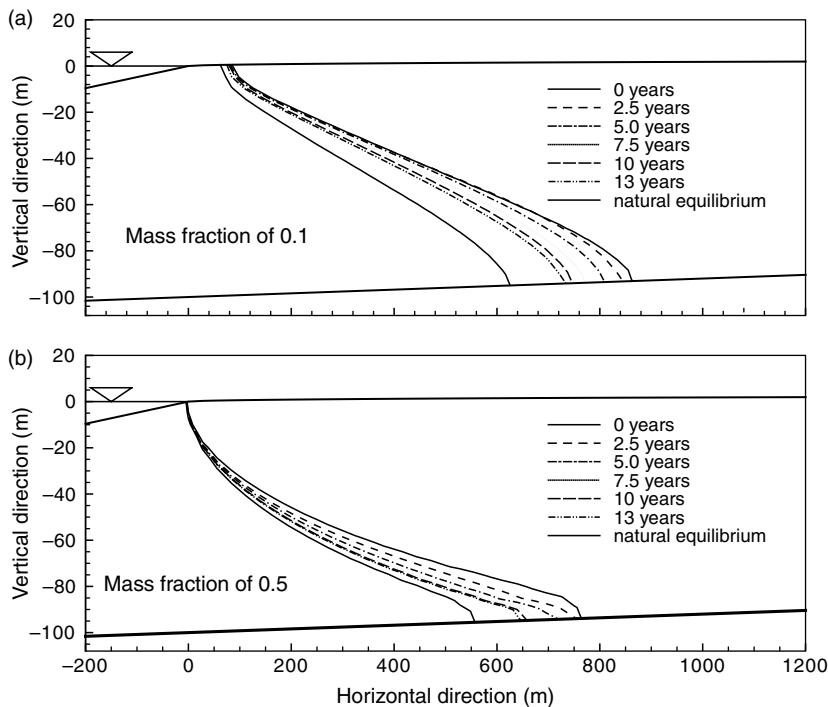

FIGURE 12.6 Transient solution of the receding sea water wedge in a phreatic aquifer after the shutoff of the three pumping wells (Example A).

the coast by pumping a third of the total fresh water discharge. The water table at the land-side boundary is lowered from 10.0 m above the sea level to 6.4 m.

Figure 12.6 shows the transient receding process of the intruding sea water wedge after the shutoff of the three pumping wells. After the wells' shutoff, the hydraulic head in the fresh water zone increases, disturbing the equilibrium maintained under the pumping conditions. This higher hydraulic head results in a higher seaward flow of fresh water, sweeping the intruding transition zone. The recovery occurs for the entire transition zone. However, the recovery process is relatively slow. After 13 years, the transition zone is approximately halfway between the initial equilibrium state under pumping conditions and that under natural equilibrium conditions. Moreover, the recovery is slowing down as it proceeds. The entire recovery process may take very long time, as demonstrated by Bear et al. (2001).

12.4.2 Example B: Sea Water Intrusion with Upconing due to Pumping

This example involves the simulation of regional sea water intrusion, combined with local transition zone upconing in a confined aquifer. The aquifer strip is 4,000 m long perpendicular to the coast, 1,000 m wide parallel to the coast, and 200 m thick. The aquifer extends 1,000 m seaward of the coast (only 500 m is shown in Figure 12.7 and Figure 12.8). The aquifer top and bottom are assumed to be horizontal surfaces. The sea bottom has a slope of 5%, varying from 0 m at the coast to 50 m below sea level at the vertical, sea-side boundary. The top and bottom boundaries of the aquifer are impervious to both groundwater flow and salt transport. An inflow flux of 0.05 m/day takes place through the vertical land-side boundary, whereas the vertical sea-side boundary and the sea bottom are assumed to be at the hydrostatic pressure of sea water. For transport, the salt mass fraction is 0 and 1 at the land-side boundary and the sea-side boundary, respectively. As in Example A, a mixed-type boundary condition is specified at the sea bottom. Initially, the aquifer is full of fresh water and sea water on the inland side and on the sea side of the coast, respectively. A uniform distribution of (isotropic) hydraulic conductivity of 30 m/day and a porosity of

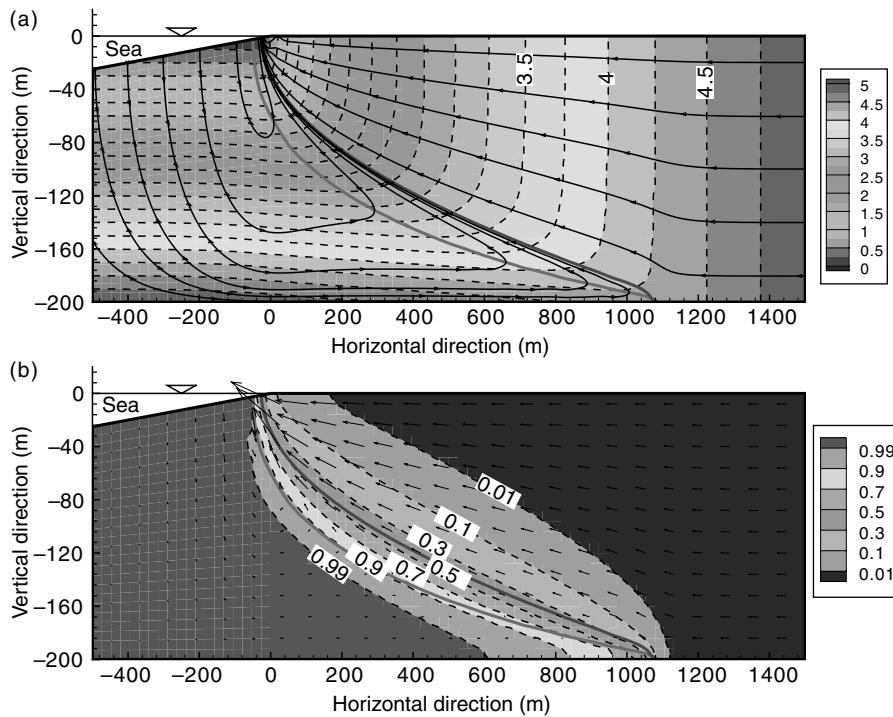

FIGURE 12.7 (See color insert following page 23-52) Steady-state solution of a sea water wedge in a confined aquifer for Example B: (a) the reference hydraulic head distribution (in dashed lines), with the separation streamline (in red line) separating streamlines (in solid lines) originating at the fresh water zone and the sea water zone, and the zero-horizontal-flux line (in pink line), and (b) the mass fraction distribution within the transition zone, and the groundwater flow velocity vector.

0.2 are used for this confined aquifer. The longitudinal and transversal dispersivities used are 10 m and 1 m, respectively. No molecular diffusion is considered, as it is negligible in comparison with dispersion. The steady-state solution of the sea water intrusion problem is obtained by simulating the transient density-dependent flow and salt transport using the FEAS code.

Figure 12.7 shows the distributions of reference hydraulic head, velocity vector, and salt mass fraction in a vertical cross section, and streamlines originating at the sea bottom, the sea-side boundary, and the land-side boundary. Fresh water flows to the sea uniformly before it reaches the sea water wedge. Above the sea water wedge, the total discharge of fresh water flows through a smaller cross section, with an increasing velocity as the sea is approached. At the coast, the cross section available for fresh water reaches its minimum, and the fresh water velocity reaches its maximum value. Sea water enters the aquifer primarily from the sea bottom; a small fraction of total sea water flux comes from the vertical sea-side boundary. As demonstrated by the velocity field and streamlines, a recirculating sea water flow occurs. For a streamline close to the coast, sea water moves downward, then turns into the transition zone, and migrates further within the transition zone to the outflow face at the sea bottom. A streamline starting at a horizontal axis of -500 m at the sea bottom shows that sea water flows downward, and then moves horizontally to the transition zone. After sea water passes through the lower portion of the transition zone, it changes direction sharply, moving to the sea. As demonstrated by the velocity magnitude, most of the sea water entering into the aquifer system comes from the small portion of the sea bottom close to the coast. Farther away from the coast, only a small quantity of sea water feeds into the aquifer system; this can also be seen from the reference head distribution 500 m away from the coast. The total sea water flow entering the transition zone moves back to the sea through a small strip of the transition zone. This strip is bounded by the lower zero-horizontal-flux line on the sea water side, and by the upper separation streamline

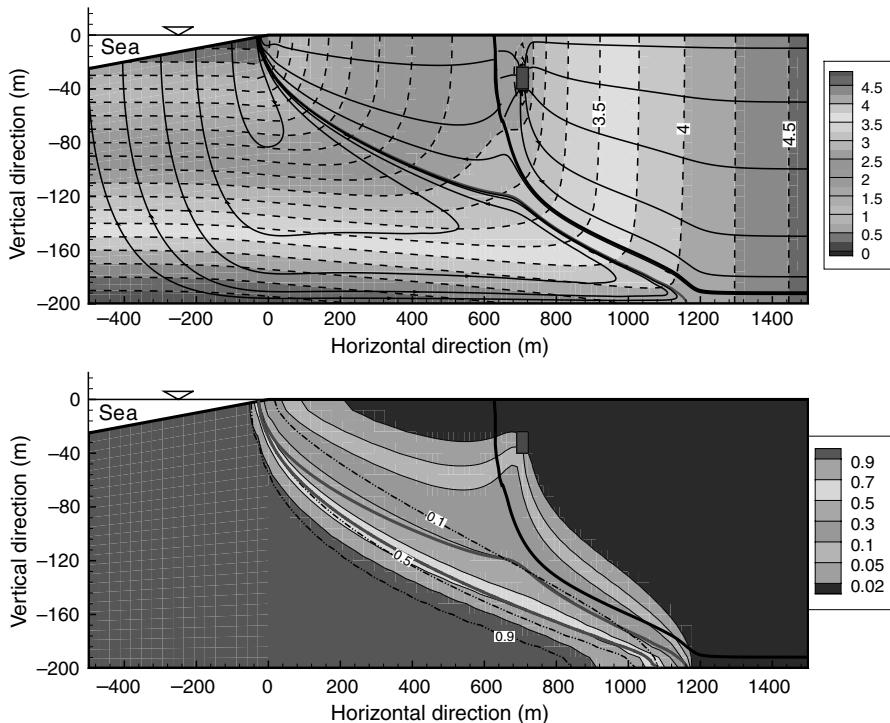

FIGURE 12.8 (See color insert following page 23-52) Transient sea water upconing in a confined aquifer at the end of 8.9 yr in Example B: (a) contours of reference hydraulic head (dashed lines), the separation streamline (red line), and streamlines (solid black lines) originating from the fresh water zone and from the sea water zone, and the capture zone (thicker solid black line), and (b) mass fraction contours (solid lines) with sea water upconing towards the pumping well, in comparison with the initial steady-state transition zone (dashed lines), and the separation streamlines for the upconing and the initial steady-state condition.

on the fresh water side (see Figure 12.7a). The “separation streamline” separates the recirculating sea water flow from the regional seaward fresh water flow, whereas the “zero-horizontal-flux” line, by definition, separates landward sea water flow on its sea side from sea-ward flow on its land side. Both lines are located within the transition zone. At the aquifer bottom, these two lines merge because no sea water flow enters this strip. Toward the sea, more sea water enters this strip, widening it. The strip reaches its maximum value at a depth of 120 m below sea level. Closer to the sea, the strip becomes narrower, but with a higher flow velocity representing more sea water flow accumulated. At the sea bottom, this strip is 22 m wide, ranging from $x = -28$ m to $x = -50$ m.

The length of the sea water wedge at the bottom is about 1080 m, with a wide transition zone. The transition zone is practically defined here as the horizontal separation between 0.99 and 0.02 salt mass fraction contour lines. It is about 500 m wide at the aquifer bottom, 700 m wide at 100 m below sea level, and 70 m at the sea level. The 0.5 contour line is close to the separation streamline, although the horizontal separation between them increases with depth. The 0.9 contour line is close to the zero-horizontal-flux line up to the depth of 140 m. This means that sea water is swept away primarily through the small strip between the zero-horizontal-flux line and separation streamline. In addition, a fraction of sea water mass dispersed into the area on the inland side of the separation streamline is swept away with fresh water flow originating in the land-side fresh water zone. In the case of no dispersion, all sea water flow is swept away through the strip between the zero-horizontal-flux line and the separation streamline, whereas fresh water flows to the sea on the inland-side of the separation streamline. This streamline may be considered as the sharp interface between sea water and fresh water. In the case in which fresh water and sea water are under hydrodynamic conditions, the zero-horizontal-flux line is different from the separation streamline, forming the pathway for recirculating sea water. Only under the Ghyben–Herzberg

assumption of hydrostatic pressure of sea water in a sharp interface model, is the zero-horizontal-flux line identical to the separation streamline, because no sea water flow is involved.

In addition to the steady-state solution of sea water intrusion in a confined aquifer, local sea water upconing induced by pumping from a well located at some distance above the interface zone, and the decay of the upconed transition zone after the well's shut-off is also simulated. The pumping well is located above the transition zone at $x = 706$ m, and is screened from -24 m to -40 m below sea level. A time-dependent pumping rate is used: a constant rate of $3000 \text{ m}^3/\text{day}$ is specified before the salt mass fraction in the pumped water reaches 3% of sea water; a constant rate of zero is specified after the well's shutoff. The transient density-dependent flow and salt transport is simulated for the upconing process under pumping and for the decay process after the well's shutoff, for a total of 13 yr. Note that this single well in the investigated aquifer strip really represents a well in an array of wells parallel to the sea spaced 1000 m apart.

Figure 12.8 shows the groundwater flow in the vertical cross section, with reference hydraulic head, streamlines, and salt mass fraction, as produced by the pumping well at the end of 8.9 yr; at that time, the mass fraction in the pumped water reaches 3% of sea water. The pumping reduces the hydraulic head at the well's screen, inducing fresh water flow toward it. In this vertical cross section, we note that most of the fresh water that enters through the land-side boundary is intercepted by the pumping well (see the capture zone shown in Figure 12.8), although only 30% of the total fresh water flow (in 3D) is intercepted and pumped out by the well. There is still a thin zone of fresh water flowing from the land-side boundary to the sea between the streamline originating immediately below the capture zone and the separation streamline. In the vicinity of the well of this thin zone, the pumping leads to a higher vertical velocity beneath the well, above the separation streamline. The pumping also reduces the hydraulic head in the area inland of the well. As a result, the separation streamline moves upward by approximately 30 m at $x = 706$ m, from the steady-state condition to its position at the end of 8.9 yr from the beginning of pumping. As the boundary condition at the sea bottom and the vertical sea-side boundary remains unchanged, a higher total sea water flow rate occurs under the pumping condition, resulting in more salt mass stored in the aquifer in the form of the salt upconed zone and within the intruding sea water wedge.

Above the separation streamline, a zone of sea water upconing toward the pumping well occurs. For example, the 5% iso-salinity contour reaches the lower portion of the well's screen, whereas the 10% contour is close to the pumping well, when salt mass fraction in the pumped water reaches 3% at the end of 8.9 years. The apparent shape of upconing sea water can be seen for lower iso-salinity contours, whereas higher iso-salinity contours (say, 30%) do not show the shape of upconing. This is consistent with the findings of Zhou et al. (2005). The development of the upconed sea water zone toward the pumping well depends on both advection and dispersion. The iso-salinity contours of lower salt mass fraction are similar to the streamlines; this is particularly true in the vicinity of the pumping well. The higher vertical velocity brings mixed water of higher salt mass fraction to the areas close to the well. However, advection alone is not sufficient to salinify the pumping well, because no streamline originating at the sea reaches the well and the well is far above the separation streamline. Dispersion also plays a key role in salinizing the well. A transition zone, with mixed water far above the separation streamline provides a possibility for the well to be more easily salinized than under the sharp interface condition. Both advection and dispersion contribute to the increase in the salinity of the pumped water, as described by the transition zone model.

The pumping also induces some additional regional sea water intrusion. For example, the 50% iso-salinity contour moves further landward by 90 m at the aquifer bottom. Other higher-mass fraction iso-salinity (say, 0.9) contours also slightly move landward, although the width of the transition zone in terms of high mass fraction (say, from 99 to 30%) remains unchanged. This is unlike the transition zone for lower mass fractions (say $\leq 30\%$), which changes significantly as a result of pumping. The separation streamline also moves toward the pumping well, with a small upconed zone beneath the pumping well. However, this upconing is far less significant than that of the lower mass fraction contours. The latter is critical for the salinization of pumping wells in coastal aquifers. This may also indicate that a sharp interface model may significantly overestimate the critical pumping rate.

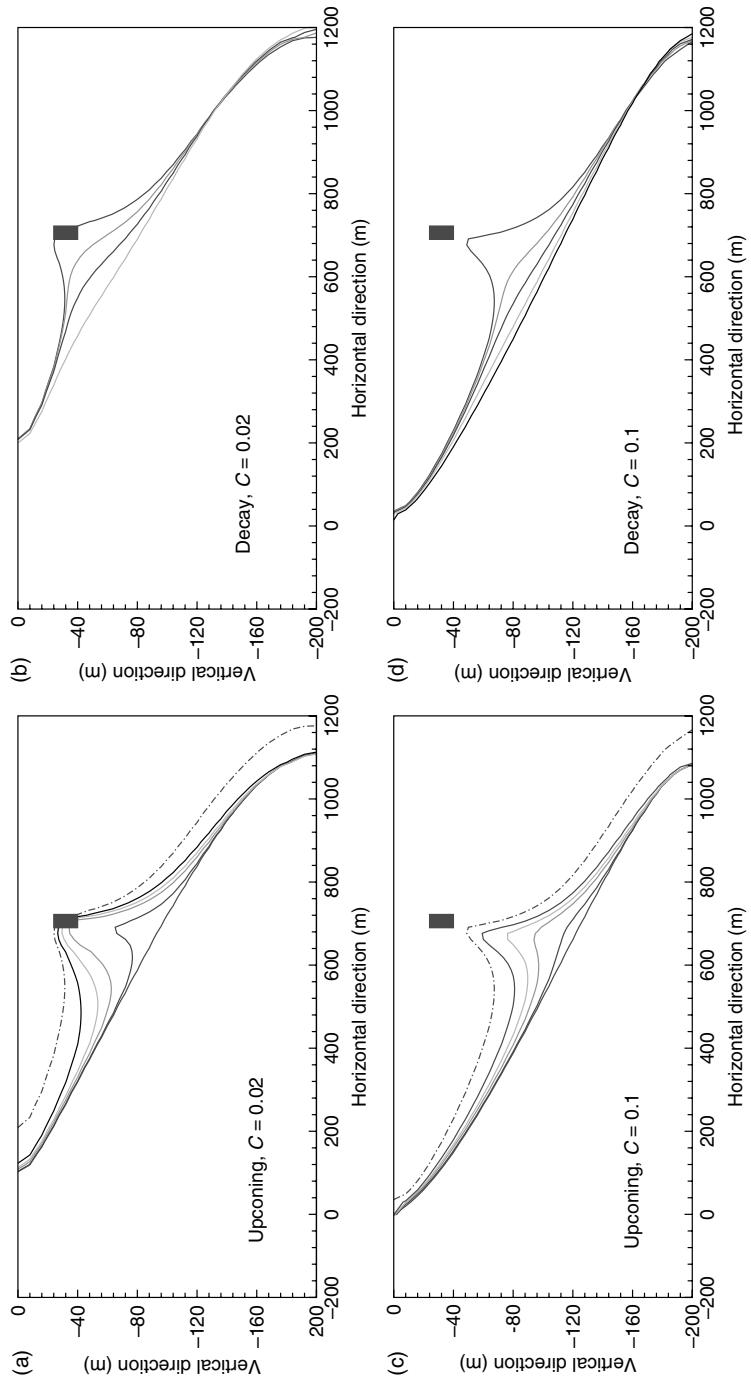

FIGURE 12.9 (See color insert following page 23-52) Transient upconing and decay processes in a confined aquifer (Example B). The times for the upconing process are 53, 239, 439, 839, and 3239 days (well's shutoff), and 3239, 3439, 3639, 4039, and 4639 days for the decay process, all from the beginning of the pumping.

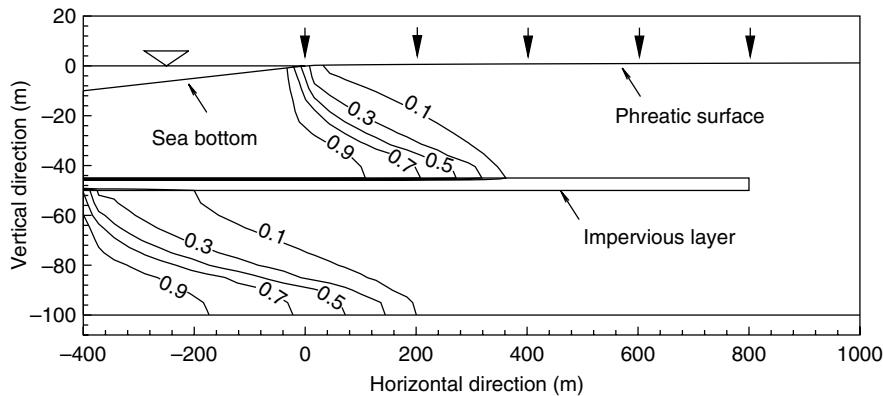

FIGURE 12.10 Steady-state solution of the multiple sea water wedges in a double-layered phreatic aquifer (Example C).

As shown in Figure 12.9, at the early stage of upconing, the mixed water of low mass fractions upcones toward the pumping well more significantly than the rise of the higher mass fraction contours. During this stage, only the mixed water in the vicinity of the well, is affected by pumping whereas the mixed water in the area close to the aquifer bottom and that close to the coast does not change significantly. This is because pumping above the transition zone lowers the hydraulic head on its land-side, and this does not change the balance between fresh water and sea water at the toe of the separation streamline. The enhanced sea water flow from the sea brings more sea water to the upconed sea water zone. This gradually increases the hydraulic head below the transition zone. In the second stage, the increase in hydraulic head by the upconed sea water violates the gradient balance at the toe, thus leading to additional regional sea water intrusion. Following the well's shutdown, the sea water upconed zone is swept seaward quickly because of the strong fresh water flow. The upconing occurs beneath the pumping well, although it slightly extends to its sea side, whereas the decay process occurs primarily by the seaward sweep. Particularly interesting is the observation that four years after the well's shutdown, the intruding sea water wedge in the lower portion of the aquifer has not changed significantly. This may indicate that the recovery of the aquifer from the upconing is slow, although it will eventually be completely recovered (Bear et al., 2001).

12.4.3 Example C: Sea Water Intrusion in a Double-Layered Aquifer

This example simulates sea water intrusion in a double-layered aquifer. An impervious layer extends from the sea-side boundary to 800 m inland from the coast. The layer, about 5 m thick, is located in the middle of the phreatic aquifer. This aquifer is 4000 m long, and 100 m thick. The bottom is a horizontal surface, while the top is the ground surface with the phreatic surface below it. The replenishment of a rate of 50 mm/yr is specified on the phreatic surface, and a flow rate of 0.01 m/day is specified on the land-side boundary. The other flow boundary condition is the same as in Example A. The transport condition on the vertical sea-side boundary and the sea bottom is specified as the mixed-type condition (Equation 12.27). The aquifer properties remain unchanged from Example A.

Figure 12.10 shows the steady-state solution of sea water intrusion in the double-layered phreatic aquifer. We observe two sea water wedges, separated by the impervious layer. As the flow conditions at the seaside boundary are different for the upper phreatic aquifer and the lower confined one, their reference head fields are different. A higher reference head occurs in the lower confined aquifer.

12.5 Introduction to the Management of a Coastal Aquifer

Management of a considered system means making decisions concerning the planning and operation of the system to achieve specified goals, without violating technical and non-technical constraints imposed on the

managed system. The objectives and constraints are dictated by the *policy* that governs the management of the system. An aquifer should be regarded as a system that has to be managed. Depending on the prevailing (say, regional or national) water policy, a considered aquifer may be managed as a stand-alone system, or as an element in a large water resources system that may include a number of aquifers and surface water sources that are managed as a single system. Treated sewage and desalinated sea water, or brackish water, may also constitute sources of water in the system. In such a system, water from one area may be transported and supplied in another area, and water from one source, say a surface water source, may be conveyed to be artificially injected into an aquifer (e.g., for storage purposes), in the same or in another region, to improve the overall efficiency of the considered water resources system.

Strictly, management of an aquifer means making decisions concerning the pumping and artificial recharge of the aquifer — total volume of annual withdrawal, rates, and location of wells, quality of pumped water, and the like, subject to imposed technical and non-technical constraints. These decisions are made so as to maximize or minimize the *objective function* (or functions in a multi-objective case) dictated by the imposed policy.

Examples of possible objective functions are:

- Maximize the sustainable yield of the aquifer.
- Minimize the cost of supplying the specified demand for water of a given population.

Here, *sustainable yield* of an aquifer is the annual quantity of water that can be withdrawn from the aquifer, *year after year*, as a constant volume, or as one that varies according to some rule, without violating specified constraints, especially *that the source will be preserved (quality and quantity) forever*.

Examples of possible constraints are:

- Dictated range of allowed water levels (may vary with location).
- Minimum spring discharge, or discharge to wetlands, to a stream or to a lake.
- Maximum permissible salt concentration (may vary with location) in pumped water, or in the aquifer.
- Maximum cost of supplied unit volume of water.

Examples of non-technical constraints are:

- Water rights and legal aspects.
- Allocation of water to consumers according to sector/region/type of users.
- Maximum costs, limited budget, and other economic considerations.

The management of a considered aquifer requires a calibrated hydrogeological model that describes flow and solute/contaminant transport phenomena that take place in it. This model will provide the response of the aquifer to any proposed management scheme, thus enabling the planner or decision maker to eliminate those schemes that violate the imposed constraints, and to evaluate each proposed management scheme in terms of the objective function. In fact, satisfying the flow and transport model constitutes a constraint in the management model. Unfortunately, a practical management model that incorporates this constraint is still missing and trial and error approaches are often employed. Having a calibrated hydrogeological model for a given aquifer means (1) having a good conceptual-mathematical-numerical model and a verified computer code to solve it, and (2) sufficient data to perform model calibration (=parameter estimation).

An important outcome of aquifer calibration is an estimate of the natural replenishment, whether from precipitation, as inflow through aquifer boundaries, say, from adjacent aquifers, or as inflow from streams and lakes. The replenishment may be estimated as some average value, as statistics of values, or as a relationship to precipitation (for which measured information is, usually, more readily available). Under certain conditions, the inflow from adjacent aquifers can be related to water levels in these aquifers. Knowledge of the natural replenishment is essential for determining the sustainable yield of a considered aquifer. In principle, unless imported water is added by artificial recharge techniques, in the long run, the

sustainable yield cannot exceed the natural replenishment. In fact, it must be lower, as we must allow for flushing of accumulated salts/contaminants.

With these introductory remarks in mind, let us now consider the management of a coastal aquifer. As already emphasized above, essentially, the basic approach to the management of a coastal aquifer is the same as for any other aquifer, except that the presence of the sea constitutes a continuous threat to the quality of groundwater in the vicinity of the sea through the mechanism of *sea water intrusion* (Emch and Yeh, 1998; Das and Datta, 1999; Rao et al., 2004). We shall focus on the aquifer as a stand-alone system.

In a coastal aquifer, the sustainable yield is determined so as to allow the interface (= interface zone) to encroach up to some predetermined optimal distance. The management approach should be seeking to optimize sea water intrusion according to some objective function and specified constraints, rather than to stem sea water intrusion.

For the sake of simplicity, let us assume steady flow, a sharp interface, and the Ghyben–Herzberg relationship (equivalent to the assumption of essentially horizontal flow) between the elevations above sea level of the water table in a phreatic aquifer and the depth of the interface below sea level. In this simplified Ghyben–Herzberg model, presented in Section 12.1, the volume of fresh water displaced by the advancing interface between two steady states is equal to 40 times (when density of fresh water and sea water is 1.000 and 1.025 g/cm³, respectively), the volume of water between the two steady states of the water table. Thus, for the interface to advance, large quantities of ground water (between the initial and final interfaces) have to be removed from the aquifer. In reality, however, under unsteady flow conditions, if we start from some steady state, the changes in water table elevations, say in response to excessive pumping — annual or a long-term trend — are much faster, with a corresponding rise of the interface.

As emphasized above, the extent of sea water intrusion is dictated by the level of withdrawal from the aquifer. As such, it is a decision variable in the management problem. With this in mind, a coastal aquifer may be in one of three situations:

- *Virgin conditions.* (Practically) no pumping and no/little sea water intrusion takes place. We wish to develop the aquifer by pumping up to its full or optimal (sustainable) yield, with/without artificial recharge (assuming that the natural replenishment is known).
- *Developing conditions.* Pumping and sea water intrusion take place, but no wells have been salinized (yet). We wish to continue to operate the aquifer and develop it up to its sustainable yield. We may need more wells, or move wells to new locations.
- *Excessive sea water intrusion conditions.* Withdrawal exceeds sustainable yield, and significant sea water intrusion takes place. Some wells have already been salinized. We wish to restore the aquifer to sustainable yield conditions.

In the first and second cases, withdrawal can be increased up to the estimated sustained yield. In fact, as explained earlier, for a number of years, the withdrawal may exceed the ultimate sustainable yield (obviously, if consumers are available). We often refer to this excess pumping as “pumping the one-time-reserve.” In the third case, withdrawal has to be reduced. To speed up restoration, withdrawal may at first, and for some years, be reduced to below sustainable yield, or artificial recharge increased. We have to take into account two important factors characterizing the restoration process:

- Changes in the position of the interface are slow, so that the restoration to sustainable yield with an optimal position of the interface may take many years.
- Furthermore, as in reality no sharp interface exists, as the transition zone moves seaward, it tends to widen, and it may take a very long period to really flush the saline water and reduce salinity near the coast to desirable levels (Bear et al., 2001).

An important feature that should not be overlooked stems from the fact that as the transition zone retreats, and fresh water replaces saline water in the void space, the clay fraction of the soil disperses, and the permeability is reduced.

As emphasized above, the extent of sea water intrusion depends on the flow rate of fresh water allowed to discharge to the sea. Obviously, this discharge means maintaining an appropriate seaward gradient

of water levels (or, piezometric heads in a confined aquifer). By maintaining an appropriate water table elevation at a certain distance from the sea, we can arrest the intruding sea water wedge at that (optimal) distance from the sea, thus preventing the wedge from advancing farther inland. Beyond the “fresh water mound” that can be maintained at a desired distance from the sea, we can manage the aquifer with water levels fluctuating above and even below sea level. Obviously, the issue is, then, how to maintain this mound. One obvious way is to control pumping so as to allow a certain fresh water discharge to the sea. Another option is to maintain the mound by artificial recharge through infiltration basins or an array of wells along a line parallel to the coast at the desired distance from the coast. Recharge can be implemented with imported water from other regions, and even by treated sewage (obviously, taking into account that part of the water will also flow landward).

Other “engineering” techniques have been proposed from time to time for controlling, and even preventing sea water intrusion. Among them we can mention a “trough” parallel to the coast, produced by pumping (Huisman and Olsthoorn, 1983), and an impervious or semi-pervious barrier constructed by various geomechanical techniques parallel to the coast (Todd, 1980). The latter will be effective only if it extends over a significant length.

A well located above the sea water wedge, usually, pumps saline water, even when its screen is located at some distance above the interface (or transition zone). This is due to the phenomenon known as interface “upconing.” However, if the screen is sufficiently high and the rate of pumping sufficiently small, the well will pump fresh water, thus reducing the actual discharge to the sea. In Israel, this technique — called “coastal collector” — takes the form of an array of low discharge shallow wells along a line located at a rather small distance from the sea.

As emphasized above, many coastal aquifers are contaminated from point and distributed sources at ground surface. Furthermore, groundwater in coastal aquifers, especially close to the coast, is, to some extent, saline, because of airborne salts originating in the sea. Aquifer water draining to the sea will prevent the accumulation of salts and other contaminants in the aquifer. The management of the aquifer should take this aspect into account. However, there is no need to elaborate on this topic, as, with respect to contamination, the coastal aquifer is not different from any other aquifer (except for the differences already mentioned earlier). Because of the threat to water quality in the underlying aquifer, there is a strong interaction between aquifer management and issues related to land use, with the objective of minimizing the threat to groundwater quality.

To summarize, the management of a coastal aquifer requires a calibrated model of the hydrogeology of the aquifer, preferably a 3D variable density flow and transport model. Such models are readily available nowadays. The selected management scheme should be based on an objective function and constraints dictated by the policy established within the framework of some system higher in the hierarchy, for example, the regional or national one. **The basic feature of management of a coastal aquifer is the determination of a sustainable yield that will arrest the sea water wedge at a desired distance from the sea by allowing a certain discharge of fresh water to the sea. A fresh water mound and a coastal collector are useful tools for increasing the efficiency of aquifer management.**

Glossary

Coastal aquifer management Determining the spatial distribution of water withdrawal and artificial recharge in a costal aquifer, as well as the quality of the pumped water, taking into account the relationship between the extent of sea water intrusion and the rate of fresh water discharge to the sea.

Coastal collector An array of pumping wells parallel to the coast, at a rather small distance from the latter, and with screens located at some distance above the assumed sharp interface (or the transition zone), such that when they pump at a sufficiently small rate, they do not become salinized by the upconing interface.

Density difference factor The ratio of density difference between (pure) sea water and fresh water to the density of fresh water.

Fresh water Water in a coastal aquifer, at a sufficient distance from the coast such that its salinity is not affected by the presence of sea water.

Ghyben–Herzberg assumption The assumption that in the region of sea water intrusion, with a sharp interface separating between the fresh water and the sea water bodies, fresh water equipotentials are vertical (i.e., flow is horizontal) and sea water is stationary. This leads to a fixed ratio between the elevation of the water table (or piezometric head in a confined aquifer) and the depth of the interface at that point, which depends on the density of sea water.

Reference piezometric head The piezometric head, with the density taken as some reference density, usually that of fresh water.

Sharp interface approximation The assumption that, although fresh water and sea water are miscible fluids, the body of fresh water and that of sea water in a coastal aquifer are separated by a sharp surface.

Sea water intrusion The intrusion (or additional intrusion) of sea water into a coastal aquifer as a consequence of a reduction in the fresh water flow discharged to the sea.

Sea water wedge The shape of the stationary (or steady state) body of sea water intruding into a coastal aquifer, under the sharp interface approximation

Separation streamline The 3D surface that sharply separates between streamlines originating from the inland fresh water zone and recirculating streamlines originating from the sea water zone. This separation surface is located within the transition zone. In the sharp interface approximation, the separation streamline coincides with the sharp interface.

Transition zone The zone in a coastal aquifer across which the salinity of the water varies from that of fresh water to that of sea water.

Upconing The rise of an assumed sharp interface, or of a transition zone, towards a well that pumps water from a coastal aquifer, with its screen located above that interface or transition zone.

Variable density flow Flow in a porous medium domain, in which the determination of the flux takes into account that the fluid's density depends, among other factors, on the concentration of total dissolved salts.

Zero-horizontal-flux surface The surface of zero horizontal flux, separating between the seaward and landward horizontal components of flow. The upward vertical flow through this surface eventually moves toward the sea through the volume between this surface and the overlying separation streamline surface.

Acknowledgment

The authors wish to thank Dr. Christian Langevin of the USGS for his useful review comments and suggestion, which helped us to improve this chapter. Thanks are also due to Dr. Jacob Bensabat, EWRE, who allowed us to use the FEAS code, developed jointly by Drs. Quanlin Zhou and Jacob Bensabat, for the simulation of the typical sea water intrusion cases presented in this chapter.

Further Information

The conceptual and mathematical modeling based on the sharp interface assumption can be found in many text books. Examples are Bear (1972, 1979) and Bear and Verruijt (1987). Recent applications of mathematical and numerical modeling to sea water intrusion in coastal aquifers can be found in the books of Bear et al. (1999) and Cheng and Ouazar (2004).

The FEAS code used for the typical examples in this chapter is a finite element aquifer simulator for sea water intrusion and brine transport in 2D and 3D aquifers. It can also be used to simulate coupled groundwater flow and heat transport, and multiphase flow for dense nonaqueous phase liquids (DNAPL) migration (as well as decoupled groundwater flow and solute transport in confined and unconfined aquifers). The application of FEAS to practical problems includes both sea water intrusion (Bear et al., 2001) and upconing (Zhou et al., 2005), and DNAPL migration in heterogeneous porous media (Zhou et al., 2002). For further information of the code, please contact Quanlin Zhou at Lawrence Berkeley National Laboratory or Jacob Bensabat at Environmental and Water Resources Engineering Inc., PO Box 6770, Haifa, 31067, Israel.

13.1 Introduction

Groundwater flow and heat flow are similar in that they both require gradients (hydraulic and thermal, respectively), hydraulic conductivity, and thermal conductivity, and both are assumed to take place

in a continuum in most conditions. Due to the similarities, both processes can be explained by very similar equations. Early investigators visualized these similarities and applied the already-established thermodynamic theories of Fourier and Newton to groundwater flow.

Thiem (1906) formulated equations of steady-state groundwater flow based on Fourier's steady-state equations of heat flow. Theis (1935) derived his famous similarity solution to the non-equilibrium diffusion equation for groundwater flow (Domenico and Schwartz, 1990) that had the same structure as the non-equilibrium heat flow equation as given by Fourier's similarity solution for non-equilibrium heat flow (Carslaw and Jeager, 1959; Ozisik, 1968). Aside from the historically and academically interesting parallels between the equations for both heat flow in solids (treated as a continuum) and groundwater flow in porous media (also treated as a continuum), there are applications of great practical importance and interest of groundwater flow and heat flow. Notable among these are: (1) groundwater flow and heat flow to streams and lakes, (2) heat flow in groundwater by advection and convection, (3) heat in groundwater and geochemical reactions including mineral deposition, (4) locating groundwater resources by heat profiles over an area, (5) estimating groundwater and contaminant velocities by temperature profiles in boreholes, (6) locating different aquifers by temperature profiling in boreholes, and (7) locating and analyzing geothermal heat resources for energy production.

13.2 Basic Thermodynamics

13.2.1 Heat as Energy

Energy is defined as the ability to produce change (e.g., do work), and work is expended energy (Leap, 2003). Potential energy is defined as energy available to do work but in storage, waiting to be used. The heat content (amount of heat energy) in a solid or fluid is most often measured by *temperature*—defined as the average kinetic energy of the particles in the solid or fluid being measured.

13.2.2 Temperature: Celsius and Fahrenheit

Temperature is measured by thermometers graded in the Celsius (formerly called “centigrade”) or Fahrenheit scale, or both. German-born scientist Gabriel Daniel Fahrenheit developed his scale in 1706 and Swedish astronomer Anders Celsius developed his in 1742 (Wilson and Arnold, 1958). The Fahrenheit scale is in common use in English-speaking countries, but not in England itself which now uses the Celsius scale as its primary temperature scale.

In the Fahrenheit scale, the freezing point of water is -32°F and the boiling point of water is 212°F . In the Celsius scale, the freezing point of water is 0°C and its boiling point is 100°C . Conversion from one scale to another can be accomplished by the formulas (Halliday and Resnick, 1970):

$$\text{Celsius to Fahrenheit} \quad T_{\text{F}} = 32^{\circ}\text{F} + (9/5)T_{\text{C}} \quad (13.1\text{a})$$

$$\text{Fahrenheit to Celsius} \quad T_{\text{C}} = (T_{\text{F}} - 32^{\circ}\text{F})/(9/5) \quad (13.1\text{b})$$

where C is Celsius, F is Fahrenheit, T_{F} is Fahrenheit temperature, and T_{C} is Celsius temperature.

A third temperature scale, the Kelvin scale, was invented in the 19th century by the English physicist, William Thompson who later became Lord Kelvin. This scale is used mostly in scientific work where it can be applied to entities having extremely wide ranges in temperature. This scale is also called the Absolute Thermodynamic Temperature Scale and has for its zero a temperature so cold that it is assumed that no heat energy whatsoever exists in the material being measured. Temperatures lower than this do not exist (Halliday and Resnick, 1970). On the Kelvin scale, water boils at 373.16°K and freezes at 273.16°K .

The Kelvin and Celsius scales are related by the formulas (Leap, 2003):

$$T_C = T_K - 273.16 \quad (13.2a)$$

and

$$T_K = T_C + 273.16 \quad (13.2b)$$

where T_K is temperature in degrees Kelvin.

13.2.3 Heat Units: Calories and British Thermal Units

The actual quantity of heat energy in a solid, liquid, or gas is given in both scientific and engineering units. Scientists more often use the term, calorie (cal) and engineers the term, British Thermal Unit (BTU). One calorie is the quantity of added heat that will raise the temperature of one gram of water from 14.5 to 15.5°C. Likewise, a kilocalorie (Kcal) is 1000 calories and that amount of heat will raise the temperature of one kilogram of water by one degree between the same temperature ranges. It is of interest to note that a calorie as a measure of food energy is actually a kilocalorie.

One BTU is the amount of added heat that will raise the temperature of one pound of water from 63 to 64°F. The relation between BTU's and calories is given by

$$1.000 \text{ Kcal} = 1000 \text{ cal} = 3.968 \text{ BTU} \quad (13.3)$$

13.2.4 Thermal Conductivity

Like hydraulic conductivity that expresses the ease with which a porous medium will transmit water, thermal conductivity (k) expresses the ease with which a solid, liquid, or gas transmits heat. Both porous media and heat-conducting media are considered to be continua. Hydraulic conductivity has the dimension of L/T where L is length and T is time. Thermal conductivity has the dimension of Kcal/sec meter°C.

13.2.5 Thermal Resistivity

Just as hydraulic resistivity is the inverse of hydraulic conductivity (K),

$$R_H = 1/K \quad (13.4)$$

the inverse of thermal conductivity is thermal resistivity, that is,

$$R_T = 1/k \quad (13.5)$$

13.2.6 Specific Heat of Water

The heat capacity of a substance is the quantity of heat (Q) added to the substance per unit temperature rise (ΔT), that is,

$$c = \text{heat capacity/mass} = \Delta Q/m\Delta T \quad (13.6)$$

The specific heat of water is 1 cal/g which is very high when compared with other liquids (Table 13.1).

TABLE 13.1 Comparison of Specific Heats of Various Substances.

Substance	Specific Heat (cal/g/°C)
Water	1.00
Alcohol	0.58
Sugar	0.27
Aluminum	0.21
Marble	0.21

13.2.7 Three-Dimensional Hexagonal Structure of Water

Water, H₂O, exists in the fluid state as a three-dimensional (3-D) lattice of molecules (Stowe, 1996). As water cools, the structure becomes more ordered and the molecules are closer together so that at the temperature of 4°C, water not yet frozen is at its most dense state of 1 g/cm³. As water becomes even colder and then freezes at 0°C, the 3D lattices expand slightly to accommodate a more orderly 3D lattice for the solid state. As a result, the ice is less dense than very cold not-yet-frozen water.

In the near-frozen state a little above 4°C, all the hexagons are not ordered, but in the frozen state, they are all locked together. As ice freezes and the 3D hexagon structures expand, there is created an intramolecular “porosity” that is greater than that of the unfrozen state. This increase of porosity makes ice less dense than liquid water and this is the reason that ice floats in water; the density of water is 1.00 g/cm³ and that of ice is 0.92 g/cm³.

13.2.8 Thermal Inertia

The high thermal inertia of water means that it will not warm fast due to the high amount of heat energy required to warm it. Likewise, it will not cool as fast as other liquids.

This property causes water in the seas, large rivers, and large lakes to have a moderating effect on the climate of lands that border them. Similarly, cool water pumped into aquifers in winter months gains little heat so that it is still cool for use in air-conditioning systems in the summer. This is due to the facts that (1) water has high thermal inertia, and (2) earth materials are poor conductors of heat that help to keep stored groundwater cool.

13.2.9 Viscosity and Heat

Dynamic viscosity, also called absolute viscosity, is defined as the resistance to shearing force by flowing liquids. This concept is demonstrated by moving one of two parallel plates separated by a fluid. Dynamic viscosity, μ , is given by

$$\mu = \tau / (dv/dy) \quad (13.7)$$

where τ is the shearing stress, v is the velocity of the upper and movable plate, and y is the vertical distance between the two parallel plates. Kinematic viscosity, ν , is defined as the dynamic viscosity of a fluid divided by the fluid's density, ρ :

$$\nu = \mu / \rho \quad (13.8)$$

This term is used primarily in the flow of gases in which density may change with flow whereas dynamic viscosity is used primarily in the flow of liquids.

Dimensions of dynamic viscosity are lb sec/ft² and those of kinematic viscosity are ft²/sec. Viscosity decreases with increasing temperature.

13.2.10 Relationship Between Thermal Energy and Mechanical Energy (Joule's Experiments)

James Joule (1818–1889) was an English physicist who proved the relationship between heat and mechanical energy by a series of ingenious experiments. He devised a series of paddle wheels in a container of water that were rotated by falling weights of known mass connected to pulleys that caused the paddle wheels to rotate when the weights were dropped. By measuring the temperature of the water before and after the weights fell and turned the paddle wheels, he was able to show the mechanical energy of the falling weights in terms of foot-pounds to the increase of temperature of the water. His experimental error was only 5% — remarkable for his day.

Today, scientists agree that 1 Kcal = 1000 cal = 4186 J, and 4186 J of mechanical energy will raise the temperature of 1 Kg of water from 14.5 to 15.5°C, the same amount raised by 1000 calories of heat (Halliday and Resnick, 1970). Therefore, water flowing in a surface stream or through porous media will be heated by the mechanical action of flow.

13.3 Flow of Heat

13.3.1 Thermal Gradients

The thermal gradient, dT/dx , is the rate of change of temperature with distance through a substance and k is the thermal conductivity or the ease with which the substance transmits heat; this term is discussed below.

From Equation 13.6, one can readily understand the similarities between the mathematical description of heat flow through a continuum and that of water through a continuum by the following 1D unidirectional, steady-state flow of water through a porous medium

$$dQ/dt = KA dH/dx \quad (13.9)$$

where dQ/dt is the volume of water flowing per unit time perpendicular to a unit area, A , H is the hydraulic head, K is the hydraulic conductivity, and dH/dx is the hydraulic gradient. Similarities also exist for transient flow and non-uniform flow of heat and water.

13.3.2 Heat Flux

Heat flux is simply the amount of calories of heat energy flowing perpendicular to a unit area that is perpendicular to the direction of heat flow.

13.3.3 Conduction of Heat

Heat is conducted by different substances at different rates depending upon the thermal conductivity of the substance and the thermal gradient through it. Rocks and soil are poor conductors of heat whereas, water conducts heat much faster. This is the reason the interior of Earth is so hot — rocks do not conduct heat fast enough to make it cooler.

13.3.4 Convection of Heat

As opposed to conduction of heat, convection of heat is heat transport by the actual movement of heated fluids such as gases and liquids. In this process, unlike conduction, heat can be transported

from a region of lower temperature to a region of higher temperature if the heated fluid flow is in that direction. Conduction of heat only takes place from a region of higher temperature to a region of lower temperature.

Modern geothermal heating systems employ convection to pump naturally warmer air or water from the atmosphere or groundwater reservoirs respectively into heating systems within buildings. Such systems are known as “heat-pump systems.”

13.3.5 Advection versus Convection

The terms, *advection* and *convection* are often confused and interchanged. “Convection” should be applied to movement of heat as just described and “advection” should be applied to movement of groundwater through porous media and transport of dissolved chemicals and contaminants within it.

13.3.6 Diffusion of Heat

Historically, *diffusion* referred to conduction of heat through a continuum such as a solid or liquid. The work and terminology of the French scientist, John Joseph Fourier (born 1768) carried through to the time of Theis (1935) when he developed the similarity solution (Theis solution) to the non-equilibrium “diffusion equation,” earlier called the Fourier Equation for the diffusion of heat.

Therefore, the difference between the “diffusion” of heat and the “conduction” of heat must be addressed here. In his 1807 work, Fourier showed that heat flux, q , should be proportional to the temperature gradient, dT/dx . $Q = -kdT/dx$ and k is “thermal conductivity” (Cussler, 1984). This relationship is closely parallel to Fick’s First Law of chemical diffusion (mass transport)

$$F = -D dC/dx \quad (13.10)$$

where F is the mass flux of a solute per unit area per unit time, D is the diffusion coefficient for the particular solute (area/time), C is the solute concentration, and dC/dx is the concentration gradient (mass/volume/distancce).

If concentration is changing with time, Fick’s second law is used:

$$\partial C/\partial t = D(\partial^2 C/\partial x^2) \quad (13.11)$$

and thus, it is apparent why early groundwater flow equations were called “diffusion equations.”

Today in the science of hydrogeology, including groundwater flow, the term “diffusion” is generally reserved for the actual molecular diffusion of solute along a concentration gradient. Conduction or conductance is generally applied to heat transport under a thermal gradient and “mass transport” is understood to mean the movement of solutes by both advection along a hydraulic gradient and molecular diffusion along a concentration gradient.

13.4 Sources of Heat Flow to and from Earth’s Surface

13.4.1 Solar Radiation

Heat energy from the Sun heats Earth by solar radiation. This radiation includes all wavelengths in the electromagnetic spectrum from long radio waves of 3 m to gamma rays of 10^{-12} m. The human eye can detect only radiation in the visible spectrum (i.e., white light).

Not all solar radiation reaching Earth’s atmosphere actually warms the surface. Only 50% reaches the surface and is absorbed by it. The remaining 50% is lost by backscattering into space, reflection by

TABLE 13.2 Concentric Layers of the Earth

Layer	Depth (Km)	Density Range (g/cm ³)	Average Density
Crust	0–30	2.5–3.3	2.8
Mantle	30–290	3.3–5.7	4.5
Outer Core	2900–5100	9.4–14.2	11.8
Inner Core	5100–6370	16.8–17.2	7.0

Source: From Leap, 2003, *Natural Sciences, A Study Guide*. The College Network, Indianapolis, IN.

clouds into space, reflection from Earth's surface, and absorption by the atmosphere and clouds (Leap, 2003).

Heat from solar radiation has a minor effect on groundwater. In recharge areas of permeable materials, rain during warm weather can add its heat to water being recharged from the surface to groundwater systems below. In the winter months, recharge is colder. It is for these reasons that near-surface groundwater is warmer during summer than in winter.

Cold recharge water carries greater concentrations of dissolved gases such as oxygen and carbon dioxide. The greater amount of oxygen causes greater oxidation of organic material in the soil and also of metals in mineral matter such as iron and manganese. The carbon dioxide causes increases solution of carbonate minerals.

13.4.2 Geothermal Gradient and Heat Flow

The Earth is composed of four layers as shown in Table 13.2.

The inner core is believed to be solid and the outer core, liquid. The mantle is plastic and deforms from the action of rising heat with consequent convection currents in the mantle. The crust is mainly solid except for a few isolated volcanic regions and perhaps some isolated pockets of magma that extend into the lower crust from the mantle.

The high densities of both the inner core and outer core and the increasing density from the surface to the core suggest that heavier elements such as mostly iron and nickel migrated toward the center of Earth while it was in a molten state. Along with these heavy elements, even heavier uranium also migrated downward.

The heat generated within Earth comes from (a) residual heat left over from Earth's formation, (b) heat from increasing pressure with depth, and most importantly, (c) heat from fission of radioactive elements such as uranium. Rocks have relatively low thermal conductivity and Earth releases its heat slowly. Nevertheless, it is this internal heat that causes rocks to melt in the mantle and causes convection currents in the mantle that then bring heat nearer to the surface to be released in localized areas from terrestrial and marine volcanoes and mid-ocean rifts. It is also Earth's internal heat that is the greatest source of heat in groundwater.

From the interior of Earth to its surface there is a geothermal gradient as heat is conducted to the surface. In the United States, the geothermal gradient varies from about 12 to 47°C (53 to 116°F) per kilometer (Keller, 2002). This gradient causes deeper groundwater in the United States to have an ambient year-round average temperature of about 13°C east of the Rocky Mountains. The steeper the geothermal gradient, the closer the hot rock is to the surface and the greater the flux of heat to the surface.

East of the Rocky Mountains the flux of heat to the surface is approximately 50 mW/m². However, in the Rocky Mountains and the coastal ranges of California, Oregon, and Washington heat flux ranges from 40 to 60 mW/m². Throughout most of the West, the flux varies from 60 to 100 mW/m² and in certain places, namely northern Nevada, the Cascade Mountains, the Geysers north of San Francisco, and several other isolated spots, the flux is greater than 100 mW/m² (Duffield et al., 1994).

13.4.3 Hydrothermal Activity

Where large fluxes of heat occur, groundwater is definitely warmer than in low-flux areas and often very hot. Heat is transmitted to aquifers by (1) direct conduction through rocks, especially water-saturated rocks from magma bodies at depth, and (2) by recharging surface water that comes into contact with hot rocks and is heated. The latter process is most common in geysers of hot water and steam such as those in Yellowstone National Park in Wyoming and elsewhere.

Hot springs occur in various parts of the United States, even where active volcanic emissions are long past. Some of the heat driving these springs is from past volcanic activity in areas where there is magma closer to the surface than in most areas.

The greatest number of hot springs and geysers are to be found in the western United States where the crust is geologically much younger than in the east and where volcanic activity occurs on a greater scale than in the east.

13.4.4 Geothermal Energy for Electric Power

This source of energy is utilized in areas where groundwater is heated to boiling or near-boiling by coming into contact with magma or with rocks heated by magma due to its close proximity.

The ancient Romans heated their baths and homes with water from hot springs and such uses are found today in Japan, Turkey, and Iceland. Geothermal energy for producing electrical power was first used in Italy in 1904. Electric power plants utilizing geothermal energy are still used today in the United States, New Zealand, Iceland, Mexico, and Japan (Encyclopedia Britanica, 2002).

Keller (2002) and Domenico and Schwartz (1990) discuss two ways in which geothermal energy is utilized to generate electric power with (1) vapor-dominated systems and (2) hot-water dominated systems. In vapor-dominated systems wells are drilled into aquifers sitting above hot magma in which the water is so hot that steam covers the water and is trapped between the water and an overlying layer of low-conductivity material. Extraction wells do not penetrate the hot water, but rather, terminate in the steam zone. The steam is extracted to power the turbines that in turn, spin the generators.

Spent steam is then condensed and the resulting water is then reinjected into the saturated part of the aquifer to be reheated so that new steam may be added to that already in the groundwater system. The hot-water aquifer is recharged naturally by the groundwater having a high hydraulic head in the recharge area.

In a hot-water dominated system, wells tap a hot-water aquifer above a magma body and separated from the magma by sedimentary or crystalline rocks. The hot water is brought to the surface where the pressure lower than in the aquifer, causes steam to escape from the water and the steam then drives turbines which drive generators.

The used water and condensed-steam water is reinjected into the hot groundwater system where it is recycled and reheated to be used again. The number of hot-water dominated systems is about 20 times the number of vapor-dominated systems. The latter kind are not common and have been identified only in the Geysers of California; Mt. Lassen National Park, California; and Yellowstone National Park of Wyoming.

In the United States, total power production from geothermal energy is about 3000 Mega Watts (MW) and more than 90% of this amount is generated in California. Approximately 2000 MW are generated at the Geysers Power Plant 145 Km north of San Francisco that has been in operation for many years (Keller, 2002). A typical geothermal well will produce 5 to 8 MW of power. Geothermal energy is only available as a site-specific source. At the present time, it supplies less than 1% of the electrical power produced in the United States.

Presently, fossil-fuel generated electrical power is less expensive to produce than that from geothermal sources. It is expected that geothermally-generated power is unlikely to exceed 10% of electrical power output in the near future in the United States. However, there are specific places in the United States where geothermal power can be of great utility.

Although the environmental impact of the development of geothermal energy is less troublesome than that of other forms of energy production, there are still environmental problems associated with

geothermal energy (Keller, 2002). Some impacts include gas emissions, on-site noise and land scars, thermal pollution from hot waste waters, and chemical pollution from saline and mineral-laden water.

Reinjecting spent-water back into hot-water aquifers might cause earthquakes. Finally, if too much hot water is withdrawn, it might in some cases cause subsidence of the surface. In spite of these possible, but occasional impacts, it is important to note that the geothermal plants produce less than 1% of nitrogen oxides and only 5% of carbon dioxide produced by coal-burning power plants for the same amount of energy produced (Duffield, et al., 1994). However, geothermal energy does not produce either the atmospheric particulate pollutants associated with use of fossil fuels or radioactive waste (Keller, 2002).

13.4.5 Annual Air-Temperature Changes

Domenico and Schwartz (1990) state that the thermal conductivity of air is only 0.006 cal/msec °C. This value is extremely low when compared with water that has a thermal conductivity of 0.11 cal/msec °C. Therefore, annual air-temperature changes have little or no effect upon groundwater temperatures in more temperate zones, but in high mountains and arctic regions, summer temperatures can cause melting of the upper layers of permafrost that can then re-freeze in colder months. This topic is discussed next.

13.4.6 Permafrost

Permafrost is perennially frozen earth often with included ice lenses that is found in polar latitudes and high mountains. In these areas, the mean annual temperature is low enough to make the ground temperature below 0°C (Fetter, 2001). Warm summer temperatures may cause the upper 1 to 2 m of the soil or rock to thaw and this is then known as the active layer. Below this layer the ground down to 400 m may be frozen and has likely been so since the Pleistocene Epoch (the “Ice Age”).

If such low temperatures and frozen conditions persist for two or more years, the frozen ground is then called permafrost (Cederstrom et al., 1953; Brandon, 1965; Williams, 1970).

At some depth, the maximum annual temperature is 0°C and this depth is called the permafrost table. The local depth of permafrost is dependent upon both the mean air temperature and the geothermal gradient. As a result, here may be some areas where zones of unfrozen ground exist sandwiched between the frozen layers.

Sloan and van Everdingen (1998) discussed in the following paragraphs, state that permafrost under the right temperature may contain a mixture of unfrozen water and ice, or it may contain only ice. The unfrozen water exists as thin films adsorbed on surfaces of mineral particles and the thicknesses of the films are functions of temperature (50 Å or more at 0°C; 9 Å at -5°C; and 3 Å at -193°C). It is nearly independent of the total water content (liquid plus solid), except in very dry soils.

Hydraulic conductivity in permafrost layers is a function of the temperature of the permafrost system, the thermal gradient and the available cross-sectional area of interconnected films of unfrozen water. Movement of groundwater is retarded in movement through permafrost, but permafrost acts more like a semi-confining bed of very low hydraulic conductivity and not like a completely confining bed of zero hydraulic conductivity. If the permafrost layers are fractured significantly, the higher overall hydraulic conductivity can be expected to be much higher than in unfractured permafrost.

Fetter (2001) describes groundwater below permafrost as confined. The permafrost acts as the confining layer and the confined groundwater can be artesian in nature. Saline water may occur below permafrost and is probably due to the fact that in areas where permafrost is continuous such as northern areas of Alaska, Canada, and Russia, the mean annual precipitation can range from 500 mm/yr to less than 100 mm/yr, thus restricting the amount of water available for recharge. Additionally, potential evapotranspiration exceeds precipitation over a large area of the permafrost region.

Fetter also reports that alluvial river valleys are good sources of groundwater in permafrost regions. These areas generally consist of sand and gravel and are generally unfrozen. Alluvium from large rivers will have more unfrozen ground that contains more available water than frozen ground along smaller tributaries and headwater streams.

Alluvial fans at the margins of mountains in Alaska composed of coarse sand and gravel are good sources of groundwater from below the permafrost close to rivers and lakes that may help to keep permafrost absent. Coarse-grained materials do not possess the large area of interconnected ice films on particles as found in small-grained deposits.

South-facing slopes that receive more sunlight than north-facing slopes in permafrost regions tend to be more productive for groundwater development.

13.4.7 Heat Exchange between Surface Water and Groundwater and Effects upon Aquatic Environments

Warm or hot groundwater discharging into a surface stream or lake by base flow can have both detrimental and beneficial effects on aquatic environments. This is especially obvious in geothermal areas like Yellowstone National Park where effluent from hot springs and geysers eventually empty into surface-water bodies. Certain species cannot live in excessively warm temperatures and others do not reproduce and grow well in waters of elevated temperatures; this includes both plant and animal species. However, some thermophilic bacteria such as *Thermus aquaticus* actually thrive in waters with temperatures near the boiling point such as those found in the hot springs of Yellowstone. Indeed the vibrant blue to red color bands observed within the parks, springs, and pools result from the presence of bacteria with varying temperature tolerances.

Rivers and other streams are probably less affected by warm groundwater or surface water discharge into them across the length of their reach as streams with their rather rapid flow rates can often either carry away pulses of warm water discharge or dilute them down to a lower temperature. At the point of discharge, however, warmer waters may be detrimental or beneficial depending on which types of biota are present within the stream.

Impacts are greatest in ponds and wetlands that are mostly nourished by groundwater. If this nourishing groundwater is too warm it can adversely affect or even kill wetland plants and aquatic animal species. It may also help some such as bacteria and algae (that "bloom" under warmer conditions).

For the past 35 yr, there has existed a pond in an abandoned gravel quarry on the campus of Purdue University. An impermeable bottom of clay has caused the pond to form. For many years, warm water from various water-cooled systems such as air conditioners and laboratory equipment has discharged into this pond so that the pond water is often at a temperature of 25°C. This warm water recharges the aquifer through the sides of the pond and the water then is captured by the campus water-supply wells with temperatures of 16 to 17°C, fully 5 to 6 degrees greater than the ambient groundwater temperature. This in turn diminishes the efficiency of water-cooled systems across the campus. The Indiana Department of Environmental Management will not allow the University to ditch the warm pond water to the nearby Wabash River for fear of its possible adverse impact on aquatic life in the river. Warm water from industrial plants, even though injected into the ground may find its way into surface-water bodies.

13.4.8 Effects of Groundwater-Transported Heat upon Hydrogeochemistry

In general, warmer groundwater will increase chemical activity and will cause greater dissolution of minerals in the rocks and soil through which it passes. This is especially true of minerals containing silica or silicates as well as others.

However, warm water will decrease solubility of other minerals containing carbonate as colder water will contain more dissolved carbon dioxide (CO_2) and will produce more carbonic acid (H_2CO_3) for dissolution of these minerals.

Warmer waters may actually result in degassing of CO_2 which in turn can cause mineral precipitation. If warmer groundwater moves toward the Earth's surface from great depth, as in volcanic or geothermal areas, it can cause precipitation of valuable mineral and ore deposits. Heated groundwater, dissolving minerals such as silicates, can increase both porosity and hydraulic conductivity in rocks.

Especially near convergent boundaries of tectonic plates, the high pressures and temperatures that cause melting of rocks also cause metals to be released from rocks that are partially molten. Hot water carries dissolved metal salts to host rocks where ores are deposited.

13.5 Applications

13.5.1 Using Surface Heat Distributions to Locate Groundwater Resources

Earth scientists have known for many years that groundwater modifies the heat flux coming to Earth's surface along the normal geothermal gradient. As a result, different researchers have developed governing equations and groundwater exploration methods to actually explain the effects of groundwater flow and geothermal heat flow and to explore for groundwater resources at depth.

Van Orstrand (1934) wrote that moving groundwater could transfer heat and thereby cause variations of temperature gradients. The natural heat flux to Earth's surface in the Midwest and most of the eastern United States is generally small, averaging less than 1 mW/m^2 at the surface. Bredehoeft and Papadopoulos (1965) stated that as the natural heat-flux density from Earth is usually small, the upward thermal gradient within Earth may be affected by the groundwater movement.

Basic equations for simultaneous transfer of heat and groundwater were derived by Stallman (1960). He also suggested that groundwater temperature measurements might be used to measure rates of groundwater movement.

Cartwright (1974a, 1974b) used soil temperatures to locate groundwater supplies beneath the areas tested for temperature. Generally, cooler soil temperatures indicated the presence of groundwater. This relationship between temperature and groundwater in areas of low geothermal gradient and low surface heat flux can be attributed to a combination of high specific heat and thermal inertia of water and low heat conductivity of rocks and soil. Therefore, surface water recharged to groundwater in cooler weather will not heat fast and will stand out by its low temperature. By the same principles, modern infra-red remote sensing from aircraft can locate cooler areas that lie over groundwater supplies.

13.5.2 Using Temperature/Depth Profiles in Water Wells to Determine Vertical Velocities of Groundwater Movement

Knowing the vertical velocity of groundwater from the surface downward is extremely important in estimating recharge rates from the surface and for estimating the velocity of downward migration of contaminants from the surface. Commonly, vertical velocity is determined with environmental tracers such as atmospheric tritium (Daniels et al., 1991). In these procedures, cores of soil are taken at various depths by core drilling and the water is extracted and analyzed for tritium that was recharged to the soil from the atmosphere during rain or snowmelt. An alternative method is to drill several holes in a cluster, each tapping a certain depth and then extracting water from each for tritium analysis.

In either case, the tritium collected at each sampling depth is then used to determine how far the water has traveled vertically by comparing its concentration with atmospheric concentration at recharge using the half-life of the isotope. In either method, considerable time and expense is necessary for drilling, coring, and analysis.

A much faster, more convenient, and less expensive method is determination of the vertical temperature profiles in the water columns of existing wells. The change of temperature with depth of the water column can then be used to estimate the vertical recharge rates alongside the wells. Bredehoeft and Papadopoulos (1965) derived type curves for estimating the flux of groundwater in one dimension by fitting to the type curves temperature data found in the wells with depth.

Later work by Stallman (1967) and Sorey (1971) also indicated that curvature in Earth's thermal profile can be caused by vertically moving groundwater transporting heat by advection. Other investigators have used groundwater temperatures to determine directions of groundwater flow; these include Norris and Spieker (1962a, 1962b), Winslow (1962), Schneider (1962a, 1962b, 1964, 1972), and Supkow (1970).

Taniguchi (1993) states that the groundwater fluxes estimated with type curves agreed well with estimates from hydraulic data and basin water-balance computations.

Arriaga (2002) in his research project for a Master of Science degree in the Department of Earth and Atmospheric Sciences at Purdue University used vertical temperature variations in existing wells around the Purdue University campus in West Lafayette, Indiana to determine the vertical velocity of groundwater in various locations. This research was motivated by the continuing expansion of building activities on the campus and the need to understand better the vertical recharge rates to aquifers underlying the campus, especially in the complex glacial stratigraphy with alternating aquifers and aquitards.

Arriaga (2002) measured vertical temperature profiles in 12 wells between September 2001 and April 2002. Temperatures were measured at 5-ft intervals and in some cases, 2-ft, and 1-ft intervals. The 12 wells provided continuous temperature information for the entire depth of the well and in some cases, for the entire saturated thickness of aquifers and aquitards.

The instrument used was a REELOGGERTM, a temperature probe on the end of a cable that registered well-water temperatures with a sensitivity of $\pm 0.02^\circ\text{C}$. As the probe was lowered, the water temperatures it sensed were recorded digitally on the surface for later processing by computer. Temperatures were taken in thermally-stable water columns of wells at depths opposite both aquifers and aquitards.

The flow of heat and groundwater in one dimension (vertical), assuming steady state is

$$(\partial^2 T / \partial z^2) - (c_w p_w v_z / k) (\partial T / \partial Z) = 0 \quad (13.12)$$

This is the vertical direction component of Stallman's (1960) equation for 3-D simultaneous transient flow of both heat and fluid in a fully-saturated, isotropic, and homogeneous saturated porous medium.

The analytical solution by Bredehoeft and Papadopoulos (1965) assumes an isothermal flow through aquitards with boundary conditions of

$$T_z = T_0 \quad \text{at } z = 0 \quad \text{and} \quad T_z = T_L \quad \text{at } z = L$$

where T_z is the temperature at any depth, T_0 is at $z = 0$ (uppermost temperature measurement), T_L is the temperature at $z = L$ (lowermost temperature measurement), L is the vertical distance over which temperatures are being observed, and v_z is vertical groundwater velocity.

Their solution is

$$(T_z - T_0) / (T_L - T_0) = f(\beta, z/L) = (e^{\beta(z/L)} - 1) / (e^\beta - 1) \quad (13.13)$$

where

$$\beta = c_w p_w v_z L / k \quad (13.14)$$

and is a dimensionless parameter that is positive or negative depending on whether v_z is downward or upward. Bredehoeft and Papadopoulos provide values of $f(\beta, z/L)$ for a range of parameters. They provide a set of type curves for different values of β .

The ratios $(T_z - T_0) / (T_L - T_0)$ are calculated from the measured temperature data and are plotted against the depth factor, z/L at the same scale as the type curve.

The value of β is dimensionless and is related to the curvature of a temperature-depth profile at several depths ranging from $z = 0$ to $z = L$. The thickness, L is less than or equal to the thickness of the semi-confining layer (water-saturated clay). It is through this layer that groundwater is leaking vertically with a velocity of v_z . Positive and negative values of β represent downward and upward leakage, respectively.

Once the value of β is known, the vertical groundwater velocity can be obtained by

$$v_z = k\beta / c_w p_w L \quad (13.15)$$

Typically, the value for thermal conductivity of water-saturated clay is roughly $k = 2 \times 10^{-3}$ cal/cm sec °C (Birch et al., 1942). Thermal conductivity of water-saturated sand and gravel outwash is $k = 4 \times 10^{-3}$ cal/cm sec °C. In water-saturated silts it averages $k = 2 \times 10^{-3}$ cal/cm sec °C (Wade, 1994).

Results of borehole water temperature measurements in the 12 wells showed the vertical velocities ranging from 1.71 to 1.86 cm/yr through aquitards and from 0.92 to 4.53 cm/yr in aquifers. In general, it was found that the aquifers with high horizontal conductivity had low vertical velocity components. In many aquitards the vertical velocities were greater than in aquifers as, according to the “Law of Tangents” (Fetter, 2001) and the continuity principle, water must take a shorter route through less permeable materials than through more permeable materials, and this necessitates faster vertical movement through an aquitard

$$K_1/K_2 = \tan \Theta_1 / \tan \Theta_2 \quad (13.16)$$

where K_1 is the hydraulic conductivity in layer 1, K_2 is the hydraulic conductivity in layer 2, Θ_1 is the angle made between impinging flow line and surface of layer 1, and Θ_2 is the angle made between the impinging flow line and surface of layer 2.

13.5.3 Distinguishing Different Aquifers by Temperature Profiles in Boreholes

In multiaquifer systems, some aquifers may be recharged from different areas, including melting surface snow or ice fields, or some may be deeper and warmer due to the geothermal gradient and greater heat flux into the aquifer. Such aquifers in many cases may be delineated from each other by their water temperatures if the temperatures are significantly different from one aquifer to another.

13.5.4 Expansion of Formation Water in Deep Boreholes

Often when a deep borehole (1000 to 2000 ft) is drilled into a deep aquifer and then left for some time and eventually pumped, the water level in the well will recover to an elevation slightly higher than the static water level before pumping. This behavior is due to the fact that before pumping, the water temperature equilibrates to a temperature lower than the temperature of the water in the aquifer and thus, the elevation of the water surface in the well is higher due to thermal expansion of the water during recovery after pumping.

13.5.5 Storage of Both Hot and Cold Water in Geological Formations

Cold water is stored in the sands and gravels of an abandoned channel of the Ohio River near Louisville, Kentucky. Recharged in winter months, this water is stored until warm weather periods and then used for air-conditioning purposes. Likewise, warm or hot water can be stored in permeable and porous formation for later extraction.

Storage of either hot or cold water in this manner can present some problems with temperature of the water or with chemical reactions between solutes in the water and minerals in the sediments into which it is injected. For example, hot water can speed up dissolution or precipitation of certain minerals. Cold water may cause dissolution of carbonate minerals. Precipitation of minerals can cause clogging of pores. Geological storage of either hot or cold water is possible as rocks have low thermal conductivities.

Glossary

British Thermal Unit (BTU) The quantity of heat that will raise the temperature of one pound of water by one degree Fahrenheit.

Calorie The quantity of heat that will raise the temperature of one cubic centimeter of water by one degree Celsius.

Celsius The temperature scale developed by Celsius and used mostly outside of the United States.

Continuum A continuous unbroken medium through which water or heat passes.

Diffusion Molecular diffusion is the spreading of the molecules of a solute in a liquid from a region of higher concentration to a lower concentration; heat diffusion is the spreading of heat through a continuum from a region of higher temperature to one of lower temperature.

Dynamic or Absolute Viscosity In liquids it is the resistance to shear as the liquid moves.

Energy The ability to produce change (e.g., work).

Fahrenheit The temperature scale developed by Fahrenheit and used mostly in English-speaking countries except England.

Geyser A particular tubular vent in areas of high geothermal heat that periodically gushes forth water and steam.

Heat Conduction The movement of heat through a continuum from molecule to molecule of the continuum simply under a thermal gradient.

Heat Content The actual number of calories in a sample of a material at any moment.

Heat Convection Movement of a mass of heat in a fluid (water or air) into an area that may be warmer or cooler than the fluid by forced fluid flow (e.g., by a fan).

Heat Flux The amount of heat moving perpendicular to a unit area per unit time.

Heat Pump A mechanical device that moves warm or cold air or water into a space for heating or cooling purposes respectively.

Hot-Water Dominated System A geothermal reservoir such as an aquifer, containing hot water completely filling the aquifer from top to bottom.

Hot Springs Springs from which issues hot water instead of water of ambient temperature.

Kelvin Scale A temperature scale developed by Lord Kelvin on which the lowest temperature possible, zero degree, is absolute zero at which there is no heat whatsoever in the system in question.

Kinematic Viscosity Used mostly in the study of flow of gases, it is the dynamic or absolute viscosity divided by the fluid density.

Non-Equilibrium Heat Flow Flow of heat down a thermal gradient such that it does not reach steady-state flow, but the flux changes with time and depletion of heat from storage.

Permafrost Ground containing water that is always frozen in very cold latitudes.

Potential Energy Energy that is available to produce change but is not being used.

Specific Heat The unique specific number of calories that will raise the temperature of a particular substance by one degree Celsius.

Temperature The measure of heat energy in a particular substance.

Thermal Conductivity The ease with which a substance will transmit heat.

Thermal Inertia The property that causes time delay in the warming or cooling of a fluid; water has a high thermal inertia because of its high specific heat.

Thermal Resistivity The inverse of the thermal conductivity.

Vapor-Dominated System A geothermal reservoir such as an aquifer in which steam sits between the top of the hot water and the bottom of the upper confining layer.

14.1 Introduction¹

The shallow subsurface of the earth is an extremely important geological zone, one that yields much of our water resources, supports our agriculture and ecosystems, and influences our climate. This zone also serves as the repository for most of our municipal, industrial, and governmental

¹Portions of this chapter are based on Hubbard and Rubin (2005) and Rubin and Hubbard (2005).

wastes and contaminants, intentional or otherwise. Safe and effective management of our natural resources is a major societal challenge. Contaminants associated with industrial, agricultural, and defense activities in developed countries, the increased use of chemical pollutants resulting from the technological development of countries with evolving market economies, the increased need to develop sustainable water resources for growing populations, and the threat of climate and land use change on ecosystems all contribute to the urgency associated with improving our understanding of the shallow subsurface.

It is widely recognized that natural heterogeneity and the large spatial variability of hydraulic parameters control infiltration within the vadose zone, groundwater storage, and the spread of contaminants. It is also well recognized that natural heterogeneity is typically great and can have multiple spatial scales of variability. Conventional sampling techniques for characterizing or monitoring the shallow subsurface typically involve collecting soil samples or drilling a borehole and acquiring hydrological measurements or borehole geophysical logs. When the size of the study site is large relative to the scale of the hydrological heterogeneity, or when the hydrogeology is complex, data obtained at point locations or within a wellbore may not capture key information about field-scale heterogeneity; especially in the horizontal direction. Integration of spatially extensive geophysical data with direct borehole measurements holds promise for improved and minimally invasive characterization and monitoring of the subsurface over a variety of resolutions and spatial scales.

The field of hydrogeophysics has developed in recent years to explore the potential that these methods have for mapping subsurface features, estimating properties, and monitoring processes that are important to hydrological studies, such as those associated with water resources, contaminant transport, and ecological and climate investigations. Hydrogeophysical investigations strive to move beyond the mapping of geophysical “anomalies” to provide information that can be used, for example, as input to flow and transport models. Hydrogeophysics builds on previous experience and developments associated with the mining and petroleum industries, which in the past 50 years have relied heavily on geophysical data for exploration of ore and hydrocarbons, respectively. As geophysics has been used as a tool in these industries for so long, there is a relatively good understanding of optimal data acquisition and reduction approaches as well as about petrophysical relationships associated with the consolidated, high pressure, and high temperature subsurface environments common to those industries. However, such subsurface conditions are quite different from the shallow, low temperature, low pressure, and less consolidated environments that typify most hydrogeological investigation sites. Indeed, the contrasts in shallow subsurface properties are often quite subtle compared to those of the deeper subsurface. Owing to the different subsurface conditions, the relationships that link geophysical attributes to subsurface parameters, as well as the geophysical attribute ranges, can vary dramatically between the different types of environments.

The goal of this chapter is to provide a description of practical tools for quantitative analysis of complex, heterogeneous aquifers using geophysical data and stochastic integration techniques. In Section 14.2, we review several geophysical techniques that are commonly used for hydrogeological investigation, and we provide examples of the geophysical information obtained using the methods. Section 14.3 describes hydrogeophysical concepts and approaches performed using geophysical datasets. This section gives examples of the use of geophysical data for mapping subsurface features, for estimating hydrogeological parameters, and for monitoring hydrological processes. When a detailed response analysis or confidence intervals for parameter estimation are needed, advanced stochastic techniques for integrating geophysical and hydrological data are often required. Section 14.4 develops a general framework for forward modeling using geophysical data under conditions of uncertainty by casting the hydrogeological prediction problem in a stochastic framework. This approach opens the door for estimating variables, such as permeability or concentration, in terms of their expected values and estimation variances (at a minimum) or, for a more complete characterization, through their probability distribution functions using integrated geophysical and hydrogeological datasets.

Our guiding principle throughout the chapter is the need for rational characterization approaches using geophysical data that recognizes the usual situation of data scarcity and subsurface heterogeneity.

14.2 Common Geophysical Methods for Hydrogeological Characterization

The purpose of this section is to review geophysical techniques that are most commonly used for hydrogeological characterization, including: electrical resistivity, electromagnetic, ground penetrating radar (GPR), seismic, potential field methods, and wellbore logging techniques. For each method, we provide a brief description of the underlying physical principles and instrumentation, common acquisition geometries, and general data reduction and interpretation methods. Also presented are several petrophysical relationships that may permit the transfer of geophysical measurements into estimates of hydrological parameters such as porosity and water content. These relationships are a topic of current research and thus are presented primarily to illustrate the potential that geophysical methods have for aiding subsurface characterization investigations, rather than to provide a recipe for geophysical-to-hydrogeological data transfer. We do not review other geophysical methods that offer great potential for hydrogeological characterization but that are not yet as extensively developed for such investigations, including induced polarization (IP), spontaneous potential (SP), nuclear magnetic resonance (NMR), and electroseismic methods.

We restrict our discussions to practical use and limitations of common geophysical methods; geophysical theory is beyond the scope of this book. However, references are given for each method that will allow readers to easily access more detailed information. For detailed information about acquisition, reduction, and interpretation of many geophysical methods, the reader is referred to Robinson and Coruh (1988), Burger (1992), and Telford et al. (1990).

14.2.1 DC Resistivity Methods

For groundwater studies, direct current (DC) resistivity, or electrical resistivity methods have been more frequently used than any other electrical method. Resistivity is a measure of the ability of electrical current to flow through materials; it is the inverse of electrical conductivity and is an intrinsic property of the material. Electrical resistivity is typically expressed in units of Ohm-meters ($\Omega\text{-m}$); resistivity values expressed Ohm-meters can be divided into 1000 to convert to conductivity values in milli-Siemans per meter (mS/m). Electrical resistivity methods involve the introduction of a time-varying DC or very low frequency ($<1 \text{ Hz}$) current into the ground between two current electrodes. In two-electrode systems, current flows from the positive to the negative current electrode. The currents can be envisioned to set up equipotential surfaces, with current flow lines running perpendicular to these surfaces. The fraction of current that penetrates to a particular depth is a function of the electrode spacing and the electrical resistivity distribution of subsurface materials (VanNostrand and Cook, 1966).

Most resistivity surveys utilize a four-electrode measurement approach. To obtain a value for subsurface resistivity, two potential electrodes are placed between the current electrodes, and the difference in potential or voltage (ΔV) is measured. This measurement, together with the known current (I) and a geometric factor (K), which is a function of the particular electrode configuration, can be used to calculate resistivity (ρ) for uniform subsurface conditions following Ohm's law:

$$\rho = \frac{\Delta V}{I} K \quad (14.1)$$

Equation 14.1 can also be applied when the resistivity of the ground is heterogeneous, but the more general term "apparent resistivity" (ρ_a) is used. The simplest four-electrode configuration is the Wenner array shown in Figure 14.1a, where the outer two current electrodes, labeled C1 and C2, apply a constant current, and the inner two potential electrodes, labeled P1 and P2, measure the voltage difference created by this current. The electrode spacing is a fixed value a , and the apparent resistivity of the heterogeneous

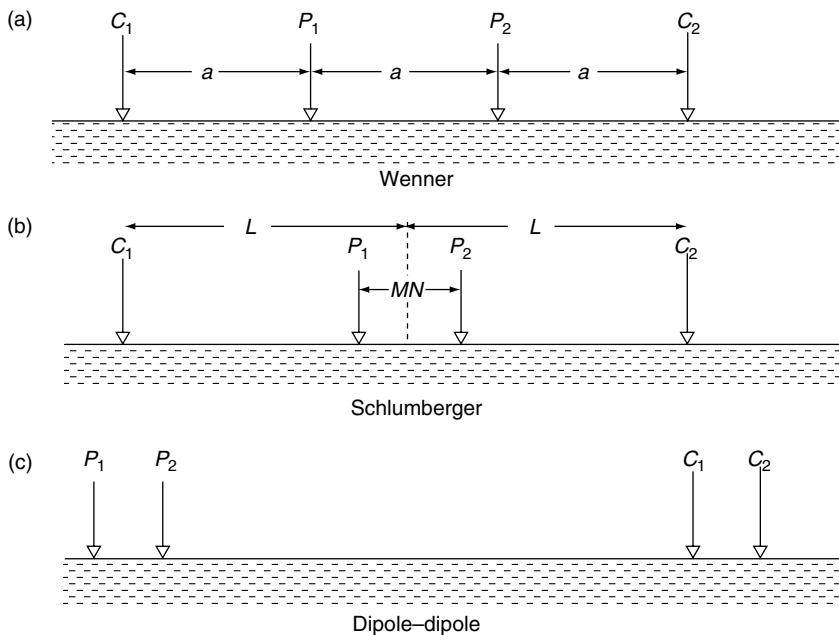

FIGURE 14.1 Common electrode configurations used to measure apparent resistivity of the subsurface. C1 and C2 are the current electrodes and P1 and P2 are the potential electrodes. (a) Wenner array. The outer two current electrodes apply a constant current, and the inner two potential electrodes measure the voltage difference created by the current. The electrodes maintain a constant spacing of “a.” (b) Schlumberger array. The spacing (MN) between the potential electrodes is much smaller than the spacing ($2L$) between the current electrodes. (c) Dipole–dipole array. The potential electrode pair functions independently from the current electrode pair, which enables a sampling in both the lateral and vertical direction of subsurface apparent resistivity. (From Burger, H. R., 1992, *Exploration Geophysics of the Shallow Subsurface*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

subsurface sampled by this array can be computed using:

$$\rho_a = \frac{\Delta V}{I} 2\pi a \quad (14.2)$$

Another commonly used electrode configuration is the Schlumberger array (Figure 14.1b), where the spacing (MN) between the potential electrodes (P1, P2) is much smaller than the spacing ($2L$) between the current electrodes (C1, C2). In the dipole–dipole array, illustrated in Figure 14.1c, the current electrode pair and the potential electrode pair are closely spaced, and there is a significant distance between the sets. Unlike the Wenner and Schlumberger arrays, which collect data in either the *profiling* or the *sounding* mode depending on electrode array geometry, the potential and the current electrodes of the dipole–dipole array function independently of each other, permitting simultaneous profiling and sounding.

Profiling is undertaken by moving the entire array laterally along the surface by a fixed distance after each reading to obtain apparent resistivity measurement over a relatively constant depth as a function of distance. For each reading, the value of apparent resistivity is assigned to the geometric center of the electrode array. Profiling is useful for relatively rapid spatial coverage. Equipment to permit continuous electrical profiling has been used in Denmark to collect electrical measurements over large areas by pulling a string of electrodes with a vehicle (Sorensen, 1996); traverses as long as 10 km have been acquired in a single day using this towed-array approach. As profiles give lateral variations in electrical conductivity but not information about vertical distribution, the interpretation of profile data is generally qualitative, and the primary value of the data is to delineate gross geologic structure and stratigraphy.

Vertical electrical sounding (VES) curves give information about the vertical variations in electrical conductivity at a single location. Soundings are obtained by “expanding” the array along a straight line so that the spacing between the individual electrodes remains equal but takes on larger values after each measurement. The depth of the measurement is a function of the electrode spacing as well as the subsurface resistivity contrasts; as the electrode spacing is increased, the current penetrates to greater depths. Such curves have been used to delineate hydrogeological units as a function of depth. Sounding curves can be quite complex when the subsurface geology is not laterally homogeneous and when there are more than two subsurface layers and the interpretation of multilayer sounding curves is not unique. To interpret electrical resistivity sounding data, various curve-fitting or computer inversion schemes are used, or the measured data are compared with model computations (Zodhy et al., 1974).

Modern electrical equipment now includes multiplexing capabilities and automatic and autonomous computer acquisition, which greatly facilitate acquisition of a combined profiling and vertical soundings within acceptable timeframes. Such surface imaging is performed by acquiring profiles along transects using different electrode spacings. For each measurement, the apparent resistivity value is assigned to the midpoint of the four electrodes. By using a combination of electrodes, a pseudo-section is developed using the midpoint location technique. Modeling of electrical imaging data can then provide estimates of subsurface electrical resistivity values in their more “correct” subsurface positions. Surface imaging, which yields two- or three-dimensional information about subsurface electrical resistivity distribution, has become a particularly powerful geophysical technique for hydrogeological mapping, parameter estimation, and monitoring.

Electrical resistivity measurements are also collected between boreholes by inserting electrodes into a wellbore or installing electrodes on the outside of wellbore casing, collecting measurements, and processing of the measurements. Crosshole electrical imaging is often referred to as electrical resistance tomography (ERT), and ERT systems are now commercially available. With the recent development of advanced and automated acquisition systems, robust inversion routines and the capability of recording >3500 measurements per hour with only one technician, ERT methods have proven to be useful for dynamic process monitoring. For example, Ramirez et al. (1993) used ERT to map the subsurface distribution of a stream flood as a function of time, and Daily and Ramirez (1995) used ERT to monitor an *in situ* remediation process for removal of volatile organic compounds from subsurface water and soil. An excellent review of surface and crosshole electrical methods for hydrogeological applications is given by Binley and Kemna (2005), and several examples of the use of such methods for hydrogeological applications is given by Daniels et al. (2005).

As electrical resistivity measurements are influenced by lithology, pore fluid chemistry, and by water content, electrical measurements can be useful for hydrogeological mapping, property estimation, and monitoring as will be shown in Section 14.3. Electrical conduction usually takes place in fluids in connected pore spaces, along grain boundaries, and within fractures; the matrix of the material is generally considered nonconductive. Material texture, porosity, presence of clay minerals, moisture content, and the resistivity of the pore fluid all affect electrical resistivity. In general, all of the following reduce resistivity: increased water content, increased salinity of water, increased clay content, and decreased grain size (Burger, 1992). Assuming that water fills the voids, resistivity is also lowered by an increase in porosity, an increase in the number of fractures, and by increased weathering. Electrical resistivity values for common materials are shown in Table 14.1. From this table, it is evident that there are wide ranges of electrical resistivity for some materials and also that resistivity values of different materials overlap. Values commonly vary over 12 orders of magnitude and have a maximum range of 24 orders of magnitude (Telford et al., 1990). However, the following general statements can be made regarding electrical resistivity:

- Resistivity is sensitive to moisture content; thus unsaturated sediments usually have higher resistivity values than saturated sediments.
- Sandy materials generally have higher resistivity values than clayey materials.
- Granitic bedrock generally has a higher resistivity value than saturated sediments and frequently offers a large apparent resistivity contrast when overlain by these sediments.

TABLE 14.1 Approximate Electrical Resistivity and Dielectric Constant Values for Typical Near-Surface Materials

Material	Resistivity (Ohm-m)	Dielectric Constant
Sand (dry)	10^3 – 10^7	3–6
Sand (saturated)	10^2 – 10^4	20–30
Silts	10^2 – 10^3	5–30
Shales	10 – 10^3	5–15
Clays	1 – 10^3	5–40
Humid soil	50–100	30
Cultivated soil	200	15
Rocky soil	1000	7
Sandy soil (dry)	7100	3
Sandy soil (saturated)	150	25
Loamy soil (dry)	9100	3
Loamy soil (saturated)	500	19
Clayey soil (dry)	3700	2
Clayey soil (saturated)	20	15
Sandstone (saturated)	25	6
Limestone (dry)	10^9	7
Limestone (saturated)	40	4–8
Basalt	100	8
Granite	10^3 – 10^5	4–6
Coal	10^4	4–5
Fresh water	30 – 10^4	81
Permafrost	10^2 – 10^5	4–8
Dry snow	10^5 – 10^6	1
Ice	10^3 – 10^5	4–12

Second Edition, Cambridge University Press, Cambridge; Ulriksen, P. F., 1982, Application of impulse radar to civil engineering, Ph.D. thesis, Lund University, Sweden.

Empirical formulae as well as theoretical models have been used to relate apparent resistivity measurements to hydrological parameters of interest. An excellent compendium of petrophysical relationships between electrical and hydrogeological properties is given by Lesmes and Friedman (2005). Archie's (1942) empirical relationship is perhaps the most widely used relationship to relate electrical conductivity to water-saturated hydrogeological properties. A modified version of Archie's relationship for variably saturated materials is given by:

$$\rho_{\text{eff}} = a\phi^{-m} S^{-n} \rho_w \quad (14.3)$$

where ρ_{eff} is the effective electrical resistivity of the sample, ρ_w is pore water resistivity, ϕ is fractional porosity, S is fractional water saturation, and n , a , and m are constants. The cementation index, m , ranges from approximately 1.3 for unconsolidated sands to 2 for consolidated sandstones; the saturation index, d , is about 2 for consolidated rocks and ranges from 1.3 to 2 for unconsolidated sands; and a ranges from 0.6 to 1 (Ward, 1990; Schon, 1996). Equation 14.3 is generally used for well log interpretation, but if ρ_{eff} , ρ_w , and ϕ can be independently measured, and m reasonably estimated, then the fractional water saturation can be found using electrical surveys (Ward, 1990). This concept was used by Pfeifer and Anderson (1995) to monitor the migration of tracer-spiked water through the subsurface using electrical measurements.

Site-specific petrophysical relationships have also been used to transform electrical measurements into estimates of hydrogeological properties or units. For example, site-specific petrophysical relationships have been developed between electrical measurements and hydraulic conductivity or transmissivity in porous aquifers (Kelly, 1977; Heigold et al., 1979; Kosinski and Kelly, 1981; Mazac et al., 1985; Huntley,

1986; Purvance and Andricevic, 2000). These studies suggest that the petrophysical relationships can be categorized into two groups. For coarse-textured, clay-free soils, permeability and electrical conductivity tend to be positively correlated, because they both increase with increasing porosity. With finer-textured soils, surface conductivity effects play a role, and permeability and electrical conductivity tend to be inversely correlated. Although the development of petrophysical relationships for near surface materials is still a topic of research, more petrophysical investigations for hydrogeological applications have been performed using electrical measurements than using other types of geophysical measurements.

The wide range of values of electrical resistivity in natural materials and the sensitivity of electrical resistivity to hydrogeological properties (such as moisture content, type of pore fluid, porosity, and lithology) have rendered electrical resistivity a useful tool for a wide range of hydrological investigations. Because of the myriad of influences on apparent electrical resistivity measurements, it is typically not possible to estimate hydrogeological properties, such as lithology or hydraulic conductivity, using electrical data without other constraining information. The increasing ease of use and reasonable cost of electrical equipment have greatly expanded the ability to use this method to survey large areas or to perform time-lapse imaging of dynamic processes.

14.2.2 Electromagnetic Induction

The use of electromagnetic techniques for groundwater and environmental site assessments has increased dramatically in recent years. Controlled-source inductive electromagnetic (EM) methods use a transmitter to pass a time-varying current through a coil or dipole on the earth's surface. This alternating current produces a time-varying magnetic field that interacts with the conductive subsurface to induce time-varying eddy currents. These eddy currents give rise to a secondary EM field (Figure 14.2). Attributes of this secondary magnetic field, such as amplitude, orientation, and phase shift, can be measured by the receiver coil and, by comparing these attributes with those of the primary field, information about the presence of subsurface conductors, or the subsurface electrical conductivity distribution, can be inferred.

As with electrical resistivity measurements, electrical conductivity measurements made using EM methods are also affected by moisture content, type of pore fluid, porosity, and lithology. EM methods

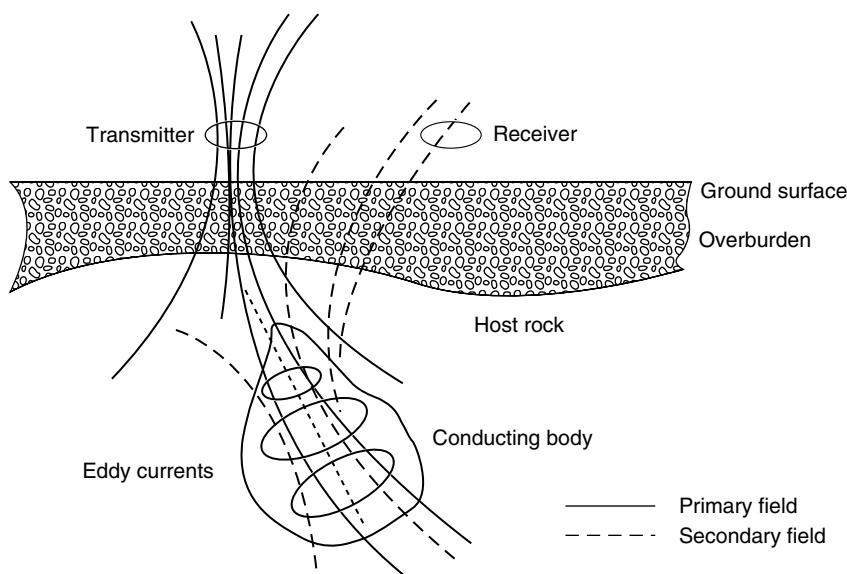

FIGURE 14.2 Electromagnetic induction technique. Changes in the primary magnetic field with time-induce eddy currents in the subsurface that give rise to a secondary EM field. (From Best, M. E., 1992, *Geological Association of Canada Short Course Notes Volume 10*. Wolfville, Nova Scotia, May 28–29. With permission.)

tend to require less time to acquire than DC resistivity methods and have the capability to image deeper subsurface regions. However, the interpretational methods necessary to extract qualitative information can be more complicated than those used with resistivity methods. As a conductive subsurface environment or target is required to set up the secondary field measured with inductive EM methods (Figure 14.2), EM methods are best suited for use when attempting to detect the presence of high-conductivity subsurface targets, such as salt water saturated sediments or clay layers. However, because coils do not require contact with the ground, EM methods are often more successful in electrically resistive or paved areas than DC resistivity method, which require electrode contact.

Electromagnetic instrumentation can take on many different forms. Most EM systems consist of a source that transmits a systematically-varying EM field, one or more receivers to measure the components of the total (primary and secondary) magnetic field and sometimes the components of the electric field, and the necessary electronic circuitry to process, store, and display the signals (Best, 1992). As with resistivity data, EM induction data can be collected in profile or sounding mode. The mode of acquisition and the resolution and penetration of the data are governed by the subsurface conditions, the domain (frequency or time) under which the system operates, and the coil configuration. For frequency domain systems, high transmitter frequencies permit high-resolution investigation of subsurface conductors at shallow depths while lower transmitter frequencies permit deeper observations but at a loss in resolution. Time domain systems measure the secondary magnetic field as a function of time, and early-time measurements yield information about the near-surface, while later-time measurements are increasingly influenced by the electrical properties of deeper layers. The depth of penetration and resolution are also governed by coil configuration; the measurements from larger coil separations are influenced by electrical properties at greater depths, while smaller coil spacings sample from the near-surface. Thus, to collect an EM profile, the coil spacing must be constant *and* the frequency or time of measurement fixed. To collect an EM sounding, measurements are collected at the same surface location using different frequencies, different observation times, *or* different coil spacings. Although still a research topic, EM crosshole geometries have been used for dynamic process monitoring (Wilt et al., 1995).

As electrical conductivity is the inverse of electrical resistivity, the discussion regarding the relation of electrical resistivity to lithology or hydrological parameters given in Section 14.2.1 can be applied in an inverse manner to electrical conductivity measurements. For example, electrical conductivity is higher for saturated sediments than for unsaturated sediments, and clayey materials generally have higher electrical conductivities than sandy materials. The introduction of contaminants into an aquifer may alter the electrical conductivity of the pore fluid. EM methods can be used to detect contaminants (Greenhouse and Harris, 1983) if:

- The contrast between the electrical conductivity of the contaminant and the original pore fluid is at least 10%.
- The plume or contaminated aquifer occupies a significant fraction of the zone of influence of the measurement.
- Variations in electrical conductivity due to other factors that affect electrical conductivity, such as lithology, are smaller than or separable from variations in electrical conductivity due to the contaminant.

Organic contaminants generally reduce electrical conductivity and are more difficult to detect over background variations than inorganic contaminants, which typically increase the electrical conductivity, but EM has been successful at detecting both organic and inorganic groundwater contamination plumes (Buselli et al., 1990).

Reviews of the instrumentation available for EM induction systems, their applicability for environmental site characterization, and EM interpretational methods are given by Frischknecht et al. (1991), Hoekstra and Blohm (1990), Goldstein (1994), Mac Lean (1992), and McNeill (1990). Examples of investigations that have used EM inductive methods to investigate hydrogeological parameters include those of Sheets and Hendricks (1995), who used EM induction methods to estimate soil water content, and Kachanoski et al. (1988), who used EM induction methods to investigate the spatial variations of soil

texture and pore fluid. An excellent review and discussion of the use of controlled source EM methods for hydrogeological investigations is given by Everett and Meju (2005).

14.2.3 Ground Penetrating Radar

Ground penetrating radar (GPR) methods use electromagnetic energy at frequencies of 10 to 1000 MHz to probe the subsurface. At these frequencies, the separation (polarization) of opposite electric charges within a material that has been subjected to an external electric field dominates the electrical response. The dielectric constant or relative permittivity, which is the ratio of the electric permittivity of the material relative to the electric permittivity of free space, is used to describe these high-frequency electric properties. GPR systems consist of an impulse generator that repeatedly sends a particular voltage and frequency source to a transmitting antenna. The GPR technique is similar in principle to seismic and sonar methods. In the case of the most commonly used bistatic systems, one antenna, the transmitter, radiates short pulses of high frequency (MHz to GHz) electromagnetic waves, and the other antenna, the receiver, measures the characteristics of the (modified) signal as a function of time. When the source antenna is placed on the ground surface, spherical waves are radiated both upward into the air and downward into the soil. Some of the propagating energy travels into the subsurface and is reflected by subsurface dielectric contrasts; these arrivals are known as GPR reflections. Some of the energy travels in the near subsurface along the air-ground interface; these arrivals are known as GPR groundwaves. In general, GPR performs better in unsaturated coarse or moderately coarse textured soils; GPR signal strength is attenuated in electrically conductive environments, such as systems dominated by the presence of clays or that have high ionic strength pore fluids.

Dielectric constants are affected by material saturation, porosity, material constituency, temperature, and pore fluid composition. Approximate dielectric constants for common near-surface materials are given in Table 14.1. This table shows that most dry materials have dielectric constants of 3 to 7, which are much lower than the dielectric constants of saturated materials.

The most common GPR acquisition mode is surface common-offset reflection, which involves the collection of one trace per surface location from a transmitter-receiver antenna pair (Figure 14.3a). With this acquisition mode, data are displayed as two-dimensional wiggle trace profiles. Such profiles can be displayed in real time during data collection and can be stored digitally for subsequent data processing. Resolution of GPR reflection data, defined as the ability of the system to distinguish two signals that are

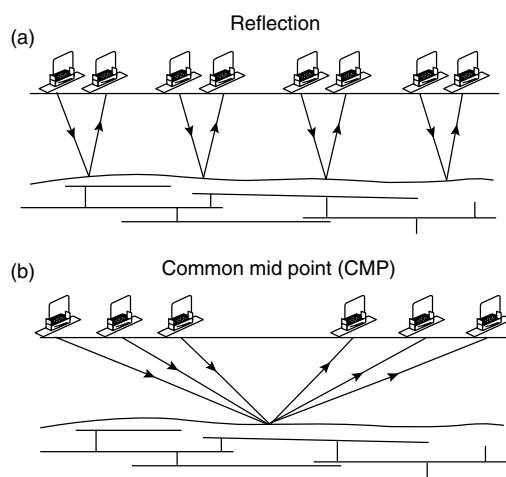

FIGURE 14.3 GPR acquisition geometry: (a) common-offset reflection mode and (b) common-midpoint mode. (From Annan, A. P. and S. Cosway, 1992, Ground penetrating radar survey design. Proc. of the Symposium on the Applications of Geophysics to Engineering and Environmental Problems [SAGEEP], Chicago. With permission.)

close together in time, varies as a function of antenna frequency and the electrical properties of the host material. Davis and Annan (1989) suggest that for a wet soil, vertical resolution on the order of 7 m is possible using 10 MHz radar antennas, 0.5 m resolution is possible using 100 MHz radar antennas, and less than a centimeter resolution is possible using 1000 MHz radar antennas. Increasing the frequency increases the resolution but decreases the penetration depth. Also affecting the radar signal penetration depths are the radar system performance, reflection properties at boundaries where electrical properties vary, and attenuation that is controlled by scattering, electrical properties of surface and subsurface materials, and geometrical spreading losses. Generally, one chooses a radar center frequency that yields both sufficient penetration and resolution; for field applications this is often between 50 and 200 MHz. It is, however, possible to collect radar data at the same location using several different frequency antennas. The use of multiple frequency antennas enables sampling over a greater depth range with optimal resolution for all depths (Smith and Jol, 1992).

Estimation of the dielectric constant is necessary to infer quantitative hydrogeological information from GPR data. For the high frequency range of interest used with GPR methods, the propagation phase velocity (V) in a low electrical conductivity material can be related to the dielectric constant (κ) as (Davis and Annan, 1989):

$$\kappa \approx \left(\frac{c}{V} \right)^2 \quad (14.4)$$

where c is the propagation velocity of electromagnetic waves in free space (3×10^8 m/sec).

Information about the dielectric structure of the shallow subsurface can be obtained via velocity analysis of reflection GPR data acquired with surface common-midpoint (CMP) or velocity analysis of transmitted signals acquired with crosshole acquisition geometry and the relationship shown in Equation 14.4. GPR CMP geometry results in gathers of traces where the midpoint between the transmitting and receiving antennas is common to several antenna pairs as shown in Figure 14.3b. GPR CMP data have been processed using a standard seismic data processing sequence to obtain estimates of dielectric constants at one location and as a function of depth (e.g., Fisher et al., 1992; Lunt et al., 2005).

Crosshole tomographic GPR techniques consist of measuring direct electromagnetic energy from a transmitter in one borehole to a receiving antenna in another borehole. A typical cross-hole tomographic geometry consists of sources and detectors located in separate boreholes. Direct energy from the transmitter in one borehole is received by several receivers that are connected by a cable in the other borehole. The vertical source position is changed, and the recording is repeated until the source has occupied all positions in the source borehole. The interwell area is discretized into a grid composed of cells or pixels, and inversion algorithms are used to transform the recorded travel time and amplitude information into estimations of velocity and sometimes attenuation at each pixel (Peterson et al., 1985; Peterson, 2001). Crosshole acquisition geometry has also been used with electrical and electromagnetic methods to produce high-resolution images of electrical conductivity between two boreholes.

Although both multi-offset GPR acquisition and tomographic methods yield information about electromagnetic velocity (and through Equation 14.4, dielectric constants), these datasets are time consuming to acquire, and thus are not well suited for rapid mapping of dielectric constants at the field scale. Dielectric constant can also be obtained using common-offset GPR acquisition approaches, provided some additional information is available. The use of GPR groundwave data, collected using common-offset acquisition geometry, for dielectric constant mapping was first suggested by Du and Rummel (1994). The groundwave is the part of the radiated energy that travels between the transmitter and receiver through the top of the soil. Recent experiments by Hubbard et al. (1997a), Huisman et al. (2002, 2003), and Grote et al. (2003, 2005) have confirmed that this is a viable approach for mapping dielectric constant, and that the information could be accurately transformed into estimates of shallow soil water content. An example of the use of GPR for water content estimation is provided in Section 14.3.

If the depth to a reflector is known or can be reasonably estimated, GPR reflection travel time data collected using common offset approaches can also be used to estimate the velocity, or with Equation 14.3,

the dielectric constant values of the subsurface. This method was used by Lunt et al. (2005) to map the dielectric structure of an agricultural site. The reflection method has an advantage over the groundwave method in that it can penetrate deeper into the subsurface. However, the reflection approach requires both a good reflecting horizon and information about the depth to the horizon, which can limit the applicability of this approach over large distances.

Petrophysical models can be used to link dielectric estimates obtained from GPR data to hydrogeologic parameters. Most commonly, dielectric constant estimates are used to obtain estimates of water content. For example, Topp et al. (1980) used a regression analysis to obtain an empirical relation between dielectric constant and volumetric moisture content (θ):

$$\theta = -5.3 \times 10^{-2} + 2.92 \times 10^{-2}\kappa - 5.5 \times 10^{-4}\kappa^2 + 4.3 \times 10^{-6}\kappa^3 \quad (14.5)$$

Greaves et al. (1996) used the Topp equation to transfer interval velocity estimates obtained from surface CMP GPR data into subsurface water content estimates, and Hubbard et al. (1997b) successfully used the relation to transfer dielectric constants obtained from crosshole radar measurements into water content estimates. For a sand-clay system, Wharton et al. (1980) used a mixture formula to express the bulk dielectric constant as a function of the dielectric constants of air (κ_a), water (κ_w), sand (κ_s), and clay (κ_{cl}), as well as the porosity (ϕ), fractional water saturation (S_w), and the volumetric clay fraction (V_{cl}):

$$\kappa = [(1 - \phi)V_{cl}\sqrt{\kappa_{cl}} + (1 - \phi)(1 - V_{cl})\sqrt{\kappa_s} + S_w\phi\sqrt{\kappa_w} + (1 - S_w)\phi\sqrt{\kappa_a}]^2 \quad (14.6)$$

Knoll et al. (1995) found under laboratory conditions that Equation 14.6 fit the observed dielectric behavior of a constructed unconsolidated sand–clay mixture. They converted the relation between effective dielectric constant, saturation, porosity, and clay fraction shown in Equation 14.6 to a relation between effective dielectric constant, saturation, and intrinsic permeability using petrophysical relationships. Their petrophysical formulas, which were developed theoretically and verified in the laboratory, are shown in Figure 14.4. These curves reveal that the dielectric constant is a function of both saturation and intrinsic permeability and that the dielectric constant is much more sensitive to saturation state than to the intrinsic permeability when the permeability values are high. Using the petrophysical relations given by Knoll et al. (1995), Hubbard et al. (1997b) developed a technique to estimate permeability and saturation in bimodal systems using CMP or crosshole GPR data; this example will be discussed in Section 14.4.

The petrophysical relations discussed above were all based on a pore fluid of water; however, contaminants may have a different dielectric constant than water and may be detectable in these cases using radar methods. GPR methods have been used for imaging perchloroethylene (PCE) contamination (Greenhouse et al., 1993) and trichloroethylene (TCE) contamination (Brewster and Annan, 1994). Because of the high frequencies employed, GPR offers perhaps the best resolution of any surface geophysical technique when operating under optimal conditions. An excellent overview of the GPR method is given by Annan (2005).

14.2.4 Seismic Methods

Seismic reflection, crosshole transmission, and refraction methods use artificially generated, high-frequency (100 to 5000 Hz) pulses of acoustic energy to probe the subsurface. These pulses can be delivered to the subsurface with hammer blows, weight drops, blasting caps, rifle or shotgun slugs, piezoelectric devices, or vibrators. These disturbances are produced at a point and propagate outward as a series of wavefronts. The passage of the wavefront creates a motion that can be detected by a sensitive geophone and recorded on the surface; the path that the energy follows is conceptualized by a ray drawn normal to the wavefront.

According to the theory of elasticity upon which seismic wave propagation is based, four different waves are produced by a disturbance, and these waves travel with different propagation velocities governed by the elastic constants and density of a material. One type of wave is transmitted by a back-and-forth particle movement in the direction of the propagating wave. This type has the greatest speed and is thus the first

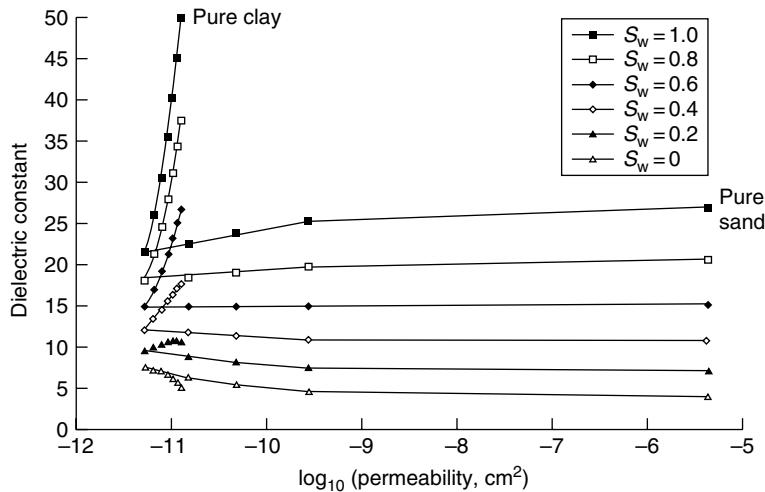

FIGURE 14.4 Petrophysical curves of Knoll et al. (1995) relating dielectric constant to fractional water saturation (S_w) and permeability. (From Knoll, M., R. Knight, and E. Brown, 1995, Can accurate estimates of permeability be obtained from measurement of dielectric properties? SAGEEP Annual Meeting Extended Abstracts. Orlando, FL, Apr. 23–26. With permission.)

to arrive at a geophone; for this reason it is called the P (primary)-wave. Other terms for this wave are the compressional or longitudinal wave. Approximate values for P-wave velocities in near surface materials are given in Table 14.2. The particle motion of transverse waves is perpendicular to the direction of the wavefront propagation. Transverse waves, also called S (secondary or shear)-waves, have lower velocities than the P-wave and thus arrive later in the recording. In contrast to both P- and S-waves, which are transmitted through the interior of a solid and are thus classified as body waves, surface waves, including both Raleigh and Love waves, are confined to a region near the free surface of a medium. Because it is easiest to detect the P-wave energy, most seismic exploration techniques have focused on the use of this wave, and in the following discussion, we also concentrate exclusively on information available from P-waves.

Figure 14.5 shows the major paths of P-wave energy upon disturbance in a horizontally layered, two-medium system where the *seismic velocity* of the upper layer is less than that of the lower layer. The first arrival at the detector or geophone is the (compressional) air wave, which is followed by the direct compressional wave that propagates along a path from the disturbance to the geophone. P-wave energy is reflected from the interface and also refracted from the head wave that travels along the interface. In addition to these compressional arrivals, ground motion from Raleigh surface waves, or ground roll, also contributes to the signal recorded at a geophone. The events commonly used for interpretation are the reflected P-waves, the direct P-waves, and the refracted P-waves. Different seismic methods focus on different seismic wave arrivals — reflection techniques focus on reflected arrivals, crosshole methods mainly utilize direct waves, and refraction methods are designed to detect refracted head waves. The principles of each of these different seismic methods are briefly described below, and an excellent review of shallow seismic acquisition and processing techniques is given by Steeples (2005).

14.2.4.1 Seismic Reflection

The surface reflection technique is based on the return of reflected P-waves from boundaries where velocity and density (or seismic impedance) contrasts exist. Seismic reflection data are usually collected as common-shot or common-receiver gathers that are sorted during processing into common-midpoint or CMP gathers. These gathers of traces represent reflections from a subsurface location (the midpoint) that has been sampled by several source–receiver pairs. Although processing of near surface seismic data often follows the procedures developed for petroleum reservoirs (e.g., Yilmaz, 1987), the acquisition parameters for shallow seismic campaigns are different from those used to image deeper reservoirs (e.g., Pullan

TABLE 14.2 Seismic P-Wave Velocities for Typical Near-Surface Materials

Material	Approximate P-wave Velocity (m/sec)
<i>Unconsolidated Materials</i>	
Weathered layer	300–900
Soil	250–600
Alluvium	500–2000
Clay	1100–2500
Unsaturated sand	200–1000
Saturated sand	800–2200
Unsaturated sand/gravel	400–500
Saturated sand/gravel	800–2200
Unsaturated glacial till	400–1000
Saturated glacial till	1700
<i>Consolidated Materials</i>	
Sandstone and shale	2000–4500
Chalk	2300–2600
Limestone	2000–6000
Coal	2200–2700
Basalt	5400–6400
Granite	5000–6400
Metamorphic	3500–7000
<i>Other</i>	
Water	1400–1600
Ice	3400–3800
Air	331.5

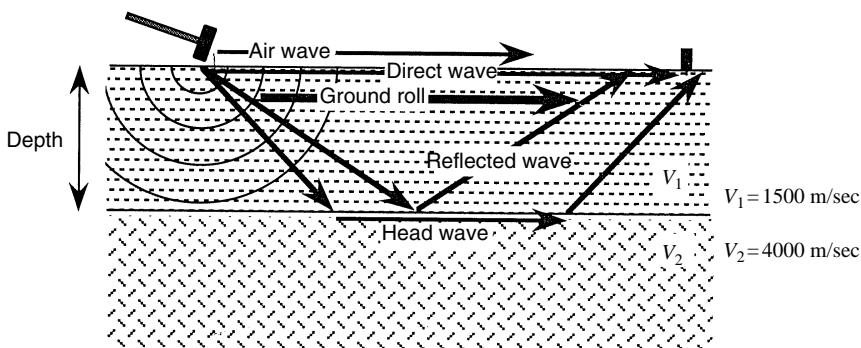

FIGURE 14.5 Major raypaths of P-wave energy. (From Burger, H. R., 1992, *Exploration of Geophysics of the Shallow Subsurface*. Prentice Hall, Englewood Cliffs, NJ. With permission.)

and Hunter, 1990). Due to the lack of well-defined velocity contrasts in unconsolidated and unsaturated materials (Table 14.2), seismic reflection data acquisition is often difficult in the near-surface. Hunter et al. (1984) demonstrated the importance of selecting the appropriate distance between the seismic source and the seismic geophones for near-surface seismic reflection imaging, and Doll et al. (1994) reviewed various types of sources for collecting near-surface seismic data.

Computer-based processing of seismic reflection data generally produces a wiggle-trace profile that resembles a geologic cross section; Figure 14.6 is an example of a seismic reflection section over a steep-sided valley that is floored by bedrock. An interpreted borehole log has been inserted into the section

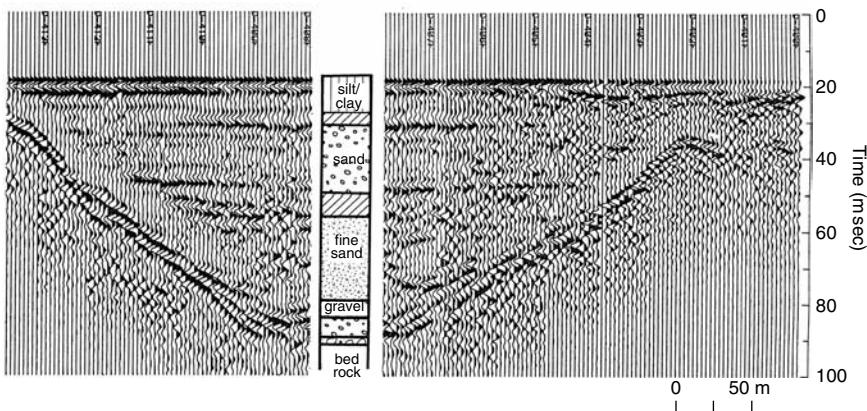

FIGURE 14.6 High resolution near-surface seismic section over a steep-sided valley. Interpreted borehole log inserted at the borehole location reveals that reflections imaged are interfaces between different hydrostratigraphic units. (From Pullan, S. E. and Hunter, J. A., 1990, Delineation of buried bedrock valleys using the optimum offset shallow seismic reflection technique, in *Geotechnical and Environmental Geophysics*, Vol. 3, Geotechnical, S.E.G. Investigations in Geophysics 5, Ed. Stanley Ward, pp. 75–87. With permission.)

at the borehole location and reveals that the seismic reflections correspond to interfaces between sands, clays, gravels, and bedrock. The vertical resolution of a few meters shown in this figure is an example of good quality surface seismic data collected in an area favorable for seismic data acquisition with careful attention to acquisition parameters. Seismic reflection methods have also been used to delineate the water table (Birkelo et al., 1987), to delineate shallow faults (Treadway et al., 1988), and to map shallow bedrock (Miller et al., 1989).

14.2.4.2 Seismic Refraction

With refraction methods, the incident ray is refracted along the target boundary before returning to the surface (Figure 14.4). The refracted energy arrival times are displayed as a function of distance from the source, and interpretation of this energy can be accomplished by using simple software or forward modeling techniques. The arrival times and distances can be used to obtain velocity information directly. Refraction techniques are most appropriate when there are only a few shallow (<50 m) targets of interest, or where one is interested in identifying gross lateral velocity variations or changes in interface dip (Lankston, 1990). Seismic refraction methods yield much lower resolution than seismic reflection and crosshole methods. However, because refraction methods are inexpensive and acquisition may be more successful in unsaturated and unconsolidated environments, it is sometimes chosen over reflection methods for applications such as determining the depth to the water table and to the top of bedrock, the gross velocity structure, or for locating significant faults. A review of the refraction method is given by Lankston (1990).

14.2.4.3 Tomography

Seismic tomography is commonly used in the petroleum industry, but has also been used for hydrogeological applications. As with radar tomography, the multiple sampling of the intrawell bore area permits very detailed estimation of the velocity structure. Although the majority of the crosshole tomographic seismic data sets have been collected for research projects, the extremely high resolution of up to 0.5 m offered by this method suggests that it offers extremely useful information for hydrogeologic characterization and monitoring. As seismic P-wave velocities can be related to lithological and hydrogeological parameters as discussed above, this extremely high resolution method is ideal for detailed stratigraphic and hydraulic characterization of interwell areas (e.g., Hyndman et al., 1994, 1996; Hubbard et al., 2001; Chen et al., 2005). Although not yet established as a field method, seismic imaging of organic contaminants in the

laboratory has provided a fundamental step toward the application of seismic tomographic imaging of interwell contamination (Geller and Myer, 1995). Recently, time-lapse seismic tomographic data have been used to image the evolution of products associated with field-scale remediation, such as the generation of gasses and precipitates (Hubbard and Williams, 2004). The processes of crosshole seismic data inversion and incorporation of these data with hydrological data are discussed in detail in Chapter 15 of this volume (Hyndman, 2006).

14.2.4.4 Seismic Petrophysics

Information about seismic velocity is available through seismic data processing of reflection CMP, refraction, or tomographic data. Seismic P-wave velocity is affected by porosity, permeability, pore fluid type, depth of burial, consolidation, and temperature. Table 14.2 reveals that unique relations between seismic P-wave velocities and lithology generally do not exist. However, some generalities can be made regarding seismic velocities and lithology (Burger, 1992):

- Velocities in unsaturated sediments are lower than in saturated sediments.
- Velocities in unconsolidated sediments are lower than in consolidated materials.
- Velocities are very similar in unconsolidated, saturated sediments.
- Velocities in weathered rocks are lower than in similar but unweathered rocks.

In general, then, it is possible using seismic velocity to distinguish dry from saturated sediments and sediments from consolidated rocks.

Empirical, mechanistic, and theoretical approaches have been used to relate seismic P-wave velocity to hydrogeological parameters. For example, a velocity (V)–porosity (ϕ) relationship is given by the Wyllie time-average equation using estimated matrix velocity (V_m) and pore fluid velocity (V_f) values:

$$\frac{1}{V} = \frac{1 - \phi}{V_m} + \frac{\phi}{V_f} \quad (14.7)$$

Marion et al. (1992) used a theoretical microgeometrical approach to relate seismic P-wave velocity to pressure and porosity within an unconsolidated, sand-clay system. This relation was verified empirically in the laboratory, and the model was extended by Rubin et al. (1992) to investigate the relationship between log permeability, effective pressure, and seismic P-wave velocity. Regression techniques are commonly used to relate site-specific measurements, such as velocity, porosity, and lithology. For example, Klimentos (1991) used regression analysis to obtain a relation between velocity, porosity, and clay content in a consolidated, sand-clay system. As is described in a very thorough review on seismic petrophysics given by Pride (2005), a universal relation between permeability and seismic velocity does not exist: the relationship depends on how the geologic materials were formed and have evolved over time.

14.2.5 Potential Field Methods

14.2.5.1 Gravitational Methods

Measurements of the changes in gravitational acceleration can be used to obtain information about subsurface density variations. As density is a bulk property of rocks and tends to be consistent throughout a geological formation, gravity methods are used to identify gross features based on density variations. Due to the lower resolution offered by this method, it is not commonly used for detailed site characterization. It does, however, provide an inexpensive way to detect or map targets such as the interface between sedimentary overburden and bedrock or locations of significant faults. Gravity methods have also been used to detect sinkholes, other subsurface voids, and landfill boundaries. The common measuring device is a gravimeter, an instrument that is portable and easy to use. A spring balance inside the gravimeter measures differences in the weight of a small internal object from location to location; the weight differences are attributed to changes in the acceleration of gravity due to lateral variations in subsurface density.

Measurements can be collected at a regional or local scale depending on the station spacing, which is usually less than half of the depth of interest.

Gravity measurements must be adjusted prior to interpretation by comparing the observed gravity values with the calculated response of a homogeneous formation. The theoretical response to the gravitational field due to such factors as the datum, latitude, tidal, altitude, terrain, drift, and regional gradient are calculated and subtracted from the raw data to yield what is called a gravity anomaly field (Zodhy et al., 1974). A Bouguer anomaly refers to the value that is obtained after latitude corrections, elevation corrections, and (sometimes) terrain corrections have been applied to the gravity data. Anomaly field interpretations are non-unique; a large number of hypothetical features with varying density, depth, and shape can produce the same gravity anomaly. Qualitative interpretation usually consists of constraining a profile or contoured anomaly map with other known geologic information. Forward modeling techniques and characteristic curve matching are also used for interpretation. Reviews of the gravity technique and applications to environmental studies are given by Hinze (1990) and by Butler (1991).

14.2.5.2 Magnetic Methods

Magnetic methods measure the direction, gradient, or intensity of the earth's magnetic field. The intensity of the magnetic field at the earth's surface is a function of the location of the observation point in the primary earth magnetic field as well as local or regional concentrations of magnetic material such as magnetite, the most common magnetic mineral. Magnetometers are used to measure the total geomagnetic field intensity or relative values of the vertical field intensity, and magnetic gradiometers measure the horizontal and vertical gradient of this magnetic field. After correcting for the effects of the earth's natural magnetic field, magnetic data can be presented as total intensity, relative intensity, and vertical gradient anomaly profiles or contour maps. Interpretation of magnetic surveys generally involves forward modeling or mapping of the anomalies and correlating them with other known geologic information. This interpretation is non-unique.

Magnetic methods are generally used to identify gross features at a resolution similar to that of seismic refraction and gravitational methods. As magnetic signatures depend to a large extent on magnetic mineral content, which is low in most sediments that comprise aquifers, magnetic field work is not commonly employed for near-surface investigations. It is used, however, to map the depth to basement rock, provided that it contains sufficient magnetic minerals. Magnetic methods with fine station spacing and high lateral resolution (a few meters) are now one of the most commonly used geophysical methods for site investigation due to their ability to locate metal objects such as drums and abandoned drill hole casings that are buried in near-surface sediments. A review of magnetic methods as applied to environmental problems is given by Hinze (1990).

14.2.6 Borehole Geophysical Methods

Borehole geophysics refers to the process of recording and analyzing of geophysical log measurements collected within wellbores. This information can be used together with direct measurements (such as core samples) or hydrological information (such as flowmeter or pumping tests) to develop site-specific petrophysical relationships. Log data are also useful to "tie" together more direct information collected at the wellbore location with geophysical signatures of property variations collected using surface geophysical data. With a combination of well log and surface geophysical data, hydrogeological information measured at the wellbore can be extrapolated between boreholes.

The volume of material sampled by the borehole log, or the volume of investigation, is related to the log type, source-detector spacing, and subsurface material, and thus varies with well site conditions and logging parameters employed. Interpretation of the recorded log data often involves comparing several different logs displayed side-by-side or by cross-plotting data from one log against data from other logs, core analyses, or tests. For hydrocarbon exploration, the decision to test and complete a well is based to a large extent on geophysical log information, and as a consequence, most of the interpretation guidelines for borehole geophysics have been developed for borehole and rock environments encountered in petroleum

exploration. Excellent references for borehole geophysics applied to hydrogeologic investigations are given by Keys (1989) and Kogr et al. (2005), which are the references for the following information where not otherwise cited. A review of the process of drilling, coring, and sampling water wells is given by Shuter and Teasdale (1981).

Borehole measurements are made by lowering a sonde into the borehole on the end of an electric cable. The sonde is a probe, generally 2.5 to 10.0 cm in diameter and 0.5 to 10.0 m in length, which encloses sources, sensors, and the electronics necessary for transmitting and recording signals. Measurements made in the borehole are recorded on the surface in analog form on chart paper or in digital form as shown in Figure 14.7, which is an example of several logs that have been collected in a shallow water well.

The following discussion focuses on the underlying physical principles of logging methods that are currently used in groundwater applications or that have potential for aiding these investigations, including caliper, electric, nuclear, and acoustic.

14.2.6.1 Caliper Logs

Caliper logs are mechanical or acoustic tools that measure the diameter of the borehole. The mechanical caliper tool is a single arm connecting between one and six caliper probes that are pressed against the borehole wall by spring pressure. As the tool is pulled up the borehole, the mechanical caliper probes move in response to changes in borehole diameter and the acoustic calipers measure the reflection transit time of an acoustic signal from the borehole wall. Changes in the diameter of the borehole affect the response of all geophysical tools, and thus a caliper log is generally collected in conjunction with all logging types to aid in interpretation and correction. As sloughing of the material is a function of the material cohesiveness and thus of the lithology, caliper logs are also used to indicate lithology or fracture zonation.

14.2.6.2 Electric Logs

Electric logs measure potential differences due to the flow of electric current in and adjacent to the well. There are many different types of electric logs, all of which must be run prior to casing and in saturated boreholes.

Single-point resistance is a very simple tool that is used to measure resistance by passing a constant current between an electrode in the well and another located on the surface. Electrical resistivity, includes the dimensions of the material being measured and is an intrinsic property of the material. Resistance depends on the material composition as well as on the cross-sectional area and length of the current path through the medium. Electrical resistance (r), measured in Ohms (Ω), is related to resistivity (ρ) by

$$r = \frac{\rho L}{S} \quad (14.8)$$

where S is the cross-sectional area normal to the flow of current (m^2) and L is the length of the current path in meters. The single-point resistance log shown in Figure 14.6 reveals the usefulness of this tool for high resolution lithological identification; the sand and gravel units characteristically give a higher resistance reading than the silts and clays. *Resistivity* measurements are made by sending a current through electrodes lowered down the borehole and recording the voltage across other electrodes located on the sonde. Resistivity calculations are performed using Ohm's law (Equation 14.1). Resistivity logs are commonly used to calculate water quality, as well as saturation and porosity (Equation 14.3). Short and long *normal, focused, and lateral* logs are all resistivity methods that differ by the electrode configuration on the sonde, and *microresistivity* logs employ electrodes that are forced to contact the borehole wall. All configurations measure the resistivity of the subsurface material, pore fluid, borehole fluid, or some combination of these. *Dipmeter* tools use three or four contact microresistivity probes connected to a single arm that press against the borehole walls to measure resistivity simultaneously at multiple orientations within the borehole. Interpretation involves correlating resistivity measurements made from each probe to estimate primary sedimentary structure orientation of the units penetrated by the wellbore. Computer analysis of dipmeter data is most effective. A *spontaneous potential* (SP) log measures the natural potential difference

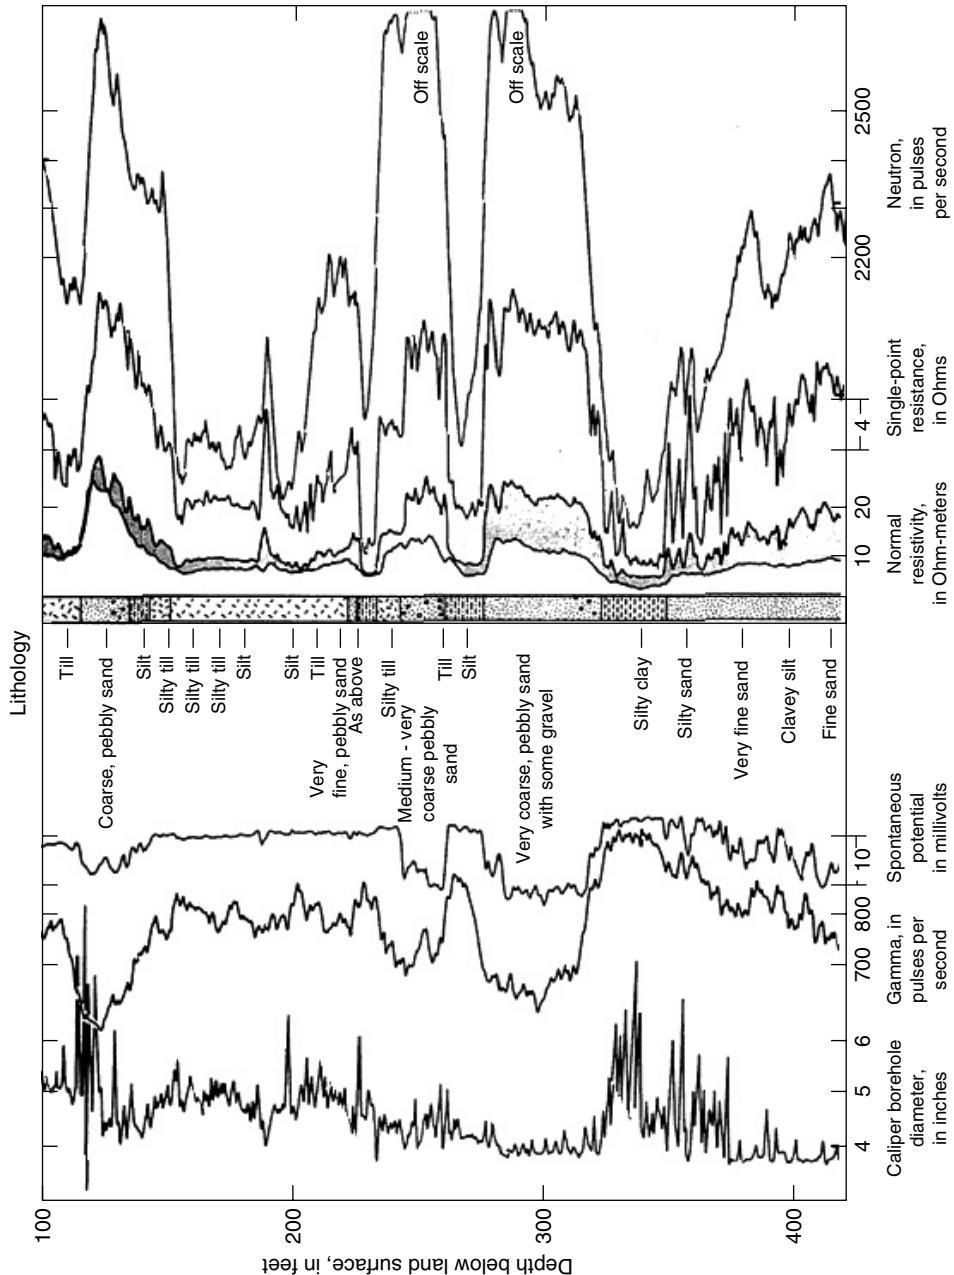

FIGURE 14.7 Borehole geophysical and lithological logs collected at a typical shallow water well. (From Keys, S.W., 1989. *Borehole Geophysics Applied to Ground-Water Investigations*. National Water Well Association, Dublin, OH. With permission.)

between a single electrode in the wellbore and a reference electrode at the surface. These potentials exist due to a combination of electrochemical effects created, for example, by migration of ions from concentrated to more dilute solutions. Additional effects may be caused by electrokinetic (streaming) potentials that result from fluid moving in or out of the hole or redox potentials caused by ionic charge accumulation between metallic mineral grains and the fluids adjacent to the grains.

14.2.6.3 Nuclear Logs

Nuclear logging entails the detection of unstable isotopes near the borehole. The considerable advantage of nuclear logs over electric logs is that they can be run after casing has been installed. As isotopes decay, they emit radiation such as gamma photons or rays from the nucleus. Gamma proton and neutron radiation sources are often used in borehole applications because of their ability to penetrate dense material such as rock and casing. Borehole geophysical tools that measure radioactivity of nearby formations may be classified as those that detect natural gamma radiation, those that employ controlled gamma rays to induce radiation, and those that use neutron sources to induce nuclear processes. The radioactivity is measured as electronic pulses, and the quantity and amplitude of the pulses yield information about the surrounding formation. Logging tools that use artificial radioisotopes as sources are regulated by governmental agencies and require a license for use.

The *gamma log* uses a scintillation detector to measure total naturally occurring gamma radiation of the material penetrated by the borehole within a selected energy range. The three most common naturally occurring radioactive materials that affect the gamma log are potassium-40, uranium-238, and thorium-232. The usefulness of this log lies in the fact that these isotopes are generally more abundant in shales and clays and less common in sands and calcareous materials, and that measurements can be reliably made above the water table. The gamma log shown in Figure 14.6 reveals the characteristically high gamma log count rate associated with silts and clays. In addition to the count rate that is measured with the gamma log, the *gamma-spectrometry* method records the amplitude of the pulses over a wide energy range. Analysis of this energy permits more diagnostic information on lithology and also permits estimation of the type and quantity of radioisotopes that may be contaminating the groundwater.

Gamma-gamma or *density* logs record gamma radiation that originates from an artificial gamma source in the well that is backscattered by the borehole and surrounding material. The count rate of the backscattered gamma rays can be related to the electron density of the material that is in turn proportional to the bulk density of the material. If the fluid and grain densities are known, the bulk density measured with the gamma-gamma log can be used to calculate porosity:

$$\phi = \frac{\text{grain density} - \text{bulk density}}{\text{grain density} - \text{fluid density}} \quad (14.9)$$

As moisture content affects the bulk density of materials, gamma-gamma logs can be used to record changes in moisture above the water table.

Neutron tools consist of an artificial low-energy wellbore neutron source and one or two neutron detectors. The neutrons emitted by the source lose energy upon collision with other elements in the vicinity of the borehole. As hydrogen has a mass similar to the neutron, it is the most effective element at slowing the neutrons. The quantity of slowed neutrons is thus interpreted to be proportional to the quantity of hydrogen present, which is in turn interpreted to be proportional to the moisture content or saturated porosity.

14.2.6.4 Acoustic Logs

Acoustic (sonic or velocity) tools transmit an acoustic pulse from a source, through the fluid and material in the vicinity of the borehole, and to the detector. All acoustic logs require saturated borehole conditions for signal transmission. These tools emit an acoustic source at frequencies of 10 to 35 KHz (0.01 to 0.035 MHz) which creates compressional or P-waves. As the waves travel, some of the energy is refracted back to two receivers located on the sonde. The difference in travel time between the receivers is used to

calculate interval velocity, which is recorded as a function of depth in the wellbore. *Acoustic waveform* logging entails the recording and interpretation of the entire waveform rather than just the time of the first arrival of energy as is recorded with the acoustic log. Analysis of the amplitude, frequency, and other components of the wave train may yield information about the quality of the bond between casing and cement and cement and borehole wall. Additionally, attributes of the signal can yield information about the formation penetrated by the borehole. For example, correlations have been found between attenuation and permeability of fractures.

The *acoustic televIEWer* (ATV) emits high frequency (1.3 MHz) acoustic energy toward the borehole wall. The transducer rotates clockwise at about three rotations per second. During rotation, the transducer sends signals toward and receives signals from the borehole wall. Fractures or other openings in the borehole wall force the signal to travel farther through the fluid and thus to be more attenuated. Attenuation causes amplitude variations that can be visually captured by adjusting the contrasts on the display. The display can be thought of as a cylinder that has been opened along the north side and flattened to provide a 360-degree ultrasonic picture of the borehole wall. Planar horizontal features that intersect the well will appear on this display as dark horizontal bands and planar dipping features that intersect the well will appear as dark sinusoids with the lowest point of the curve in the direction of dip.

14.3 Hydrogeophysical Concepts

In this section, we review the concepts associated with using geophysical data, such as those obtained using the methods described in Section 14.2, for hydrogeological characterization. Geophysical data can be collected from many different platforms, such as from satellites and aircraft, at the ground surface of the earth, and within and between wellbores (Table 14.3). Figure 14.8 illustrates relative length scales and resolutions associated with different geophysical (G) and hydrological (H) data acquisition categories. The scale category definitions defined in Figure 14.7 (point, local, regional) are approximate and are intended to convey the typical spatial extent associated with *investigations* rather than to imply specific notions of measurement support scales for individual instruments, averaging or dimensionality. The methods described in Section 14.2 were limited to borehole, crosshole, and surface geophysical techniques; readers interested in laboratory-scale geophysical methods for hydrogeological applications are referred to Ferre et al. (2005), and readers interested in the use of remote-sensing techniques for hydrogeological characterization are referred to Paine and Minty (2005). Figure 14.8 illustrates that tradeoffs typically exist between the resolution of measurements collected using a method having a certain acquisition geometry and the typical scale of investigation for that method. For example, core measurements provide information about a very small portion of typical field investigations at a very high resolution, while surface geophysical techniques often provide lower resolution information but over larger spatial scales. It is important to realize that the scale and resolution of a particular characterization technique may vary depending on the acquisition parameters and geometry employed. For example, electrical resistivity measurements are commonly collected from core samples, electrical logs, between wellbores, and from the ground surface; electrical measurements can thus be useful for point, local, and regional-scale investigations, and can have a range of resolutions. Additionally, varying the acquisition parameters of a particular method can change the resolution, even if the acquisition geometry stays the same. For example, collection of crosshole seismic travel-time measurements between wellbores that have a great separation distance and that have large source-receiver station spacing within the wellbores will result in a lower possible spatial resolution than seismic crosshole data collected using close wellbore spacing and source-receiver station spacing.

Tables 14.3 and 14.4 presents the surface and crosshole geophysical methods that were discussed in Section 14.2. The methods are classified according to their acquisition approach, and the table lists the geophysical attribute that is typically obtained from the method and examples of hydrogeological objectives for which each method is particularly well suited. The choice of which characterization or technique or acquisition approach to use for a particular investigation is made by considering many factors, such as: the objective of the investigation relative to the sensitivity of different geophysical methods to that

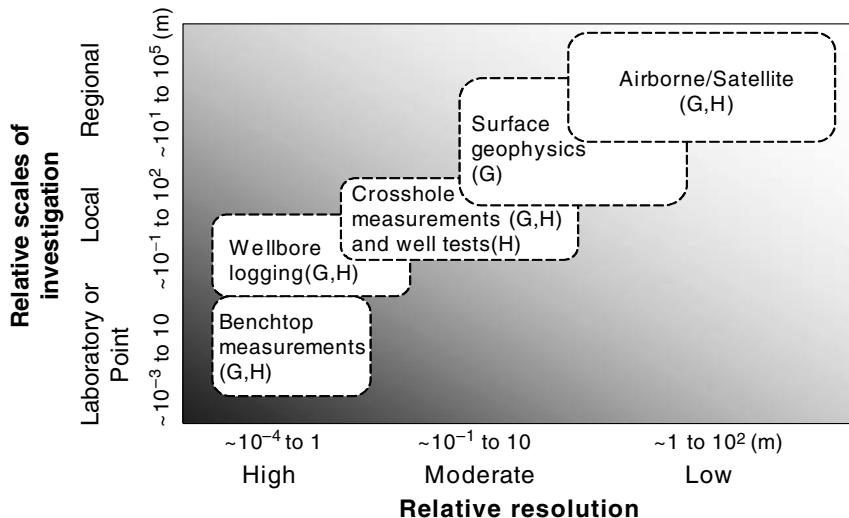

FIGURE 14.8 Chart showing trade-off between the relative resolution of the information obtained using different yet typical geophysical (G) and hydrological (H) measurement acquisition approaches and the relative scale of the investigations for which those acquisition geometries are typically used. Benchtop measurements refer to those such as core, column, and tank measurements collected within a laboratory.

objective; the desired level of resolution; conditions at the site; time, funds, and computational resources available for the investigation; experience of the investigator; and availability of other data. Some of the analyses and data-acquisition techniques described here can be carried out as reconnaissance studies, painting a picture of the aquifer using a wide paintbrush, while others can be applied at an advanced stage, resulting in a more detailed portrait. For example, in applications such as resource management and regional mass balance analyses, characterization of the aquifer through its geometry and effective properties may be all that is necessary; in fact, this may be all that can be realistically achieved given the severe data limitations usually encountered. However, studies of contaminant transport generally require detailed mapping of the spatial distribution of the hydraulic conductivity.

Data are often collected in a sequential fashion, whereby lower-resolution acquisition approaches are used for reconnaissance investigation, followed by higher-resolution approaches to provide more detailed information as needed. As there may be several plausible subsurface scenarios that could produce a given geophysical response, and because different geophysical techniques are sensitive to different properties, a combination of different geophysical techniques is often used to characterize the subsurface. Combinations of hydrogeological and geophysical data can be used to yield a better understanding of shallow subsurface parameters and processes over various scales and resolutions.

Examples of the relative value of the different methods for various surface and crosshole hydrogeological characterization objectives are given in Table 14.4. Table 14.3 and Table 14.4 suggest that geophysical data are used to assist with a wide range of hydrological objectives. These objectives can be broadly categorized into three key areas (1) Hydrogeological mapping, (2) Hydrological parameter estimation, and (3) Monitoring of hydrological processes, each of which is briefly described below.

14.3.1 Hydrogeological Mapping

Hydrogeological mapping using geophysical data is perhaps the most common hydrogeophysical characterization objective. Mapping techniques rely on the measurement of subsurface physical properties or contrasts of these properties. From these measurements, the nature and distribution of subsurface materials can often be deduced. For example, subsurface variations in elastic moduli and density cause seismic waves to travel at different speeds. Information about these changes, and thus about the nature and distribution of the subsurface materials, can be interpreted from analyzing the seismic arrival times.

TABLE 14.3 Common Geophysical Characterization Methods That are Used to Assist in Hydrogeological Investigations

Acquisition Approaches	Characterization Methods	Attributes Typically Obtained	Examples of Hydrogeological Objectives
Surface	Seismic refraction	P-wave velocity	Mapping of top of bedrock, water table, and faults
	Seismic reflection	P-wave reflectivity and velocity	Mapping of stratigraphy, top of bedrock and delineation of faults/fracture zones.
	DC resistivity	Electrical resistivity	Mapping of aquifer zonation, water table, top of bedrock, fresh-salt water interfaces and plume boundaries, estimation of hydraulic anisotropy, and estimation/monitoring of water content and quality.
	Electromagnetic	Electrical resistivity	Mapping of aquifer zonation, water table and fresh-salt water interface, estimation/monitoring of water content and quality.
	GPR	Dielectric constant values and dielectric contrasts	Mapping of stratigraphy and water table, estimation and monitoring of water content
	Gravity	Gravitational field	Mapping of sedimentary overburden, bedrock, and locations of landfill boundaries, significant faults, and sinkholes and other voids.
	Magnetics	Direction, gradient, and intensity of magnetic field	Mapping the depth to bedrock, sedimentary overburden, and locating buried metallic objects, such as waste drums and abandoned casings.
	Crosshole	Electrical resistivity (ERT)	Mapping aquifer zonation, estimation/monitoring of water content and quality
	Radar	Dielectric constant	Estimation/monitoring of water content and quality, mapping aquifer zonation
Wellbore	Seismic	P-wave velocity	Estimation of lithology, fracture zone detection
	Geophysical well logs	Many attributes, including electrical resistivity, seismic velocity and gamma activity	Lithology, water content, water quality, fracture imaging

Similarly, spatial variations in electrical and dielectric properties of subsurface materials produce spatial variations in electromagnetic and ground-penetrating radar responses, respectively. The contrasts in physical properties vary depending on which materials are juxtaposed, and the ability to detect these changes varies with the geophysical method employed. For example, consider the geologic section shown in Figure 14.9, where a saturated clay overlays a saturated sand layer, which in turn overlays a heavily fractured bedrock surface. The velocity contrast between the clay and sand layers may not be detectable using surface seismic methods, but the electrical resistivity contrast is likely sufficient to be detected using electrical methods. Depending on the method, “mapping” may pertain to the mapping of interfaces (as is

TABLE 14.4 Applications of Surface and Crosshole Geophysical Methods

Application	Surface/Crosshole Method	DC Resistivity	ERT	EM	Surface GPR	Crosshole GPR	Reflection Seismic	Seismic Crosshole	Refraction Seismic	Gravity	Magnetics
Depth to water table	4	1	4	3	1	2	0	4	1	1	0
Fresh/salt water interface	4	0	4	2	0	1	0	2	0	0	0

0 = not considered applicable; 1 = limited use; 2 = used, or could be used, but not the best approach or has limitations; 3 = has potential but not fully developed; 4 = generally considered an excellent approach, techniques are well developed.

^aThese applications are current topics of research.

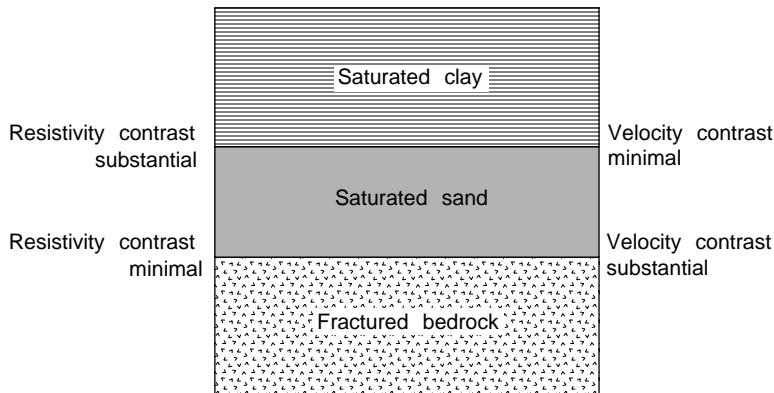

FIGURE 14.9 Schematic geological section and associated electrical resistivity and seismic velocity contrasts at the interfaces. (From Burger, H. R., 1992, *Exploration of the Shallow Subsurface*, Prentice Hall, Englewood Cliffs, NJ. With permission.)

typically the case with surface seismic and GPR methods), or the mapping of layers or units (as is the case with surface electrical or electromagnetic methods).

A common mapping approach with all surface-based geophysical methods is to compare sparse borehole data, which provide direct and detailed information about subsurface hydrogeology as a function of depth at a single location, with less invasive and more laterally continuous geophysical data. As geophysical responses can be non-unique and ambiguous, a comparison between direct measurements and geophysical attributes is typically necessary to interpret the geophysical data in a hydrogeologically meaningful manner. In some cases, this procedure is routine, whereas in other cases it can be quite challenging and demand frameworks for integration. Advanced stochastic techniques for handling more challenging integration problems are discussed in Section 14.4.

Geophysical methods are commonly used for hydrogeological mapping of the geometry of subsurface interfaces or units, the water table, top of bedrock, plumes, faults, and fresh–salt water interfaces. Figure 14.10 shows an example of hydrogeological mapping using 100 MHz GPR data within in an Atlantic Coastal Plain aquifer of Virginia (modified from Hubbard et al., 2001). The locations of the key reflectors visible on the GPR profile were compared with hydrogeological features detected using wellbore data. Once the GPR signatures were “matched” with the features identified using borehole data, the GPR data were then used to delineate key features laterally away from the boreholes. As shown in Figure 14.10, within the top 15 m of this sedimentary subsurface, the GPR profile reveals the water table, key unconformities, several stratigraphic packages, and the top of a subregional aquitard. As was illustrated in Figure 14.6, seismic profiles can also be useful for indicating the interfaces between hydrogeologically significant units.

An example of the use of both electrical profiling and sounding acquisition modes to map hydrogeological units is shown in Figure 14.11a and Figure 14.11b. The map shown in Figure 14.11a is a contour map produced from the resistivity measurements of several profiles collected near San Jose, CA, using an a-spacing (see Figure 14.1a) of 6.1 m (Zodhy et al., 1974; Burger, 1992). Contours of equal apparent resistivity delineate an approximately east-west trending apparent resistivity high. The geologic cross section (BA) shown in Figure 14.11b is based on four expanding-spread traverses (soundings), the apparent resistivity profile information, and information from three boreholes whose locations are indicated on the cross section. The cross section reveals that the high-resistivity area shown on the apparent resistivity map of Figure 14.11a is a zone of gravel and boulders that defines the location of a buried stream channel.

An example of the use of surface EM data for delineating a subsurface conductor is illustrated in Figure 14.12. Figure 14.12a shows an apparent conductivity contour map obtained from interpretation of frequency domain Geonics EM-34 profiling measurements over a brine evaporation pit (Hoekstra et al., 1992). Several measurements were collected, as shown by the dots in Figure 14.12a, using a single frequency and a fixed coil spacing of 20 m. An apparent electrical conductivity high trending from the

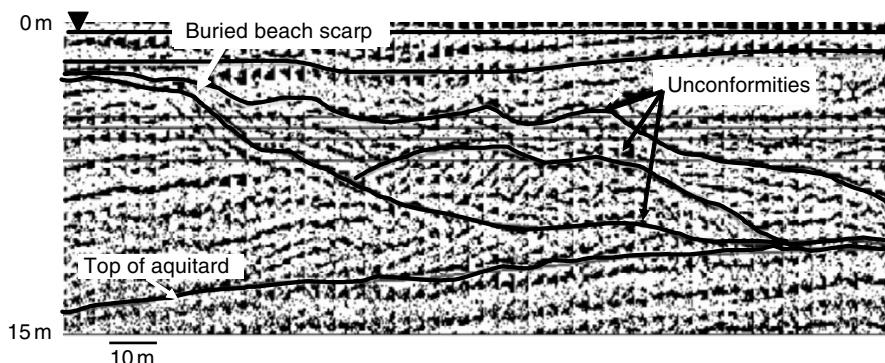

FIGURE 14.10 Example of the use of surface 100 MHz GPR data for mapping shallow subsurface features. (From Hubbard and Rubin, Chapter 1 in *Hydrogeophysics*, Kluwer, the Netherlands, 2005).

brine pond to the southwest is interpreted to be the main direction of contaminant migration. Five EM soundings at the locations indicated by the numbered boxes in Figure 14.12a were collected with the time domain Geonics EM-47 and inverted to yield electrical conductivity estimations as a function of depth. The geologic cross section shown in Figure 14.12b was obtained from lateral interpolation between the five soundings. This cross section suggests that there is a high-conductivity layer beneath stations 2 and 3, interpreted to be the area of brine contamination from the brine pond shown in Figure 14.12a.

An example of the use of gravity data for hydrogeological mapping is shown in Figure 14.13. In this study, gravity data were collected to determine the depths to bedrock in an urban area where the drilling of numerous wells was not feasible (Kick, 1985). Detailed gravity measurements were collected by siting gravity stations at 40-ft intervals and obtaining detailed elevation information that was necessary for the elevation correction at these stations. After corrections were applied to the gravity measurements, the Bouguer gravity values were plotted against distance (Figure 14.13a). A regional gravity trend, obtained from a smoothed version of the data in conjunction with the state gravity map, is also shown in Figure 14.13a. This regional trend was removed from the gravity curve to enhance the local effects such as those caused from soil thickness variations; the new data are called the residual gravity data. The interpretation of the residual gravity data is shown in Figure 14.13b. This figure demonstrates that, in all cases except one, the bedrock depths interpreted from the residual gravity data are close to those confirmed by borehole data.

Many more excellent examples of hydrogeological mapping using geophysical datasets are given at the regional scale by Paine and Minty (2005), at the local scale in the saturated sediments by Hyndman and Tronicke (2005), and at the local scale within the vadose zone by Daniels et al. (2005). It is useful to note that most hydrogeological mapping investigations involving geophysical data provide qualitative information about the location of key boundaries or units. Exceptions to this trend include the quantitative studies by Copty et al. (1993) and Hubbard et al. (2005), who used Bayesian techniques to integrate wellbore and surface-based geophysical information for the estimation of lithology and water average water content, respectively.

14.3.2 Hydrogeological Parameter Estimation

To understand, remediate, predict, or manage hydrological systems, information about the states, flowpaths, and fluxes of water through the system is often required, as is information about the controlling characteristics, such as the lithology, porosity, or hydraulic conductivity. For example, mathematical models are used to simulate contaminant plume transport over time for designing effective remediation plans, and to simulate aquifer depletion vs. recharge over time and for designing sustainable resource extraction programs. Such mathematical modeling requires accurate and sufficient hydrological parameter input. Given the difficulty of obtaining sufficient characterization data for model parameterization at

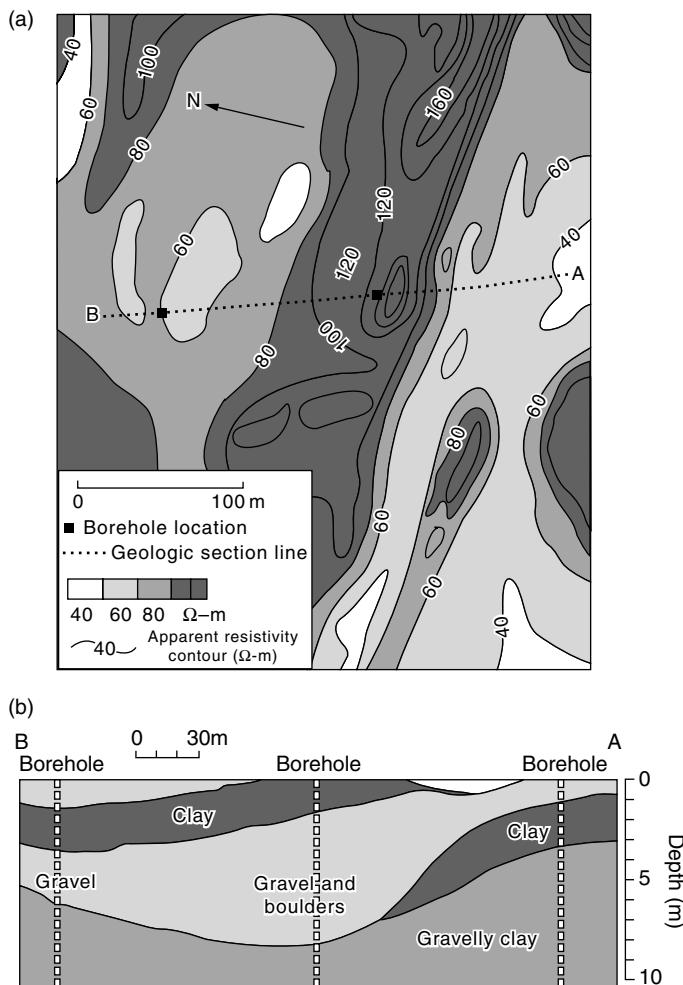

FIGURE 14.11 Resistivity survey used to delineate lateral and vertical variations in subsurface stratigraphy. (a) Contour map produced from resistivity measurements collected using many constant-spread Wenner profiles with an “a” spacing of 6.1 m. (From Zodhy A. A., G. P. Eaton, and D. R. Mayhey, 1974, Applications of surface geophysics to groundwater investigations. Techniques of Water Resources Investigations of the U.S. Geological Survey, Book 2, Chapter D1 and Burger, H. R. 1992, *Exploration Geophysics of the Shallow Subsurface*. Prentice Hall, Englewood Cliffs, NJ. With permission.) The contours of equal apparent resistivity delineate an approximately east–west trending apparent resistivity high. (b) A geologic cross section (BA) based on four electrical resistivity soundings, the apparent resistivity information from the profiles, and from three boreholes whose locations are shown above the cross section. The cross section reveals that the high-resistivity trend shown in (a) is a zone of gravel and boulders that define the location of a buried stream channel.

a reasonable spatial scale using conventional datasets, it is generally felt that computational flow and transport abilities have surpassed the ability to adequately parameterize the synthetic aquifer domains. As a result, the predictive capability of these models is limited, and a significant disconnect has developed between the state-of-the-art associated with modeling and the use of these models to manage practical problems on a regular basis.

As geophysical data offer the potential to provide high resolution information about the controlling hydrogeological parameters in a minimally invasive fashion, they have a large role to play in the interrogation and management of hydrological systems. The ability to estimate subsurface hydrogeological properties using a particular geophysical approach is a function of the relation between the property

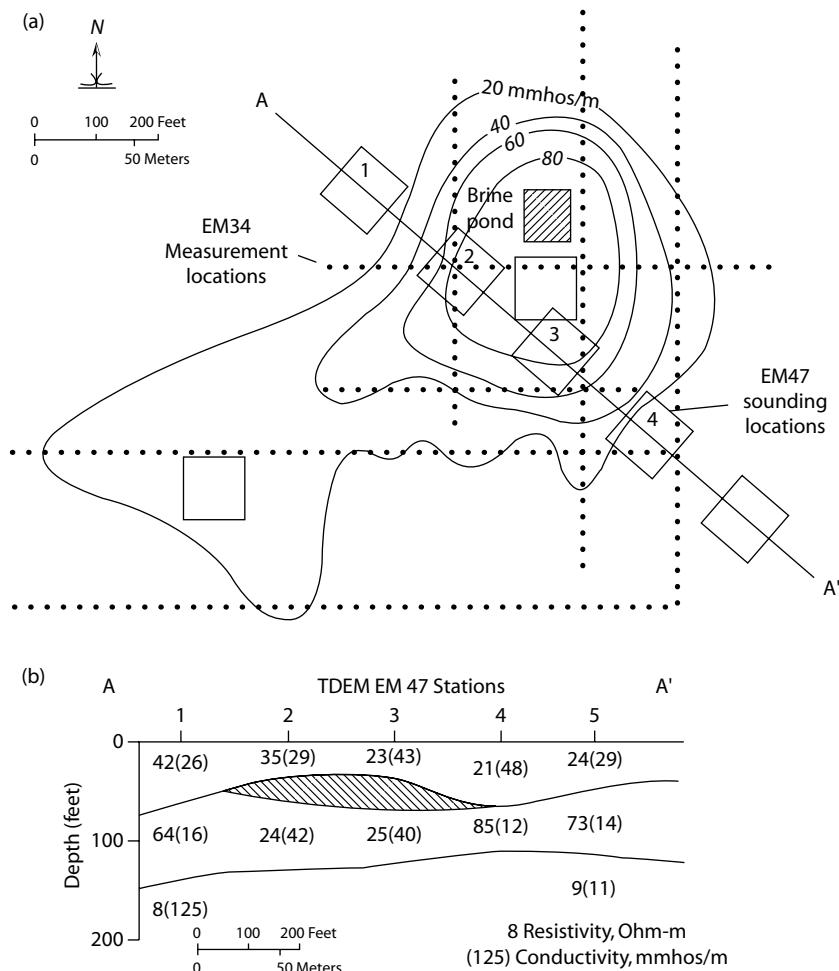

FIGURE 14.12 (a) Apparent conductivity contour map over a brine evaporation pit interpreted from EM profiles. (b) Geoelectric cross section along A-A' traverse interpreted from five EM soundings whose locations are indicated by the five numbered boxes shown in (a). (From Hoekstra, P., R. Lahti, J. Hild, R. C. Bates, and D. Phillips, 1992, *Groundwater Monitoring Rev.*, 12(4), 110–117. With permission.)

under consideration and geophysical attributes, the availability of direct measurements for calibration, the magnitude of the property variations and contrasts, and the spatial scale of the changes relative to the scale of the objective target. The majority of the hydrogeophysical studies that have focused on hydrogeological parameter estimation have been performed using crosshole acquisition geometries because they provide high-resolution information about geophysical attributes with a support scale that is often comparable to direct borehole measurements, thereby minimizing the scale matching problem.

Different approaches have been used for obtaining estimates of hydrogeological parameters using geophysical data. In some cases, the geophysical attributes can be directly “transferred” to estimates of hydrogeological parameters using a published petrophysical relationship or a relationship that has been developed specifically for the site under investigation. In recent years, several studies have developed stochastic frameworks for using geophysical data in hydrogeological site characterization as will be described in Section 14.4. Geostatistical approaches for fusing hydrogeological and geophysical data have been illustrated by many investigators (e.g., Poeter et al., 1997; Yeh et al., 2002). Bayesian approaches for estimating conductivities using head and conductivity measurements (as well as seismic data) have been reported by Rubin et al. (1992), Carty et al. (1993), Carty and Rubin (1995), Chen et al. (2001),

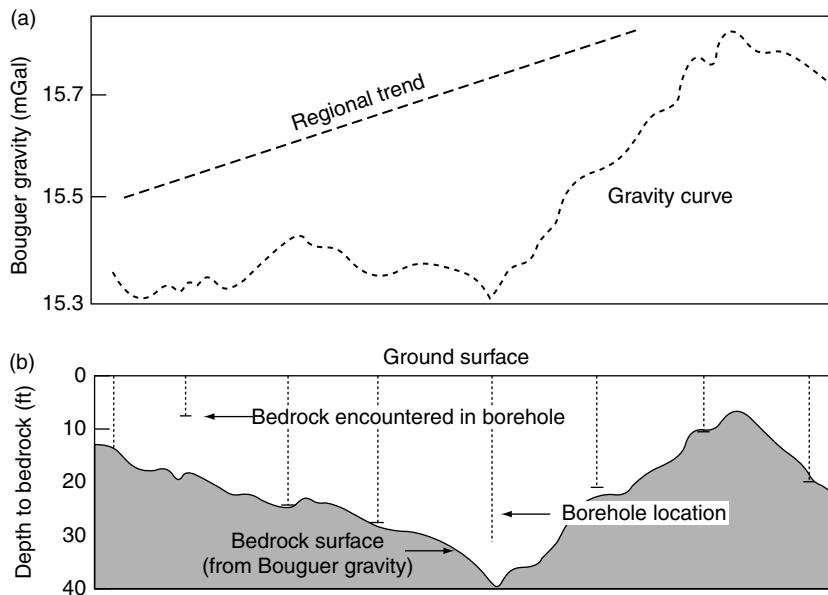

FIGURE 14.13 Interpretation of gravity data to estimate the depth to bedrock (Kick, 1985). (a) Bouguer gravity curve obtained from reduced gravity measurements and regional gravity trend. (b) Interpretation of the local gravity data after removal of the regional trend showing that the bedrock depths interpreted from the gravity data are similar to those confirmed by borehole information. (From Kick, J. F., 1985, Depth to bedrock using gravimetry, geophysics: the leading edge of exploration, *Soc. Exploration Geophysicists*, 4(4), 38–42. With permission.)

and Chen and Rubin (2003). Hubbard et al. (1997b) employed a Bayesian technique to incorporate GPR into mapping the spatial distribution of saturation and permeability as will be described in Section 14.4. Knight et al. (1997) and Hubbard et al. (1999) combined geophysical and hydrogeological data for estimating the spatial correlation structure of the log-permeability. An application of these concepts to estimate hydraulic conductivity was given by Hubbard et al. (2001) and will be described in Section 14.4. Purvance and Andricevic (2000) estimated the spatial distribution of the hydraulic conductivity and its spectral density using electrical and hydraulic conductivities. Day-Lewis et al. (2000) reported an application of the use of geophysical methods for investigating fractured terrains. Hyndman et al. (1994) and Hyndman and Harris (1996) used stochastic techniques and geophysical data to delineate hydrogeological units, and Hyndman and Gorelick (1996) used a stochastic approach to jointly invert geophysical and tracer test data. More recently, other investigators have experimented with the use of the sampling-based Markov chain Monte Carlo (MCMC) method to integrate often complex and nonlinear geophysical and hydrogeological data sets. For example, the MCMC approach was used by Chen et al. (2005) for estimating sediment geochemical parameters, such as Fe(II) and Fe(III), as well as lithology, using GPR crosshole attenuation data through the dependence of both radar attenuation and sediment geochemistry on lithology. Results from this study are illustrated in Figure 14.14. Estimates such as these can be very useful in parameterizing reactive flow and transport models used for predicting contaminant or bacterial transport, or for assessing redox conditions. Other hydrogeophysical estimation studies are described in Hyndman and Tronicke (2005), Daniels et al. (2005), and Linde et al. (2005). Although predominantly performed at the “local” scale, these recent studies highlight the promise of geophysical data for providing quantitative hydrogeological parameter estimates. Section 14.4 will further explore the potential of stochastic methods for providing the systematic framework needed to handle complexities that sometimes arise in fusing disparate hydrogeological–geophysical data sets, such as those associated with spatial variability, measurement error, model discrimination, and conceptual model uncertainty.

14.3.3 Hydrological Process Monitoring

In addition to geophysical data collected at one point in time to characterize systems in a static sense, geophysical data can be collected at the same location as a function of time. Observing the data as “time difference” sections (measurements collected at an earlier time subtracted from measurements collected at a later time), or “time-lapse” sections, enhances the imaging of subtle geophysical attribute changes caused by natural or forced system perturbations. Time-lapse imaging also decreases the dependence of the geophysical measurements on both the static geological heterogeneities and on data inversion procedures and associated artifacts. Difference images are most commonly obtained from crosshole data sets, but have also been obtained using measurements acquired with surface, airborne, and single borehole acquisition modes. These data sets have been used to elucidate dynamic transformations and thus have the potential to assist in understanding hydrological or remediation processes, such as monitoring infiltration or hydraulic fracturing, imaging injected fluids such as steam or remediation amendments, and tracking the spread of contaminant plumes.

An example is given in Figure 14.15, which illustrates the use of time-lapse, crosshole 100 MHz GPR velocity data collected over a period of a year at an important aquifer in the United Kingdom (from Binley et al., 2002). These estimates show how high rainfall, which occurred in March 1999, increased the subsurface moisture content. This figure also shows the emergence of a drying front in the fall and winter of 1999, and the influence of an impeding layer (that exists between 6 and 7 m depth) on the infiltrating water front. Monitoring using such approaches is extremely useful for understanding complex hydrological processes. The use of noninvasive or minimally invasive geophysical measurements such as these, collected over a prolonged time period, will likely become a standard monitoring approach for improving our understanding of subsurface fluxes and our ability to manage water resources.

14.4 Stochastic Forward and Inverse Modeling Using Hydrogeophysical Datasets

Successful integration of geophysical and hydrogeological datasets represents a recent and major breakthrough in hydrogeological site characterization. As was previously discussed, the value of integrating these datasets for characterization lies in the extensive spatial coverage offered by geophysical techniques and in their ability to sample the subsurface in a minimally invasive manner. However, this breakthrough is associated with a few difficulties. One difficulty resides in the non-unique relationships that sometimes exist between hydrogeological and geophysical attributes; integration of hydrogeological and geophysical data under non-unique conditions has been investigated by Rubin et al. (1992), Copty et al. (1993), Hubbard et al. (1997b), Kowalsky et al. (2004b, 2004c, 2005), Chen et al. (2005), Hou and Rubin (2005), and Hubbard and Rubin (2000). This non-uniqueness can exist even under idealized conditions of error-free

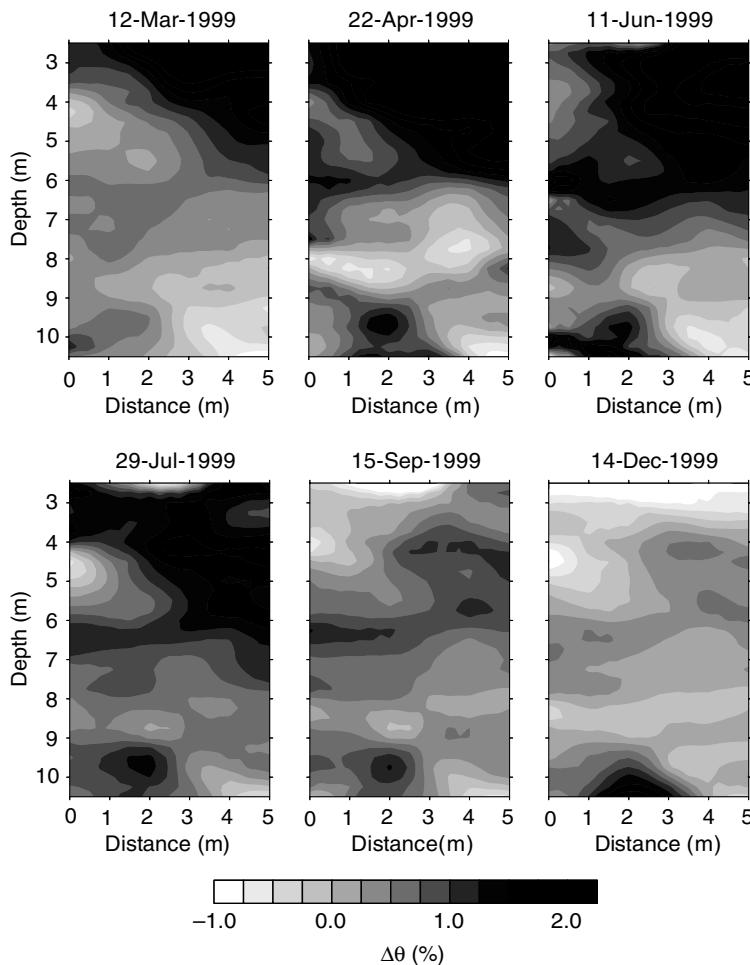

FIGURE 14.15 Percent change in volumetric water content obtained over time using time-lapse GPR velocity information associated with natural precipitation and drying. Changes in moisture content are shown relative to those estimates obtained using GPR data collected on February 1, 1999 (modified from Binley et al., 2002, *J. Hydrology*, 267(3–4), 160–172).

measurements in natural systems comprised of multiple hydrogeologically significant units (i.e., Prasad, 2003), and it is only exacerbated by measurement errors. In applications, the situation becomes even more difficult because the rock type at the location associated with the geophysical attribute is almost always unknown, and thus the applicable petrophysical model is also almost always unknown. Another difficulty stems from the disparity between the spatial resolution of the geophysical attributes and the scale that characterizes the hydrogeological attributes, collected for example, through boreholes (cf. Ezzedine et al., 1999). This scale disparity hinders efforts to develop unique and accurate relations between the two types of measurements, and introduces another source of uncertainty. It is obvious that the characterization techniques developed under such conditions must recognize these difficulties, and furthermore, that they must quantify their effects on estimation uncertainty. This leads us to formulate our data integration techniques under the very wide umbrella of stochastic techniques (Rubin, 2003). In this section, we shall present different concepts and ideas for dealing with these issues. The commonality among these concepts is in making uncertainty and spatial variability an integral part of the solution, in consistently attempting to address the challenge of estimation uncertainty, and in minimizing arbitrariness and subjectivity.

In this section, we start by setting a general framework for forward modeling under conditions of uncertainty. This is done by casting the hydrogeological prediction problem in a stochastic framework, and thus opening the door for estimating variables such as pressure or concentration in terms of their expected values and estimation variances, at a minimum, or through their probability distribution functions, for a more complete characterization of uncertainty. In hydrogeological applications, we can distinguish between dependent variables, such as concentration or soil moisture, and independent ones, such as hydraulic conductivity. The dependent variables are related, often through complex and nonlinear relationships, to the independent ones. Through these relationships, the uncertainty in estimating the independent variables can be propagated to the dependent variables. This error propagation is the essence of forward modeling: the goal is to express the uncertainty in the dependent variables as a function of the uncertainty in all the variables that affect them. Our discussion will continue by focusing on methods for estimating the uncertainty in the independent variables. The goal here is to model the effects of spatial variability and data scarcity, while utilizing data obtained from conventional hydrogeological testing as well as data from geophysical surveys. The goal is also to utilize data of different quality, starting with precise measurements and ending with information of a more qualitative nature, commonly referred to as “soft” data. We refer to this as hydrogeophysical inverse modeling. We shall discuss alternative approaches for inverse modeling, such as the maximum likelihood and maximum a posteriori methods. By emphasizing their origin in Bayes’ theorem, we will be able to present entropy-based concepts intended to improve their accuracy and generality.

14.4.1 Forward Modeling with Parameter Error

Let us consider a random variable Z . This variable can be an independent variable, such as permeability or porosity, or a dependent variable, such as pressure head, concentration, or soil moisture. To model its uncertainty, we opt to define Z as a random variable and strive to model it through a probability distribution function (pdf), or through its statistical moments. The variable Z is characterized through its pdf $f_Z(z|\underline{\theta})$, where $\underline{\theta}$ is a vector of the parameters. This vector may include the parameters of spatial correlation models (e.g., a semivariogram model) employed for conditioning the pdf on measurements, as well as parameters of petrophysical, correlation, or numerical models employed for relating between Z and other attributes or with primitive variables.

Defined as a random variable, Z can be characterized through its moments. The N th moment of Z is given by:

$$\langle Z^N | \underline{\theta} \rangle = \int_{-\infty}^{\infty} z^N f_Z(z|\underline{\theta}) dz \quad (14.10)$$

The moments of Z conditional to measurements can be obtained by replacing $f_Z(z|\underline{\theta})$ with the conditional pdf $f_Z(z|\underline{\theta}, \{M\})$, where $\{M\}$ is the vector of measurements. For a given vector $\underline{\theta}$, $f_Z(z|\underline{\theta})$ or $f_Z(z|\underline{\theta}, \{M\})$ can be obtained, for example, through Monte Carlo simulations (Rubin, 2003).

To account for parameter error, the parameter vector $\underline{\theta}$ is viewed as a realization of a random process characterized by the p -variate pdf $f_{\underline{\theta}}(\theta_1, \dots, \theta_p)$, where p is the number of parameters in $\underline{\theta}$. The expected value in Equation 14.10 must be taken over by all possible combinations of parameters, weighted by their probabilities:

$$\langle Z^N \rangle = \int_{\theta} \int_{-\infty}^{\infty} z^N f_{Z,\underline{\theta}}(z, \underline{\theta}) dz d^p \underline{\theta} = \int_{\theta} \int_{-\infty}^{\infty} z^N f_Z(z|\underline{\theta}) f_{\underline{\theta}}(\theta_1, \dots, \theta_p) dz d^p \underline{\theta} \quad (14.11)$$

where \int_{θ} implies integration over the entire vector space of $\underline{\theta}$, and $f_{Z,\underline{\theta}}$ is the joint pdf of Z and $\underline{\theta}$. The second equality in Equation 14.11 is based on Bayes’ theorem. Integrating over the parameter space yields

the marginal pdf of Z in the joint attribute-parameter space. This marginal is expected to be defined over a broader range than the one defined by the pdf of Z conditional on a given set of parameters, and it will lead to a larger variance, which reflects the effects of the parameter error. It is imperative to formulate inverse modeling strategies that can quantify the estimation errors of the parameters $\underline{\theta}$; an extensive discussion of various error types is provided in Rubin (2003, Chapter 13).

The integration in Equation 14.11 calls for a systematic screening of the multidimensional parameter space, which can be quite tedious. Some simplification is possible using the Monte Carlo integration. Applications of Equation 14.11 are discussed in Rubin and Dagan (1992), Maxwell et al. (1999), Rubin (2003), and Hou and Rubin (2005).

14.4.2 Inverse Modeling

This section discusses different strategies for determining the statistical distributions of hydrogeological parameters and their estimation errors. It is common to employ direct measurements of the attribute for this purpose, as well as measurements that can be related to the attribute using forward models, and hence the name “inverse modeling.” For example, inverse modeling of the spatial distribution of hydraulic conductivity may involve hydraulic conductivity and head measurements, and in that case will rely on the flow equation to relate between the two. Or it may employ a geophysical signal of some sort, and in this case will employ an equation for modeling the propagation of that signal and possibly petrophysical models. As our understanding of inverse modeling has evolved over time, it has become obvious that its success depends on the ability to incorporate information of all types — either “hard” information, such as direct measurements, or “soft” information, such as expert opinions given possibly in the form of pdfs, geophysical measurements, or information borrowed from geologically similar formations, used as preliminary (or prior) information.

Stochastic inverse modeling is a formulation of inverse modeling in a probabilistic framework. Employing a stochastic paradigm eliminates the problem of non-uniqueness (Carrera and Neuman, 1986a, 1986c) and introduces a rational approach for modeling uncertainty (Rubin, 2003). Stochastic inverse models are commonly based on Bayes’ theorem. Bayesian-related methods commonly include a statement of a prior pdf of the parameters, and a likelihood function that relates the attribute to the output of the forward model. Using the prior and the likelihood function, Bayes’ theorem is then employed to define a posterior pdf (or a posteriori pdf). Bayes’ theorem serves to update the plausibility of a proposition as the state of information changes because of the availability of new data. The Bayesian framework is broad enough to allow for a remarkably large number of different interpretations.

As prior information is an important component of Bayes’ theorem, we shall start our discussion by considering methods for defining minimally subjective prior pdfs. This will help us in understanding the significance and implications of choosing a model for the prior pdf. Armed with this knowledge, we shall proceed to discuss the maximum likelihood (ML) and maximum a posteriori (MAP) methods, which offer alternative interpretation of Bayes’ theorem.

A complementary classification of the various methods that we shall present is as follows (1) The sequential approach, where the focus is on defining a pdf structure and identifying its parameters, and subsequently applying it for point estimation; (2) methods that assume a pdf structure and focus on identifying its parameters, sometimes simultaneously with spatial (point) estimation.

14.4.2.1 Bayesian Estimators

A general statement of Bayes’ theorem must include the prior and posterior pdfs. The starting point is of course the prior pdf. In this section, we present several different approaches for estimating the prior pdf.

Let the pdf $g_{\underline{\theta}}(\underline{\theta}|I)$ denote the prior pdf of the vector of parameters $\underline{\theta}$, which summarizes, in a probabilistic manner, our understanding of the values $\underline{\theta}$, and can assume direct or indirect measurements of these parameters based on other sources of information. Such information may include expert opinions or information borrowed from geologically similar sites (cf. Chapters 2, 3, and 13 of Rubin, 2003). As soon as measurements at the site become available, they can be used for updating the prior pdf (Hou and

Rubin, 2005). This can be done by viewing the measurements as realizations of a space random function (SRF) X . The pdf of $\underline{\theta}$ conditioned on the vector of N measurements, \mathbf{X} , where $X_1 = x_1, \dots, X_N = x_N$, denoted by $f_{\underline{\Theta}|\mathbf{X}_1, \dots, \mathbf{X}_N}(\underline{\theta} | x_1, \dots, x_N, I)$, is called the posterior distribution of $\underline{\Theta}$, and it is given by:

$$f_{\underline{\Theta}|\mathbf{X}_1, \dots, \mathbf{X}_N, I}(\underline{\theta} | x_1, \dots, x_N, I) = \frac{f_{X_1, \dots, X_N|\underline{\Theta}, I}(x_1, \dots, x_N | \underline{\theta}, I) g_{\underline{\Theta}|I}(\underline{\theta} | I)}{f_{X_1, \dots, X_N|I}(x_1, \dots, x_N | I)} \quad (14.12)$$

where $f_{X_1, \dots, X_N}(x_1, \dots, x_N | I)$ is the marginal of the joint pdf of \mathbf{X} and $\underline{\Theta}$. In cases where several types of data are available, the vector \mathbf{X} should be redefined accordingly, for example X_i , $i = 1, \dots, M$, for the M measurements of one attribute, and X_i , $i = 1, \dots, M + 1, \dots, N$, for the measurements of the other type.

The posterior distribution incorporates all information available, including measurements and prior knowledge. The function $f_{X_1, \dots, X_N|\underline{\Theta}, I}(x_1, \dots, x_N | \underline{\theta}, I)$ is the probability of making the observations for a given $\underline{\Theta} = \underline{\theta}$, and it is commonly referred to as the likelihood function. If we want to estimate $\underline{\theta}$, we need to adopt a decision rule, for example, we may take for estimator that $\underline{\theta}$ that maximizes the posterior distribution, or we could just estimate $\underline{\theta}$ with the mean or median of the posterior distribution. None of these choices reflects the width of the distribution. Rather, the pdf of the parameters should be considered in its entirety, and not just through a subset.

14.4.2.2 A Systematic Approach to Defining a Prior Probability

How do we estimate the prior pdf of unknown model parameters, $g_{\underline{\Theta}|I}(\underline{\theta} | I)$? The determination of the statistical properties of the unknown model parameters, and at a more fundamental level, the statistical model itself, are the major impediments to the effective use of probabilistic models. It is common to assume a model for the prior, and then to update it as additional information becomes available. But one can argue that the choice of the prior model is arbitrary. How significant is the choice of a prior? Jaynes (1968) stated, “Since the time of Laplace, applications of probability theory have been hampered by the difficulties in the treatment of prior information,” and “Therefore, the logical foundations of decision theory cannot be put in fully satisfactory form until the old problem of arbitrariness (sometimes called ‘subjectiveness’) in assigning prior probabilities is resolved.”

Instead of postulating a prior pdf, we can infer it from measurements based on assumptions or axioms. One such approach is based on the principle of minimum relative entropy (MRE), the application of which to hydrogeology was pioneered by A. Woodbury and coworkers. The MRE approach (Woodbury and Rubin, 2000; Woodbury and Ulrych, 2000; Rubin, 2003) couples between Bayes’ theorem and entropy measures of information. It represents the general approach of inferring a probability distribution from constraints that incompletely characterize that distribution (Hou and Rubin, 2005). These constraints can be (but are not limited to be) in the form of averages or higher-order moments, following Equation 14.10. In the context of groundwater, such constraints can be, for example, the average and variance of the hydraulic conductivity obtained from a limited number of tests, from empirical determination, or from an informed guess.

Entropy is a measure of the amount of uncertainty in a pdf. The principle of MRE states that of all the probabilities that satisfy the given constraints, choose the one that has the highest entropy with respect to a known prior, which is the one that is the most uncommitted, or the least prejudiced, with respect to unknown information. The model identified based on MRE can be interpreted as the one which fits all the constraints and the one which has the greatest “spreadout” that can be realized in the greatest number of ways. The pdf thus identified can be used as priors for any of the inverse methods described below.

14.4.2.3 The Maximum Likelihood and Maximum A Posteriori Concepts in Inverse Modeling

In this section, we examine and formulate the inverse problem based on ML and MAP concepts. Both methods are based on Bayes’ theorem, but with different interpretations assigned to the prior and to the inferred parameter values.

14.4.2.3.1 The Maximum Likelihood Method

The ML formulation discussed below employs only information available from measurements and ignores prior information. In the absence of any prior information I , the likelihood function defined in Equation 14.12 becomes $f_{X_1, \dots, X_N | \underline{\Theta}}(x_1, \dots, x_N | \underline{\theta})$. Let us denote it by $L(\underline{\theta} | x_1, \dots, x_N)$. L gives the likelihood (or in fact, the pdf) that the random variables X_1, \dots, X_N , assume the particular values x_1, \dots, x_n . X_i can denote, for example, the log-conductivity (with $X_i = X(\mathbf{b}_i)$ being the log-conductivity at location \mathbf{b}_i) and $\underline{\Theta}$, which will include the parameters of the X SRF (such as its mean, variance, and the parameters of its correlation function). For a given vector $\underline{\theta}$, the particular values of the random variables most likely to occur are the values x_1, \dots, x_N that maximize $f_{X_1, \dots, X_N | \underline{\Theta}}(x_1, \dots, x_N | \underline{\theta})$, or in fact, those values that define its mode.

Let us now consider a particular vector of observations x_1, \dots, x_N . We wish to find the particular combination of parameters of $\underline{\Theta}$, denoted by $\hat{\underline{\theta}}$, which maximizes the likelihood function $L(\underline{\theta} | x_1, \dots, x_N)$ or, in other words, maximizes the probability of observing X_1, \dots, X_N , equal to x_1, \dots, x_N , respectively. This vector, $\hat{\underline{\theta}}$, which is a function of the measurement vector x_1, \dots, x_N , is called the maximum likelihood estimator of $\underline{\Theta}$. The maximum likelihood estimator is the solution for the set of equations:

$$\frac{\partial L(\underline{\theta})}{\partial \theta_j} = 0, \quad j = 1, \dots, p \quad (14.13)$$

where p is the number of parameters in $\underline{\Theta}$. Both the logarithm of L and L have their maxima at the same value of $\underline{\Theta}$, and it is sometimes easier to find the maximum of the logarithm of the likelihood (or the minimum of the negative log-likelihood).

The pioneers in bringing the concept of maximum likelihood to hydrogeology are Peter Kitanidis and his coworkers. The foundations for their work were laid in Kitanidis and Vomvoris (1983), followed by Hoeksema and Kitanidis (1984, 1985), where they considered the problem of identifying the spatial distribution of the log conductivity.

One application of these ideas in hydrogeophysics is provided by Hubbard et al. (1997b). It demonstrates the power of using Bayesian concepts in the case where non-unique petrophysical relationships exist. In that study, numerical experiments were performed to investigate the utility of ground-penetrating radar (GPR) data for saturation and permeability estimation under a range of hydrogeological conditions. As described in Section 14.2.3, GPR is a noninvasive, high-resolution geophysical method, and estimates of dielectric constants can be extracted from both surface and crosshole GPR data. Petrophysical relations can then be used to transfer these dielectric constants into saturation or permeability estimates.

Petrophysical curves that illustrate a plausible relationship of saturation and dielectric constant as a function of facies (and corresponding permeability) for a synthetic sand–clay system are shown in Figure 14.16. These curves illustrate the non-uniqueness that sometimes exists when trying to map a geophysical attribute (such as dielectric constant obtained from radar data) into a hydrological estimate (such as saturation or facies permeability). For example, in the case study shown in Figure 14.16, for each dielectric

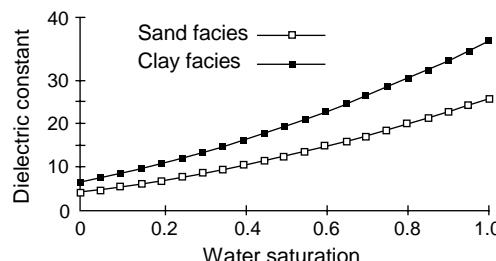

FIGURE 14.16 Example of a non-unique petrophysical relationship between dielectric constant and water content in a sand–clay system (modified from Hubbard et al., 1997, and reduced from Knoll et al., 1995 shown in Figure 14.4.)

constant value obtained from the radar data in the bimodal system under consideration, two values of saturation (S_1 and S_2) are possible, depending on whether the facies at that subsurface location is a clay or a sand, both with associated distinct permeability values. With two possible values for the saturation, the pdf of the saturation S can be expressed as follows:

$$f_S(s | S_1, S_2) = p\delta(s - S_1) + (1 - p)\delta(s - S_2) \quad (14.14)$$

where p denotes the probability to observe $s = S_1$, and δ is the Dirac delta function. The probability is related to the expected value of S , $\langle S \rangle$, through the relationship (Hubbard et al., 1997b, Equation 9):

$$p = \frac{\langle S \rangle - S_2}{S_1 - S_2} \quad (14.15)$$

Hence, once $\langle S \rangle$ is defined, the pdf of s is also defined. The saturation S that maximizes the probability to observe the measured dielectric constant is equal to S_1 if p is larger than 0.5, and to S_2 otherwise. The S thus chosen is the ML estimator, because we choose for $\hat{\theta}$ the value of S that maximizes the probability to observe the measured dielectric constant. Hubbard et al. (1997) suggested a couple of alternatives for computing $\langle S \rangle$: the first was based on numerical infiltration simulations, and the second was based on kriging borehole saturation measurements.

The vector $\hat{\theta}$ that minimizes $-\ln L$ is the ML estimator. Once it is determined, we can estimate the variances and covariances of the parameters. We can define the matrix $\underline{\underline{B}}$ of order p , where

$$B_{ij} = \frac{\partial}{\partial \theta_i} \left(\frac{\partial}{\partial \theta_j} \ln L \right) \quad (14.16)$$

which is known as the Fisher information matrix. The matrix $\underline{\underline{\Sigma}} = \underline{\underline{B}}^{-1}$ is referred to as the Cramer–Rao lower bound of the estimation error covariance (Schweppe, 1973), and its (i, j) term provides an estimate for the estimation error's variance–covariance matrix for the vector $\underline{\theta}$. Once the parameters of the X SRF are identified, the spatial distribution of X , conditioned on the measurements, can be determined using geostatistical methods such as kriging (when only X measurements are available) and co-kriging (when other types of measurements are also available).

14.4.2.3.2 The Maximum A Posteriori Approach

MAP extends ML to situations where prior information does exist. This extension provides for a wide range of alternative interpretations and approaches. The MAP concept is illustrated in Figure 14.17. Figure 14.17a schematically shows an example of a prior log-conductivity pdf at a single subsurface location. Figure 14.17b illustrates the joint distribution as well as the likelihood function. The geophysical data are given in the form of a precise measurement (solid line) and, alternatively, in the form of a distribution, representing imprecise data (dashed line). Uncertainty in the geophysical attribute can stem from many factors, such as the choice of tomographic data inversion approach and parameters, acquisition and data reduction errors, and variable coverage/sensitivities (cf. Peterson, 2001; Alumbaugh et al., 2002; Binley et al., 2002). In the first case, the likelihood function is defined over a much narrower range of conductivity values, which will limit the range of physically plausible conductivity values.

Using the likelihood function for the precise information, the prior pdf can be updated using Bayes' theorem (Equation 14.12), to obtain the posterior pdf, as illustrated by the solid line in Figure 14.17c. We note that the high quality of the geophysical data renders this posterior pdf considerably sharper than the prior pdf (compare solid-line log-conductivity distributions in Figure 14.17a and 14.17c), because Bayes' theorem indicates that reconciliation between the prior pdf and the geophysical attribute is possible by assigning a larger probability to the higher log conductivities. In the case of imprecise geophysical data, as illustrated by the geophysical attribute distribution in Figure 14.17b, the improvement in the posterior pdf (shown by the dashed line in Figure 14.17c) is not as significant as when precise geophysical data are used.

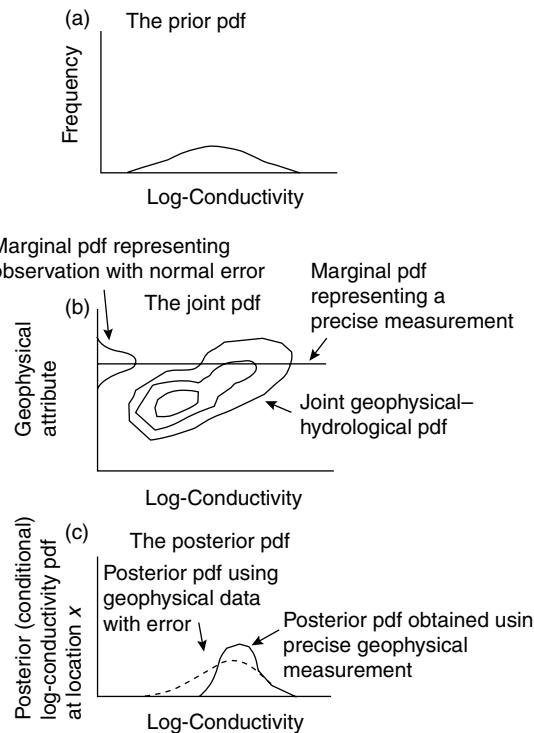

FIGURE 14.17 Example of the MAP approach to hydrogeophysical data fusion: (a) example of a prior log-conductivity pdf at a single subsurface location; (b) example of the joint geophysical–hydrological pdf, as well as marginal pdf representing a geophysical observation with normal error (dashed line) and marginal pdf representing a precise measurement (solid line); (c) posterior pdfs at a single subsurface location obtained by fusing the prior log-conductivity pdf, joint pdf, and marginal geophysical pdf within the MAP formalism. The solid posterior pdf was obtained using the precise geophysical measurement, while the dashed posterior pdf was obtained using the geophysical observation with normal error (shown in Figure 14.17b).

The posterior pdf is not as sharp because the improvement of the posterior compared to the prior depends on the amount of information provided by the geophysical data. This example illustrates the essence of MAP as a “reconciliation” between prior information, usually in the form of direct measurements of the attribute of interest, and additional information of varying quality. The information used for updating the prior pdf can be either empirically correlated or functionally related to the attribute of interest.

For discussion of the mathematical aspects of MAP, let us consider the case of identifying the spatial distribution for hydraulic conductivity based on measurements of conductivity as well as auxiliary information denoted by h . Such information can obviously include geophysical information collected through various types of geophysical surveys. Let us denote a finite-sized vector of conductivities (or log conductivities, which is more commonly employed) and h measurements distributed over the aquifer by $z = (z_h, z_a)$, with z_a denoting the vector of conductivity measurements and z_h denoting the h measurements. Let us now denote, by the vector of order p , the conductivities that we wish to estimate, for example, at the nodes of a numerical grid. Let us define the functional relationship between z_a and a in the form $z_a = \mathbf{F}_a(a) + \mathbf{v}_a$, where $z_{a,i}$ and $v_{a,i}$ denote the i th conductivity measurement and the measurement error, respectively. \mathbf{F}_a represents the large-scale trend of the conductivity, given for example in the form of a spatial distribution of the conductivities over a grid or by a set of polynomials. Similarly, let us define the measurements vector $z_h = \mathbf{F}_h(a) + \mathbf{v}_h$, where \mathbf{F}_h represents the large-scale trend of the h , with $v_{h,i}$ denoting the measurement error at x , owing to instrumentation and recording error, data reduction procedures, and the small-scale fluctuations of the actual point values from the corresponding large-scale trends. Note that \mathbf{F}_a and \mathbf{F}_h may include parameters whose values are unknown and need to be

identified. The formulation below can be used to identify \mathbf{a} at unknown locations, as well as the unknown parameter values, although in our discussion below we shall concentrate on \mathbf{a} . It is common to assume that the measurement errors are zero mean, and that \mathbf{v} and \mathbf{a} are uncorrelated. These two relationships can be summarized by the following measurement equation (cf. McLaughlin and Townley, 1996):

$$\begin{bmatrix} z_h \\ z_a \end{bmatrix} = \begin{bmatrix} \mathbf{F}_h(\mathbf{a}) \\ \mathbf{F}_a(\mathbf{a}) \end{bmatrix} + \begin{bmatrix} \mathbf{v}_h \\ \mathbf{v}_a \end{bmatrix} = \mathbf{F}(\mathbf{a}) + \mathbf{v} \quad (14.17)$$

The MAP estimator of \mathbf{a} , $\hat{\mathbf{a}}$, is the one most likely given the measurements (unlike ML, which seeks \mathbf{a} that maximizes the probability of observing the measurements). It is defined based on Bayes' theorem by the posterior pdf:

$$f_{a|z}(\mathbf{a}|z) = \frac{f_{z|\mathbf{a}}(z|\mathbf{a})f_a(\mathbf{a})}{f_z(z)} = \frac{f_v(z - \mathbf{F}(\mathbf{a}))f_a(\mathbf{a})}{f_z(z)} \quad (14.18)$$

where f_a and $f_{a|z}$ are the prior and posterior pdfs of \mathbf{a} , $f_{z|\mathbf{a}}$ is the conditional pdf of \mathbf{a} given z , and f_z and f_v are the measurement and measurement-error pdfs, respectively. The second equality in Equation 14.18 follows from Equation 14.17 and from the independence of \mathbf{a} and \mathbf{v} . The MAP estimate $\hat{\mathbf{a}}$ corresponds to the mode of $f_{a|z}$.

If f_a and f_v are multinormal with covariance matrices $\underline{\underline{c}_a}$ and $\underline{\underline{c}_v}$, the posterior pdf becomes:

$$f_{a|z}(\mathbf{a}|z) = c(z) \exp \left\{ -\frac{1}{2} [\mathbf{z} - \mathbf{F}(\mathbf{a})]^T \underline{\underline{c}_v}^{-1} [\mathbf{z} - \mathbf{F}(\mathbf{a})] \right\} \exp \left\{ -\frac{1}{2} [\mathbf{a} - \bar{\mathbf{a}}]^T \underline{\underline{c}_a}^{-1} [\mathbf{a} - \bar{\mathbf{a}}] \right\} \quad (14.19)$$

where $c(z)$ is a normalization factor not depending on \mathbf{a} , and $\bar{\mathbf{a}}$ is the prior mean of \mathbf{a} .

Assuming \mathbf{v} to be normal is quite common, because it is the simplest model, requiring to state only mean and variance. However, it turns out that it is also the safest assumption, if all that is known about \mathbf{v} is its mean and variance, since as can be shown using MRE considerations, normal distribution in that case is the least informative, and hence is minimally subjective. If the variance is not known precisely, Equation 14.19 can be written as a pdf conditional on a given variance σ_v : $f_{a|z,\sigma_v}(\mathbf{a}|z, \sigma_v)$, and the dependence on σ_v can be eliminated by taking the expected value over the range of σ_v (see Woodbury and Rubin, 2000; Woodbury and Ulrych, 2000 and Hou and Rubin, 2005).

It is convenient to find the MAP estimate by minimizing $-2\ln[f_{a|z}]$. The MAP estimate $\hat{\mathbf{a}}$ is then the \mathbf{a} that minimizes the weighted-least-squares criterion (Schwepppe, 1973; Carrera and Neuman, 1986a, 1986b; Tarantola, 1987):

$$[\mathbf{z} - \mathbf{F}(\mathbf{a})]^T \underline{\underline{c}_v}^{-1} [\mathbf{z} - \mathbf{F}(\mathbf{a})] + [\mathbf{a} - \bar{\mathbf{a}}]^T \underline{\underline{c}_a}^{-1} [\mathbf{a} - \bar{\mathbf{a}}] \quad (14.20)$$

which yields a compromise between the prior estimate (represented here by the term on the right) and the weighted-least-squares fit (which is summarized by the first term). Kawalsky et al. (2004b, 2005) showed how to minimize (14.20) and how to generate multiple realizations conditional to measurements.

Numerical solutions for the above minimization problems are generally found with iterative search algorithms such as the Gauss–Newton method. Note that the number of unknown parameters may be large, on the order of the number of grid blocks. This number may be reduced by zonation, which calls for identifying areas of uniform conductivity (thus potentially reducing the number of unknowns), but this procedure is not without its problems, as we shall discuss below.

The concept underlying Equation 14.20 attaches a probabilistic interpretation to \mathbf{v} , which is viewed as a measurement error vector. If instead, we view the \mathbf{z} as SRFs, with \mathbf{F} representing their expected values, then $\mathbf{z} - \mathbf{F}(\mathbf{a})$ contains the local fluctuations of the SRFs from their expected values, and it represents the effects of natural heterogeneity rather than measurement error. Furthermore, the matrices in Equation 14.20 describe now the covariances between SRFs, which can be developed from physical

principles (Rubin, 2003; Chapters 4 and 6). This is the concept underlying the inverse method of Kitanidis and Vomvoris (1983), and Rubin and Dagan (1987a, 1987b, 1988).

Equation 14.20 can be used to identify other formulations of the inverse problem. One formulation is the least squares method. Least squares estimates minimize:

$$[z - \mathbf{F}(\mathbf{a})]^T \underline{\underline{c}_v^{-1}} [z - \mathbf{F}(\mathbf{a})] \quad (14.21)$$

and ignore the prior information term. The least squares estimator obtained by minimizing Equation 14.21 is equivalent to a Gaussian ML estimator with known statistical properties. We note from Equation 17.9 that the likelihood function is:

$$f_{z|a}(z|\mathbf{a}) = f_v[z - \mathbf{F}(\mathbf{a})] \quad (14.22)$$

and that the ML estimator is obtained by minimizing $-2\ln f_{z|a}$. For a Gaussian f_v and a known covariance function, the ML estimator will be obtained by minimizing Equation 14.22.

McLaughlin and Townley (1996) note that ML estimators are equivalent to MAP estimators when the prior covariance matrix $\underline{\underline{c}_a}$ (Equation 14.21) is arbitrarily large, implying that the prior information is uninformative. They note further that an uninformative prior is pessimistic, as we can usually put some bounds on the range of values that parameters such as conductivity can assume. Most regression and ML algorithms provide for such constraints in their search algorithm. Bounded least squares or ML estimators, which assume that f_v is Gaussian and that the prior probability is uniform between the specified bounds, are in fact equivalent to a MAP estimator, where the performance criteria to be minimized is given by:

$$[z - \mathbf{F}(\mathbf{a})]^T \underline{\underline{c}_v^{-1}} [z - \mathbf{F}(\mathbf{a})] - \ln f_a(\mathbf{a}) \quad (14.23)$$

and where the prior pdf f_a is a positive constant when \mathbf{a} lies within the bounds, and 0 otherwise. As this performance criterion imposes an infinite penalty on estimates lying outside the bounds, it will enforce the constraints. Hence, MAP offers flexibility by being able to handle prior information. A MAP generalization of the Fisher information matrix $\underline{\underline{B}}$ (see Equation 14.16) is provided in McLaughlin and Townley (1996) and Rubin (2003).

The error matrices $\underline{\underline{c}_a}$ and $\underline{\underline{c}_v}$ of Equation 14.20 pose a difficult challenge because they are generally not known, at least not a priori. MRE offers ideas on how to address this issue (see our discussion following Equation 14.19). Another way to approach this issue is by defining $\underline{\underline{c}_a}$ and $\underline{\underline{c}_v}$ as diagonal matrices, in the form $\underline{\underline{c}_a} = \sigma_a^2 \underline{\underline{I}}$ and $\underline{\underline{c}_v} = \sigma_v^2 \underline{\underline{I}}$, where σ_a^2 and σ_v^2 are the error variances and $\underline{\underline{I}}$ is the identity matrix. With these definitions, Equation 14.20 becomes proportional to:

$$[z - \mathbf{F}(\mathbf{a})]^T [z - \mathbf{F}(\mathbf{a})] + \beta [\mathbf{a} - \bar{\mathbf{a}}]^T [\mathbf{a} - \bar{\mathbf{a}}] \quad (14.24)$$

where β is the ratio σ_v^2/σ_a^2 , and it can be used to change the relative weights of the two terms in Equation 14.24. A small σ_a^2 indicates a greater confidence in the prior, and hence a larger weighting in the form of a larger β . The parameter β can be determined by numerical experimentation. For example, we can use a training set of data to identify an optimal β . Equation 14.24 can be viewed as the weighted least squares representation of MAP, with the term on the right representing the prior, acting to regularize the solution, and the term on the left representing updating through the acquisition of additional measurements.

Hydrogeophysical inverse modeling based directly or indirectly on Equation 14.18 was included in the work of Ezzedine et al. (1999), who reported on a Bayesian method for using borehole and surface resistivity data for lithology estimation, and in Day-Lewis et al. (2000), who reported an approach for conditioning geostatistical simulation of high-permeability fracture zones in multiple dimensions to hydraulic-connection data inferred from wellbore tests, and in Chen et al. (2001) and Chen and Rubin (2003).

14.4.3 Point Estimation with Known Parameters

The formulations of Section 14.4.2 are commonly applied in two different modes. The first mode calls for identification of nodal values (e.g., conductivity values at nodes over a grid). The second mode calls for defining the parameters of interest as SRFs as a first step and their identification using ML or MAP, which is then followed by mapping the spatial distributions of the parameters using methods such as kriging or co-kriging (see Chapter 16 of this volume or Chapter 3 of Rubin, 2003). The second mode originated in the works of Kitanidis and co-workers and was subsequently pursued by Rubin and Dagan (1987a, 1987b, 1988). One immediate advantage of the second mode is the reduction in the number of target parameters at the inversion stage. In other words, high resolution on the grid does not translate into a large number of target parameters, with its associated difficulties, including non-uniqueness, instability, and non-identifiability (see Carrera and Neuman, 1986a, 1986b, 1986c).

For example, if we are interested in mapping the spatial distributions of the conductivity, then the second mode will include the following two steps: (1) Identifying the parameters of the conductivity (or log-conductivity) SRF, such as its mean and spatial covariance parameters, using all available data; and (2) Mapping the spatial distribution of the conductivity, conditional to all available data, using a statistical interpolation or simulation techniques (Kowalsky et al. 2004b, 2005) technique. Such mapping also includes characterization of uncertainty, which can be accomplished to varying degrees of completeness and accuracy.

As discussed in the previous section, MAP and ML formulations applied in the first mode produce MAP or ML estimates and estimation variances of the target parameters. As we shall show below, separating the identification problem from point estimation, as done in the second-mode applications, allows us to obtain more complete characterization of estimation uncertainty and better flexibility in conditioning the estimates on the various types of information available. Below, we discuss the second mode, and while its first stage was discussed in Section 14.4.2, we focus here on the stage of deriving spatial distributions over the computational grid, with the SRF parameters already known.

14.4.3.1 Bayesian Point Estimators and Conditioning on “Hard” and “Soft” Information

The most straightforward approach to mapping spatial distributions is via kriging or co-kriging. Kriging provides an estimate and a kriging variance (Chapter 3 of Rubin, 2003). We should note the following: (1) The kriging variance can be viewed as a measure of uncertainty, but cannot be used to compute confidence intervals unless the estimation error is normally distributed. While this is often assumed, it is not part of the kriging algorithm. Hence, as kriging estimates are not characterized by any underlying statistical distributions, their characterization of uncertainty is lacking. (2) Kriging methods rely on two-point correlations, in the form of covariances or semi-variograms, to project measurements onto unsampled locations. Such forms of correlation are efficient in capturing linear correlations, but fail in the presence of nonlinearity. Measures to amend for this limitation can be found in nonlinear transformations of the target variable, such as log-transforms or indicator transforms (Chapter 3 in Rubin, 2003), but such transforms are not always efficient in removing nonlinearity. This is particularly true for the case of inherent non-uniqueness in the correlation structure (i.e., stemming from physical principles, not from measurement errors). For example, Rubin et al. (1992) and Copty et al. (1993) considered the ramifications of incorporating information from a non-unique relationship between permeability and seismic velocity in sandy clays for hydrogeological parameter estimation, where a given value of seismic velocity can be interpreted as an indication of high or low permeability, depending on the porosity.

To address these challenges, we choose to concentrate here on Bayesian conditioning. Let us consider an estimate of Z at \mathbf{x} , conditional to a measurement of Z at \mathbf{x}' , $Z(\mathbf{x}')$. The conditional pdf of $Z(\mathbf{x})$ is obtained from Bayes' theorem as follows:

$$f_{Z(\mathbf{x}), Z(\mathbf{x}')} (z|z') = \frac{f_{Z(\mathbf{x}), Z(\mathbf{x}')} (z, z')}{f_{Z(\mathbf{x}')}(z')} \quad (14.25)$$

Thus, $f_{Z(\mathbf{x}), Z(\mathbf{x}')} (z|z') dz$ is the probability to observe $Z(\mathbf{x})$ in the vicinity dz of z , given that $Z(\mathbf{x}') = z'$. When the bivariate distribution of $Z(\mathbf{x})$ and $Z(\mathbf{x}')$ is normal, the conditional pdf is also normal. Furthermore, in that case, the mean of the conditional distribution is equal to the kriging estimate, and the variance is equal to the kriging variance (with one important difference: as now we do have an underlying statistical distribution, the variance can be employed to determine confidence intervals; see Chapter 2 in Rubin, 2003). All this is also true when conditioning on a larger number of measurements. Finally, as Equation 14.25 models the joint distribution of Z at \mathbf{x} and \mathbf{x}' through a bivariate pdf and not through the two-point correlation, such as used by kriging estimators, it opens the door for dealing more effectively with nonlinear correlations (cf. Rubin et al., 1992; Copty et al., 1993; Ezzedine et al., 1999; Hubbard et al., 1997b).

Heretofore, we have assumed that $Z(\mathbf{x}')$ is measured without error, and hence we refer to it as “hard” data. Equation 14.25 provides the means for conditioning on hard data. In applications, however, it is very likely that we would want to condition on a range of values for $Z(\mathbf{x}')$. Such a range of values may represent a distribution of values resulting from measurement errors, or a situation where $Z(\mathbf{x}')$ was not measured, but rather estimated (e.g., by expert opinion, from geophysical data, or by analogy to a set of measurements collected under similar conditions). Several case studies illustrating different methods of extracting hydrogeological property information using geophysical data were given in Section 14.3. We refer to such imprecise information as soft data, and identify the need for conditioning on soft information. Rubin (2003, Chapter 3) proposed to condition on the soft information by modeling it as a probabilistic distribution of \bar{Z} , the estimator of $Z(\mathbf{x}')$, in the form of a pdf $f_{\bar{Z}}(\bar{z})$, defined over a range of values, A . The distribution of Z conditional to \bar{Z} is thus (Chapter 3 in Rubin, 2003):

$$f_{Z(\mathbf{x})|Z(\mathbf{x}')}(z|z' \in A) = \int_A f_{Z(\mathbf{x})|Z(\mathbf{x}')}(z|z') f_{\bar{Z}}(z') dz' \quad (14.26)$$

which implies taking the expected value of the conditional estimate over the range A . In the limiting case of precise measurements at \mathbf{x}' , the soft data pdf $f_{\bar{Z}}(\bar{z})$ is equal to the Dirac delta, $f_{\bar{Z}}(\bar{z}) = \delta(\bar{z} - z')$, and Equation 14.26 simplifies to Equation 14.25. The estimator in Equation 14.26 is exact in the sense that as \mathbf{x} approaches \mathbf{x}' , the conditional pdf approaches the pdf of the soft data, $f_{\bar{Z}}(\bar{z})$. In the limiting case of a Dirac, $f_{\bar{Z}}(\bar{z}) = \delta(\bar{z} - z')$, $Z(\mathbf{x}')$ will approach z' , which is the better-documented case of the exactitude property.

14.4.3.1.1 An Example Based on the Normal Linear Methods.

As was earlier discussed, one of the challenges in using geophysical data for estimating hydrogeological parameters is understanding or developing a meaningful relationship between the two different types of measurements. Relationships between hydrogeological and geophysical parameters in sediments typical of near-surface environments have been a topic of research in recent years (e.g., Marion et al., 1992; Knoll et al., 1995; Mavko et al., 1998; Slater and Lesmes, 2002; Prasad, 2003). Chen et al. (2001) presented a method to formulate a site-specific petrophysical model in a probabilistic fashion using likelihood functions. Their formulation was based on co-located geophysical and hydrogeological data collected at a site, and they used normal linear regression models to relate the disparate parameters. A review of their approach is given here.

Following Chen et al. (2001), let Y denote the SRF of the log conductivity, and let v_g , α , and v_s denote GPR velocity, GPR attenuation, and seismic velocity, respectively. The posterior pdf of $Y(\mathbf{x})$ is obtained using Bayes’ theorem as follows:

$$\underbrace{f'_Y[y(\mathbf{x})|v_g(\mathbf{x}), \alpha(\mathbf{x}), v_s(\mathbf{x})]}_{\text{posterior}} = \underbrace{\text{CL}[y(\mathbf{x})|v_g(\mathbf{x}), \alpha(\mathbf{x}), v_s(\mathbf{x})]}_{\text{Likelihood function}} \underbrace{f_Y[y(\mathbf{x})]}_{\text{prior}} \quad (14.27)$$

Rubin et al. (1992) considered a simplified version of Equation 14.27, whereby the only data available for updating was the seismic velocity. Similar formulations can be written for different types of data combinations.

Note that the likelihood function in Equation 14.27 is a trivariate pdf. It can be expressed as a product of three univariate conditional pdfs:

$$L[y(\mathbf{x})|v_g(\mathbf{x}), \alpha(\mathbf{x}), v_s(\mathbf{x})] = f_{v_g}[v_g(\mathbf{x})|y(\mathbf{x})] f_\alpha[\alpha(\mathbf{x})|y(\mathbf{x}), v_g(\mathbf{x})] f_{v_s}[v_s(\mathbf{x})|y(\mathbf{x}), v_g(\mathbf{x}), \alpha(\mathbf{x})] \quad (14.28)$$

With this representation, the problem of identifying a trivariate pdf is replaced with that of identifying three univariate pdfs.

The normal linear regression model reported in Chen et al. (2001) provides a systematic approach to the inference of the conditional pdfs shown in Equation 14.28. In this approach, each of the univariate pdfs is modeled as a normal, nonstationary pdf. Consider, for example, one of the univariate pdfs forming the likelihood function:

$$f_{v_s}[v_s(\mathbf{x})|y(\mathbf{x}), v_g(\mathbf{x}), \alpha(\mathbf{x})] \quad (14.29)$$

It is assumed to be normal with a nonstationary mean $\mu(\mathbf{x})$, which is further assumed to be a member of the linear function space G , whose basis functions consist of m monomials, g_i , $i = 1, \dots, m$, formed from a combination of powers and products of $y(\mathbf{x})$, $v_g(\mathbf{x})$, and $\alpha(\mathbf{x})$, such as: 1, $y(\mathbf{x})$, $v_g(\mathbf{x})$, $\alpha(\mathbf{x})$, $y^2(\mathbf{x})$, $v_g^2(\mathbf{x})$, $\alpha^2(\mathbf{x})$, $y(\mathbf{x})v_g(\mathbf{x})$, $v_g(\mathbf{x})\alpha(\mathbf{x})$, and so on. It is modeled as follows:

$$\mu(\mathbf{x}) = \sum_{i=1}^m \beta_i g_i(\mathbf{x}) \quad (14.30)$$

The variance of the distribution is taken to be stationary. The final set of functions used to model the mean is determined by a model selection procedure, which will be described below.

The coefficients β_i are estimated by minimizing the residuals sum of squares:

$$\sum_{j=1}^n [v_s(x_j) - \mu(x_j)]^2 \quad (14.31)$$

Let $\underline{\beta} = (\beta_1, \beta_2, \dots, \beta_m)^T$ and $\underline{Z} = [v_s(\mathbf{x}_1), v_s(\mathbf{x}_2), \dots, v_s(\mathbf{x}_n)]^T$, where the exponent T denotes the transpose operator. The estimate $\hat{\underline{\beta}}$ of $\underline{\beta}$ that minimizes Equation 14.31 is given by:

$$\hat{\underline{\beta}} = (\underline{\underline{D}}^T \underline{\underline{D}})^{-1} \underline{\underline{D}}^T \underline{Z} \quad (14.32)$$

where $\underline{\underline{D}}$ is a design matrix, given by:

$$\begin{pmatrix} g_1(\mathbf{x}_1), g_2(\mathbf{x}_1), g_3(\mathbf{x}_1), \dots, g_m(\mathbf{x}_1) \\ g_1(\mathbf{x}_2), g_2(\mathbf{x}_2), g_3(\mathbf{x}_2), \dots, g_m(\mathbf{x}_2) \\ \vdots \\ g_1(\mathbf{x}_n), g_2(\mathbf{x}_n), g_3(\mathbf{x}_n), \dots, g_m(\mathbf{x}_n) \end{pmatrix} \quad (14.33)$$

Once $\hat{\underline{\beta}}$ is obtained, the mean and variance of the pdf $f_{v_s}[v_s(\mathbf{x})|y(\mathbf{x}), v_g(\mathbf{x}), \alpha(\mathbf{x})]$ are defined by:

$$\hat{\mu}(\mathbf{x}) = \sum_{i=1}^m \hat{\beta}_i g_i(\mathbf{x}) \quad (14.34)$$

and

$$\hat{\sigma}^2 = \frac{1}{n-m} \sum_{j=1}^n [\nu_s(\mathbf{x}_j) - \mu(\mathbf{x}_j)]^2 \quad (14.35)$$

where n is the number of measurements and m the number of basis functions g_i .

Selecting and eliminating basis functions is the key to the normal linear regression model. Chen et al. (2001) includes all possible distinct monomials of powers up to 4 in the initial set of basis functions. By deleting some of the initial basis functions based on t -test and p -value selection criteria (Stone, 1995) and in an iterative manner, Chen et al. (2001) obtained the final set of basis functions.

In principle, an empirical approach such as we present here is at a disadvantage compared to methods that use physically based forward models to relate between the various attributes. However, in many cases, accurate and reliable mathematical models are difficult to construct, or are subject to uncertain boundary conditions.

An application of the Bayesian approach is discussed in great detail in Hubbard et al. (2001), and is briefly summarized here. Prior estimates of hydraulic conductivity were obtained from kriging flowmeter measurements available from wellbores at a U.S. Department of Energy Bacterial Transport Site in Virginia. Updating of the prior estimates was performed using 100 MHz radar velocity data available from crosshole radar tomograms collected between the wellbores as well as a likelihood relationship developed using co-located measurements near the wellbore. Figure 14.18a (modified from Hubbard et al., 2001) illustrates the estimates of the mean hydraulic conductivity posterior pdfs along a vertical cross section at the study site, obtained using radar tomographic data and wellbore flowmeter data within a Bayesian approach. As the sediments within the saturated section at this site are fairly homogeneous (consisting predominantly of sands with different levels of sorting), the range of hydraulic conductivity is only about an order of magnitude.

Even under the relatively homogeneous conditions and with extensive wellbore flowmeter control available at this site, it was difficult to capture the variability of hydraulic conductivity using wellbore data alone. Figure 14.18b illustrates the mean values of hydraulic conductivity at each point in space obtained through kriging measurements obtained from the five wellbores whose locations are shown on the figure, or the prior pdfs at each point in space. Comparison of Figure 14.18a and 14.18b highlights how incorporation of geophysical data can lead to dramatically different estimates of hydraulic conductivity than if only wellbore data were used in the estimation procedure, especially at distances of a few meters from direct wellbore control (such as the area between wellbores T2 and M3). Recent studies have attested to the value of the geophysically obtained posterior estimates for understanding subsurface bacterial transport (Johnson et al., 2001; Mailloux et al., 2003) and for improving the prediction of chemical transport (Scheibe and Chien, 2003) at this site.

14.4.4 Model Selection

In our earlier discussion, reference was made to models (e.g., F in Equation 14.17), and we expand upon our model discussion in this section. Model development is a subjective process (see Chapter 1 in Rubin, 2003), often subject to large errors. Such errors, caused by data scarcity and errors in judgment, are unavoidable, but they should be minimized. Model selection is an attempt to address model error in a systematic manner. It requires formulation and comparison of alternative models, and elimination of all but the model that maximizes some optimality criteria. The idea (and hope) is that performing model selection will minimize modeling error. The most commonly used model selection methods include hypothesis testing (Mood et al., 1963; Luis and McLaughlin, 1992), cross-validation (Deutsch and Journel, 1998; Christensen and Cooley, 1999), Akaike's Information Criterion (AIC, see Akaike, 1974; Carrera and Neuman, 1986b), and Bayesian Information Criterion (BIC).

Cross-validation is the most intuitive approach, and it consists of dividing the data into two non-overlapping subsets. The first subset, called the training subset, is used for model development and

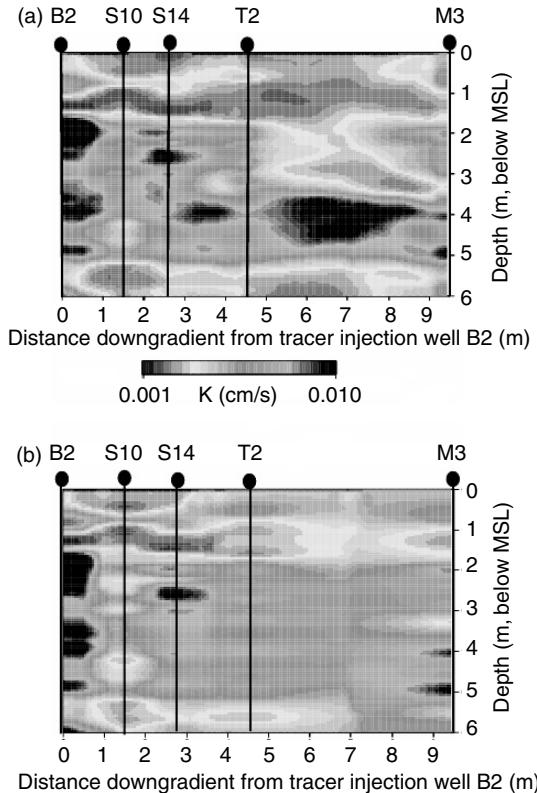

FIGURE 14.18 (a) Contoured mean values of posterior pdfs obtained using radar tomographic data conditioned to flowmeter data within a Bayesian estimation procedure; (b) Contoured mean values of prior pdfs obtained from kriging dense wellbore flowmeter measurements (modified from Hubbard et al., 2001, *Water Resour. Res.*, 37(10), 243–2456). Comparison of these figures shows that inclusion of the geophysical data significantly changes the estimates of hydraulic conductivity, especially at distances over ~ 1 m from direct wellbore control.

calibration, and a second, complementary, testing subset is used to evaluate the predictive accuracy of the calibrated model. This is done by comparing the model-predicted values at the locations where the testing data are, with the actual, measured values. Metrics are then developed based on model predictions and actual measurements, and are used to compare between models.

To demonstrate this idea, let us consider $z(\mathbf{x}_i)$, the measurement of the SRF Z at \mathbf{x}_i . A geostatistical model, identified using the training subset, is employed to obtain a kriging estimate at \mathbf{x}_i , z_i^* , and a kriging variance, σ_i^2 (see Chapter 3 of this volume). This is done repeatedly for all \mathbf{x}_i , $i = 1, \dots, N$, where N denotes the number of data in the testing subset. At the end of this exercise, the following series of analysis can be performed:

- A correlation analysis between $z(\mathbf{x}_i)$ and z_i^* , $i = 1, \dots, N$. This analysis can identify a systematic bias in the model. The absence of correlation is a positive indication.
- A correlation analysis between σ_i and $|z_i^* - z(\mathbf{x}_i)|$ for $i = 1, \dots, N$. This analysis aims at evaluating the model's ability to predict correctly the estimation error. A high degree of correlation is a positive indication.
- A correlation analysis between σ_i and $z(\mathbf{x}_i)$ for $i = 1, \dots, N$. This analysis aims to reveal heteroskedasticity. Any significant correlation here is an indication of a systematic bias (i.e., an unmodeled deterministic model component).
- Correlation analysis between the residuals $|z_i^* - z(\mathbf{x}_i)|$ and $|z_j^* - z(\mathbf{x}_j)|$ for $i, j = 1, \dots, N$. In an ideal situation, there will not be any correlation.

Additional analyses are suggested in Kitanidis (1997). These analyses provide metrics that can be used to compare between models. None of them has the power to indicate optimality, but they can definitely indicate poor performance, and upon comparison between models, they can reveal which performs better.

Can we use the ML criterion to compare between models? ML leads to optimal parameters, in a maximum likelihood sense, for a given model structure without regard to how well the model represents the real system (Carrera and Neuman, 1986a, 1986b, 1986c). The estimated parameters may be meaningless if the model fails to capture the important characteristics of the aquifer. To compensate for poor model performance, the modeler may be tempted to increase the number of model parameters (e.g., number of gridblocks used in the numerical model of the aquifer), and hence the model complexity. Obviously, a larger number of parameters will produce a better fit, but not necessarily a better model, as an increase in the number of parameters leads to larger parameter variance and to instability (in the sense that the slightest changes in data will lead to significant changes in parameter values. Hence, the ML criterion cannot be used for model selection, as it accounts for goodness of fit but not for model simplicity.

The common model selection methods attempt to balance between simplicity, usually associated with the number of adjustable parameters, and goodness of fit (Forster, 2000). The main difference between these methods is in the relative weights they give to simplicity versus goodness of fit. The AIC intends to maximize entropy and simplicity, and it selects the model that has the smallest AIC:

$$AIC(\hat{\theta}) = -2 \ln L(\hat{\theta}) + 2p \quad (14.36)$$

where $\hat{\theta}$ is the maximum likelihood estimate of the parameter vector, $L(\hat{\theta})$ is the corresponding maximum value of the likelihood criterion, and p is the number of parameters in $\hat{\theta}$. The first term on the right-hand side of Equation 14.36 is the negative logarithm of the maximum value for the likelihood criterion, while the second term penalizes complexity, expressed as the number of parameters p .

The BIC method selects the a posteriori most probable model among the proposed alternatives. That model is the one that minimizes the BIC (Forster, 2000; Gaganis and Smith, 2001):

$$BIC(\hat{\theta}) = -2 \ln L(\hat{\theta}) + p \ln(n) \quad (14.37)$$

where n is the number of measurements. Compared to AIC, BIC gives a greater weight, by a factor of $\ln(n)/2$, to simplicity. Despite the difference, both AIC and BIC support the principle of parsimony in that, all other things being equal, the model with smallest p is chosen. The relative performance of BIC vs. AIC depends on the nature of the problem, the size of the parameter vector, and the amount of available data on the dependent variables (Ye et al., 2004; Neuman, 2003).

14.4.5 Summary of Stochastic Techniques for Hydrogeophysical Investigations

The stochastic paradigm presented here offers a rational framework for analyzing spatial variability and the consequences of data scarcity, and hence for subsurface characterization. In this context, Bayes' theorem offers a flexible platform, allowing for alternative formulations, and for incorporation of complementary data of various types. There are several elements of Bayes' theorem that are needed for a successful application (which we reviewed here), including a systematic approach for modeling prior information and the likelihood function, and a rigorous model selection. For a systematic modeling of prior information, we presented the Minimum Relative Entropy (MRE) concept. The idea here is to select for the prior pdf the one with the largest entropy among all pdfs (relative to a benchmark prior) that satisfy a given set of data constraints, and in doing that, to minimize the infusion of information that is not data-based and to eliminate potential bias. This is a critical element in integration between hydrological and geophysical data. MRE is a relatively new concept in hydrogeological applications. For model selection, we reviewed a few classical, well-documented methods such as the Akaike's Information Criterion and the Bayesian Information Criterion.

14.5 Summary

In this chapter, we have provided a review of common geophysical methods and hydrogeophysical concepts, and have reviewed advanced stochastic approaches for integrating hydrogeological and geophysical data. By combining measurements made from hydrologic instruments with geophysical methods, accurate characterization and monitoring of subsurface properties can potentially be achieved with high temporal and spatial resolution over a range of spatial scales. The existence of such potential is intuitively appealing: geophysics offers a view of the subsurface from a perspective other than hydrogeology, and thus, when reconciled with the hydrogeological perspective, can help obtain a more coherent image.

What are the keys for unleashing this potential? First and foremost, in our opinion, is the availability of a systematic approach for estimation and data integration; the development of true joint hydrogeological-geophysical inversion approaches, which are distinguished from the sequential approaches used now, whereby geophysical surveys are inverted, and the outcome is then viewed as a starting point for hydrogeological inversion. True joint inversion approaches that are now in development (cf. Kowalsky et al., 2005; Linde et al., 2005) introduce geological constraints on the geophysical inversion, which will lead to better accuracy. Additional discussion is provided in Hubbard and Rubin (2002). Second is a substantial improvement in our understanding of the petrophysical models that relate between geophysical and hydrogeological attributes. An improved understanding will allow better usage of the geophysical data and will permit us to benefit from various geophysical surveys, exploring each for its proven strength. Finally, there is a need to gain more hydrogeophysical experience through practice and collaboration, and to extend the quantitative approaches that have been successfully applied at the local scale to more regional investigations of hydrological watersheds. Given that there are many nuances associated with the quantitative use of geophysical data for subsurface investigations, and that improper use of geophysical methods may reduce the overall credibility of such approaches (as discussed by Greenhouse, 1991), the use of geophysical data for quantitative parameter estimation must be approached with caution. As suggested by the National Research Council (2000), a dedicated and long-term effort is needed to investigate and document the utility of noninvasive characterization methods for a wide variety of applications, with an emphasis on research performed by multidisciplinary teams, increased accurate automation of data acquisition, data processing, and decision-making for real-time field interpretation and improved methods for transferring advanced tools and approaches to field practitioners.

Increasing population and pollution, decreasing natural resources, and changing climatic conditions all contribute to an urgency associated with improving our understanding of the shallow subsurface. Although investigators are just starting to explore the benefits of fusing geophysical and hydrogeological datasets for an improved understanding, there is already a substantial body of evidence that illustrates the potential of such endeavors.

Glossary

Conditional Monte Carlo Simulation Modeling uncertainty through generation of alternative images of the flow domain using the space random function model and, in addition, requiring that the generated images fit field data at specified locations.

Crosshole Geophysical Methods Acquisition geometry used by seismic, radar, electrical resistivity, and electromagnetic induction methods whereby energy from sources located in one borehole are recorded by sensors in another.

Dielectric Constant A measure of the separation (polarization) of opposite electrical charges within a material that has been subjected to an external electrical field.

Dynamic Process Monitoring Collection of data at the same location as a function of time. Processing of these data as “time difference” cross sections can reveal information about processes such as water infiltration, stream flooding, or contaminant plume migration.

Effective Conductivity The coefficient multiplying the expected value of the head gradient to yield the expected value of the flux. Must not depend on the parameters defining the flow problem or

the boundary conditions. In a stationary domain, the expected value of the flux is also equal to its space average.

Electrical Profiling An electrical survey made at several surface locations using a constant electrode separation distance. Electrical profiles, also called constant spread profiles or resistivity profiles, provide information about lateral changes in apparent resistivity.

Electrical Resistivity A measure of the ability of electrical current to flow through materials, measured in Ohm-m. Electrical resistivity is an intrinsic property of a material and is the inverse of electrical conductivity.

Electrical Sounding An electrical survey made at a single surface location by moving the electrodes progressively farther apart. Electrical soundings, also called expanding spread profiles, provide information about apparent electrical resistivity as a function of depth.

Monte Carlo Simulation Modeling uncertainty through generation of alternative images of the flow domain using the space random function model.

Seismic Velocity The propagation velocity of a seismic disturbance through a material. As seismic velocity is a function of the elastic parameters of a material, seismic velocity has been used to estimate lithology and porosity.

Space Random Function A probabilistic model for describing the variations of attributes such as hydraulic conductivity in heterogeneous media.

Spatial Correlation A statistical measure of similarity between attributes in a heterogeneous domain, usually as a function of separation distance between two locations. Spatial correlation is modeled through the spatial covariance or the semi-variogram.

Stationarity Invariance of the space random function model to translation in space.

Statistical Anisotropy Implies that the spatial correlations are direction dependent.

Statistical Isotropy Invariance of the spatial correlation to rotation of the separation distance.

Upscaling Representing the heterogeneous domain for modeling purposes through elements larger than the scales of heterogeneity but not large enough to warrant the use of effective properties. The effects of the sub-element heterogeneity are represented using coefficients which depend on the element size.

Acknowledgments

Funding for this study was provided by the Environmental Management Science Program, Office of Biological and Environmental Research, U.S. Department of Energy (DOE) Grant DE-FG07-96ER14726 to Susan Hubbard, and by NSF-EAR-0439649 to Yoram Rubin.

Further Information

Rubin and Hubbard (2005) provide a compilation of the fundamentals of hydrogeophysics for both the hydrogeological and geophysical perspectives. This book emphasizes the theory, assumptions, approaches, and interpretations that are particularly important for hydrogeological applications, with a focus on electrical resistivity, induced polarization, electromagnetic, GPR, logging, and seismic methods; petrophysical relationships; and case studies. Also geared toward near-surface systems, Ward (1990) provides a compilation of environmental and engineering case studies using geophysical data and Keys (1989) provides a review of well logging methods for groundwater applications. More information about the acquisition, reduction, and interpretation of geophysical methods in general is given by Robinson and Coruh (1988), Burger (1992), and Telford et al. (1990). Additional background on stochastic groundwater hydrology is provided by Degan (1989), Gelhar (1993), and Rubin (2003).

15.1 Introduction

Detailed aquifer properties are needed to predict the fate of groundwater solutes and to design efficient remediation strategies for contaminated aquifers, yet the hydrogeologic data used to estimate these properties are generally local and sparse. Low-resolution aquifer property estimates generally fail to describe the dominant flow and transport paths through an aquifer, resulting in significant errors in groundwater flow and solute transport predictions. One way to improve the resolution of heterogeneous aquifer properties involves combining densely sampled geophysical information with sparse hydrogeologic data in numerical inversions. This chapter provides: a synopsis of simulation-optimization methods; a description of surface

seismic, ground-penetrating radar (GPR), and cross-well seismic tomography methods; and a discussion of approaches to combine geophysical and hydrogeologic data with an emphasis on applications that have incorporated tracer test data.

15.2 Simulation/Optimization Methods for Aquifer Property Estimation

A powerful approach for estimating aquifer properties involves coupling nonlinear optimization methods with numerical groundwater flow and solute transport simulations. Such numerical simulations overcome the difficulties associated with incorporating highly heterogeneous aquifer properties into analytic solutions to the equations that govern groundwater flow and solute transport. The groundwater flow equation is used to solve for hydraulic head (h) given estimates of hydraulic conductivity (K) (and specific storage (S_s) for transient simulations)

$$S_s \frac{\partial h}{\partial t} = \nabla \cdot (K \cdot \nabla h) - W \quad (15.1)$$

where t is time; ∇ is the gradient operator ($\partial/\partial x, \partial/\partial y, \partial/\partial z$), x, y , and z are Cartesian coordinates, and W incorporates the source fluid fluxes. Darcy's law can then be used to approximate the average linear velocity of the fluid (V) given the calculated hydraulic head values as well as estimates of hydraulic conductivity and effective porosity (θ).

$$V = -\frac{K}{\theta} \nabla h \quad (15.2)$$

The advection-dispersion equation is used to approximate the spatial and temporal distribution of solute concentrations (C) using the calculated velocities and given estimates of the hydrodynamic dispersion tensor (D)

$$R \frac{\partial C}{\partial t} = \nabla(D \cdot \nabla C) - V \nabla C + \frac{W(C - C')}{\theta} - B \quad (15.3)$$

where $D = D(\alpha, \nu)$, α is the dispersivity, R is the retardation factor, C' is the solute concentration in the source fluid, and B is the reaction term (i.e., biodegradation). Numerical approximations of these equations, however, can easily incorporate realistic aquifer heterogeneity in three dimensions, while optimization methods provide an efficient method of adjusting aquifer properties to best match all available data.

Despite the power of optimization methods, parameters for hydrogeologic models are still often determined using trial and error calibration, which is inefficient and highly dependent on the knowledge and experience of the model operator. A more efficient and mathematically rigorous approach can be developed using weighted nonlinear least squares *regression*, which can incorporate measurement uncertainty and operator judgment through the assigned sets of weights. Regression approaches provide a consistent statistical framework for estimating aquifer properties.

The goal (or objective function) of least squares regression for aquifer property estimation is generally to minimize the weighted sum-of-squared residuals between measured and simulated values of hydraulic heads, tracer concentrations, and other measured states of the system. Other objective functions include minimizing the sum of the absolute value of residuals, or the squared residuals between some index of the data, such as spatial or temporal concentration *moments* or concentration arrival time quantiles. A well-posed problem will rapidly converge toward the *global minimum* objective value (i.e., no combination of parameters will provide a lower objective value) from a variety of starting parameter sets. Optimization methods work best when the available data (hydraulic head, tracer concentrations, advective front location,

water temperature, velocity, etc.) are highly sensitive to the estimated *aquifer properties*, such as hydraulic conductivity, dispersivity, and effective porosity. These concepts are discussed in more detail along with a discussion of other parameter estimation methods in Aster et al. (2005).

15.2.1 Tracer Tests

The main limiting factor for inferring the detailed heterogeneous structure of aquifers is the sparse nature of hydrogeologic data. Readily available hydrogeologic data include local hydraulic conductivity values from well cores, *pump tests and slug tests*, as well as hydraulic head and tracer concentration measurements at observation wells. Concentration and hydraulic head measurements provide spatially averaged information about aquifer properties, while the limited core and pump test data provide local information about some irregularly shaped region near observation wells. Unfortunately, the size and geometry of the region characterized by single well pump tests or slug tests is unknown because water preferentially flows through high conductivity regions. The hydraulic response during such tests thus provides parameter estimates for the high hydraulic conductivity regions near the well screen. Early time pump test data provide information about properties very close to the well, while later measurements provide information about more distant regions. Borehole flowmeters can also be used to measure flow rates across the screened region of a well due to natural or imposed flow conditions. This approach can provide high resolution information about heterogeneous aquifer properties as discussed by Molz (1994), however such estimates may need to be corrected for well skin effects in some environments (Barrash et al., 2006).

Tracer tests are valuable for estimating aquifer properties, such as effective porosity (θ) and dispersivity (α), yet hydraulic head should be measured at all possible locations during such tests to estimate the hydraulic conductivity field. Tracer concentration histories from a densely sampled well network provide a direct indication of transport velocities, thus providing information about the ratio of hydraulic conductivity to effective porosity for a known hydraulic gradient. Hydraulic head measurements are sensitive to the regional variations in hydraulic conductivity and provide information about the gradients. These measurements are inexpensive to obtain, and densely sampled hydraulic head data may be used in conjunction with seismic data to develop detailed hydraulic conductivity estimates, while head measurements alone provide limited information about the spatial patterns of hydraulic conductivity. In addition, head data can be used as observations for flow simulations, which are less computationally intensive than tracer transport simulations. When geophysical information is also available, it can be jointly analyzed with tracer and hydraulic data to provide high-resolution aquifer property estimates, as will be described in Section 15.6.

15.2.1.1 Natural Gradient Methods

The two main categories of tracer tests are natural gradient tests and forced gradient tests. Natural gradient methods are often preferred because they do not disturb the natural flow system and the measured concentrations are more sensitive to the aquifer dispersivity. The disadvantages of natural gradient tests include their time-consuming nature and the difficulty in designing a downgradient sampling system that adequately measures the tracer plume through time. Classic examples of natural gradient tracer experiments were conducted at the Borden Aquifer in Ontario (relatively homogeneous glacial deposit), the Cape Cod Aquifer in Massachusetts (heterogeneous glacial outwash), and the MAcroDispersion Experiment Site (MADE) in Mississippi (highly heterogeneous alluvial deposit). These tests illustrated that heterogeneous aquifer properties strongly influence groundwater flow and solute transport.

Dispersivity at the Borden site was analyzed using *spatial moments* (M) of the measured concentrations (Freyberg, 1986)

$$M_{ijk}(t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \theta C(x, y, z, t) x^i y^j z^k \, dx \, dy \, dz \quad (15.4)$$

where θ is effective porosity, C is the concentration of a specific tracer at time t and location (x, y, z) , and the indices (i, j , and k) define the components of each moment; M_{000} is the zeroth spatial moment, which is the total mass; $M_{100}, M_{010}, M_{001}$, are the x, y , and z components of the first spatial moment; and $M_{200}, M_{020}, M_{002}$, are the x, y , and z components of the second spatial moment.

The concentration covariance tensor (σ) can be defined about the center of mass as described by Freyberg (1986):

$$\begin{aligned}\sigma_{xx} &= (M_{200}/M_{000}) - x_c^2 \\ \sigma_{yy} &= (M_{020}/M_{000}) - y_c^2 \\ \sigma_{zz} &= (M_{002}/M_{000}) - z_c^2 \\ \sigma_{xy} = \sigma_{yx} &= (M_{110}/M_{000}) - x_c y_c \\ \sigma_{yz} = \sigma_{zy} &= (M_{011}/M_{000}) - y_c z_c \\ \sigma_{xz} = \sigma_{zx} &= (M_{101}/M_{000}) - x_c z_c\end{aligned}\quad (15.5a)$$

where the center of mass can be defined as:

$$\begin{aligned}x_c &= M_{100}/M_{000} \\ y_c &= M_{010}/M_{000} \\ z_c &= M_{001}/M_{000}\end{aligned}\quad (15.5b)$$

The dispersivity tensor (A , with components $\alpha_l, \alpha_t, \dots$) can then be approximated using

$$A = \frac{1}{2|V|} \frac{d}{dt}(\sigma) \quad (15.6)$$

for cases with negligible molecular diffusion, which is a common assumption for groundwater transport studies due to the larger magnitude of hydrodynamic dispersion. This analysis of the Borden tracer moments showed a significant temporal increase in both the longitudinal and transverse components of the covariance tensor (related to dispersivity with Equation 15.6), which may indicate the effects of the plume encountering more heterogeneity at larger scales (Figure 15.1). In addition, the center of mass sinks through time, especially early in the experiment, and the original plume appears to split into two distinct plumes later despite the relatively homogeneous material at this site. Sudicky (1986) developed detailed estimates of log hydraulic conductivity along two transects at this site using permeameter measurements on cores. These were used to estimate dispersivity coefficients, using the theory of Gelhar and Axness (1983), which were consistent with those obtained from the tracer test analysis.

The tracer tests at the Cape Cod site were used to analyze the heterogeneous hydraulic and chemical properties of the shallow aquifer (Garabedian et al., 1991; LeBlanc et al., 1991; Hess et al., 1992). Each tracer plume was irregular in shape and appeared to sink as it moved downgradient (Figure 15.2). Two of the likely causes for this effect are recharge-induced downward flow, and the slight density contrast between the tracer plume and the regional groundwater. The concentration moment analysis indicated an order of magnitude larger longitudinal dispersion for a reactive tracer (lithium) as compared to a nonreactive tracer (bromide) (Gelhar, 1993), which indicates the need to properly describe both the physical and chemical transport processes of aquifers.

At the MADE site in Mississippi, only about half of the injected tracer could be accounted for at late times as the tracer plume advected down an unidentified channel deposit in advance of the expanding sampling network (Adams and Gelhar, 1992; Boggs et al., 1992). This result indicates the need for a detailed tracer test design that accounts for the likely heterogeneous aquifer conditions. The tracer data clearly illustrated the effect of large-scale heterogeneities in hydraulic conductivity. This was considered

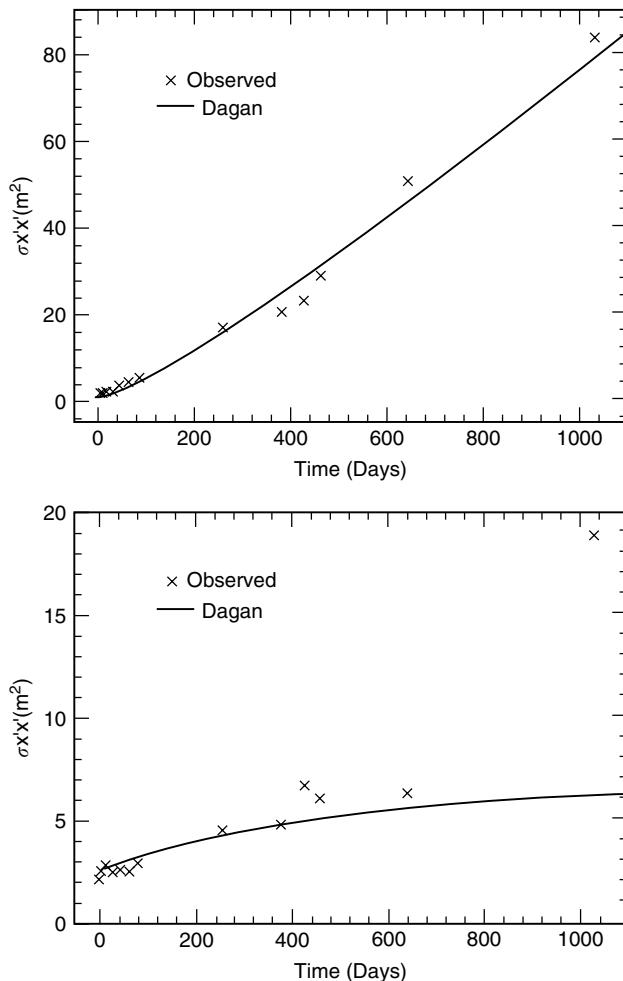

FIGURE 15.1 Plots of estimated longitudinal and transverse components of the spatial covariance tensor illustrating the temporal dependence of these statistics. These values can be used to approximate the dispersivities in these directions. (From Freyberg, D.L. 1986. *Water Resour. Res.* 22(13):2031–2046. With permission.)

a trend in the spatial covariance analysis (Rehfeldt et al., 1992), with the primary hydraulic conductivity estimates obtained using a borehole flowmeter. In addition, this experiment demonstrated the need for high-resolution noninvasive geophysical techniques to identify such large-scale heterogeneities. Barlebo et al. (2004) modeled the tracer transport from the MADE-2 tritium transport experiment by using a finite element model and optimizing hydraulic conductivity values for a small number of zones. They also evaluated detailed flowmeter estimates of hydraulic conductivity, and found that these values had significant random error and bias.

A natural gradient tracer test conducted at the Schoolcraft Plume-A Site near the town of Schoolcraft MI, was reasonably predicted using a three-dimensional finite difference flow and transport model (Biteman et al., 2004; Phanikumar et al., 2005). The hydraulic conductivity dataset for this model was developed using permeameter analysis of repacked core segments (Zhao et al., 2005), and a hydrostratigraphic analysis of minimally disturbed cores to characterize the nonstationary nature of the hydraulic conductivity at the site (Biteman et al., 2004). Unlike most sites where detailed tracer tests are conducted, the Schoolcraft Plume-A site was chosen because of its groundwater contamination. The system used to inject tracer at this site was designed to optimally mix injected solutes and microbes across a vertical transect through the aquifer (Hyndman et al., 2000), and was then used to develop and maintain

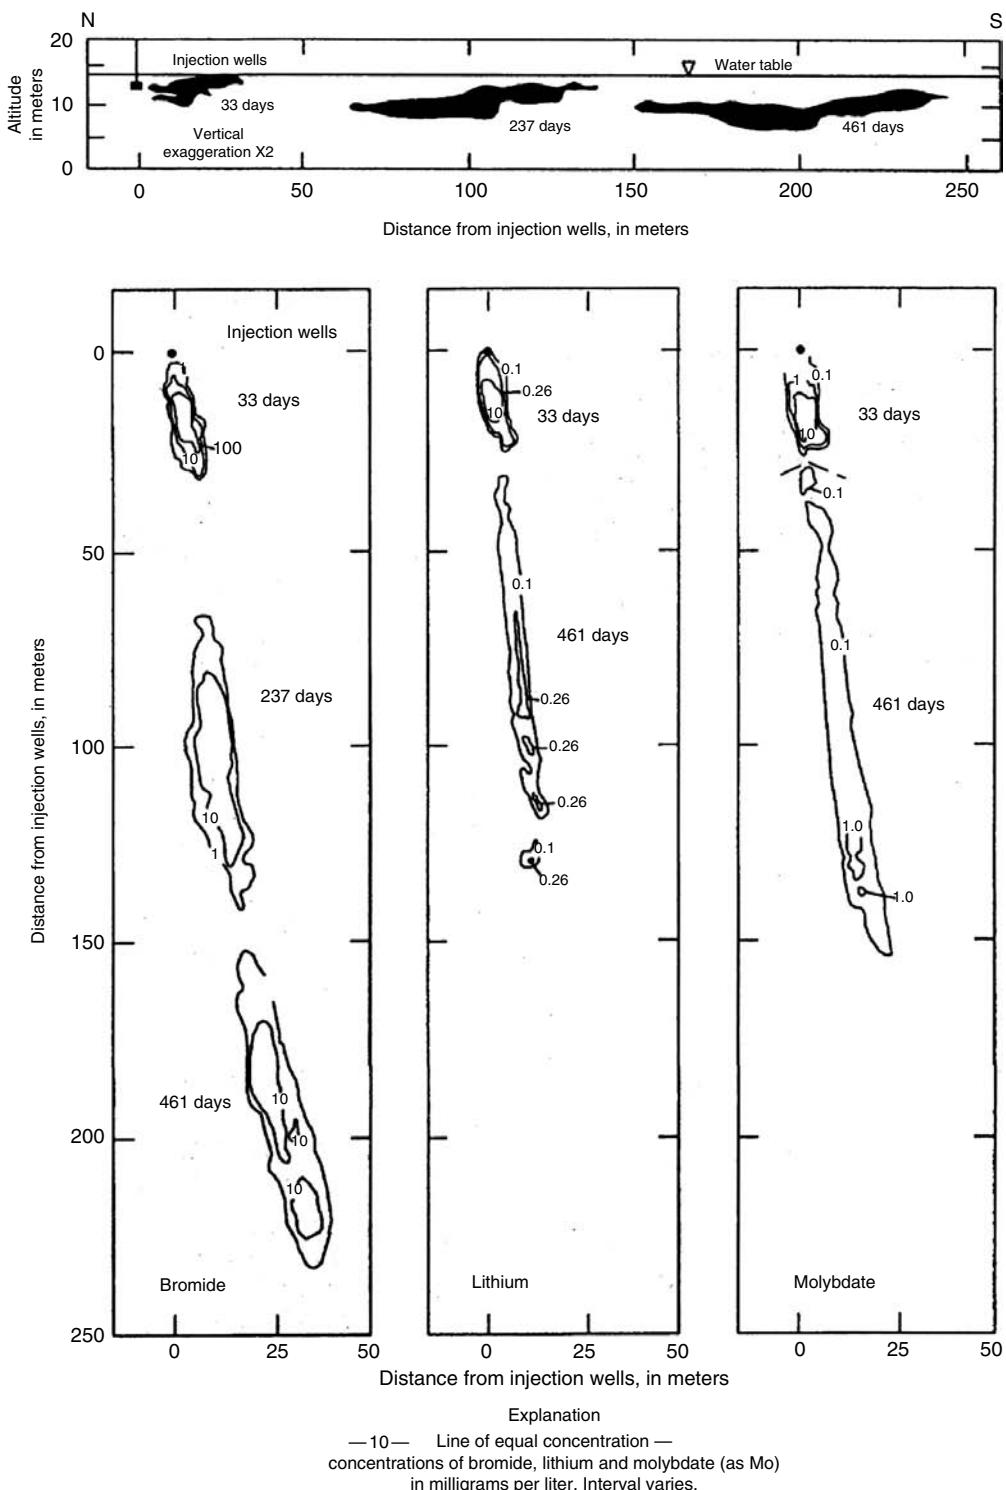

FIGURE 15.2 Vertical and horizontal plots of tracer concentration for the Cape Cod natural gradient tracer test. The variable plume geometry demonstrates the influence of physical heterogeneities on solute transport, while the difference in shapes of the three tracers illustrates the influence of geochemistry on solute transport. (From LeBlanc, D.R. et al. 1991. *Water Resour. Res.* 27(5):895–910. With permission.)

a highly effective bioremediation system (Hyndman et al., 2000; Dybas et al., 2002). Although it was possible to predict tracer transport at this site, the level of characterization required was far more than would be possible at most remediation sites.

15.2.1.2 Forced Gradient Methods

The long duration of natural gradient methods is often inconsistent with the need for rapid site assessment, thus forced gradient tests are often used in practice. The first stage of a forced gradient test is pumping for a period of time to approach steady-state hydraulic heads in the region of the test. In divergent flow tracer tests, water is pumped into a well while concentrations are measured at several different observation wells at radius (r). This type of test can be used to estimate effective porosity (θ) in a homogeneous hydraulic conductivity field using (Sanchez-Villa et al., 1992)

$$\theta = \frac{Qt_r}{\pi r^2 b} \quad (15.7)$$

where Q is the injection flow rate over the entire saturated thickness of the aquifer (b), and t_r is the concentration travel time from the injection well to the observation well (i.e., can be approximated as the peak concentration arrival time or center of mass for a pulse injection of a conservative tracer).

Convergent flow tracer tests can be used to explore anisotropy in hydraulic conductivity and dispersivity. In a convergent tracer test, water is pumped out of one well which is monitored for tracer concentrations derived from small injected tracer pulses from other wells. Each test has to be conducted at different times, or multiple tracers with similar transport characteristics must be injected into the different wells. This type of analysis showed significant directional dependence in tracer concentration histories in an anisotropic fractured gneiss and the Culebra dolomite near the Waste Isolation Pilot Plant (Sanchez-Villa et al., 1992). Simulation experiments performed by Tiedeman and Hsieh (2004) demonstrated that longitudinal dispersivity estimates from forced gradient tracer tests depend on the geometry of wells used in the test, and that in many cases such tests will underestimate the dispersivity for natural gradient tests.

At the Kesterson Aquifer in California's central valley, a forced gradient tracer test was conducted using both an injection and a withdrawal well to assess the heterogeneous properties of a shallow aquifer between these wells (Benson et al., 1991). Benson (1988) performed a series of one-dimensional transport simulations to approximate the longitudinal dispersivities of this site. This site was also used to test several approaches that combine seismic, tracer, and hydraulic data for aquifer property estimation, as described later in this chapter.

15.3 Application of Geophysical Methods to Environmental Problems

Spatially averaged hydrogeologic data can be supplemented with higher resolution geophysical information to develop detailed estimates of aquifer structure and properties. Geophysical techniques, such as seismic and radar methods, have successfully imaged a variety of subsurface features including heterogeneous lithologies in oil reservoirs, aquifers, and mines; the geometry of subsurface cavities and buried objects; variations in fluid properties and saturation; and the structure of glaciers. The following sections discuss (1) an overview of surface seismic and ground-penetrating radar methods; (2) cross-well tomography; and (3) approaches to combining geophysical and tracer data.

15.3.1 Surface Seismic Reflection and Refraction Surveys

Seismic *reflection* and *refraction* surveys have been widely used to characterize subsurface environments for decades. Such surveys provide information about the geometry and nature of subsurface lithologies for both petroleum exploration and environmental remediation work. Reflection and refraction seismic surveys generate sound waves at a near-surface source (e.g., hammer on a steel plate, explosion)

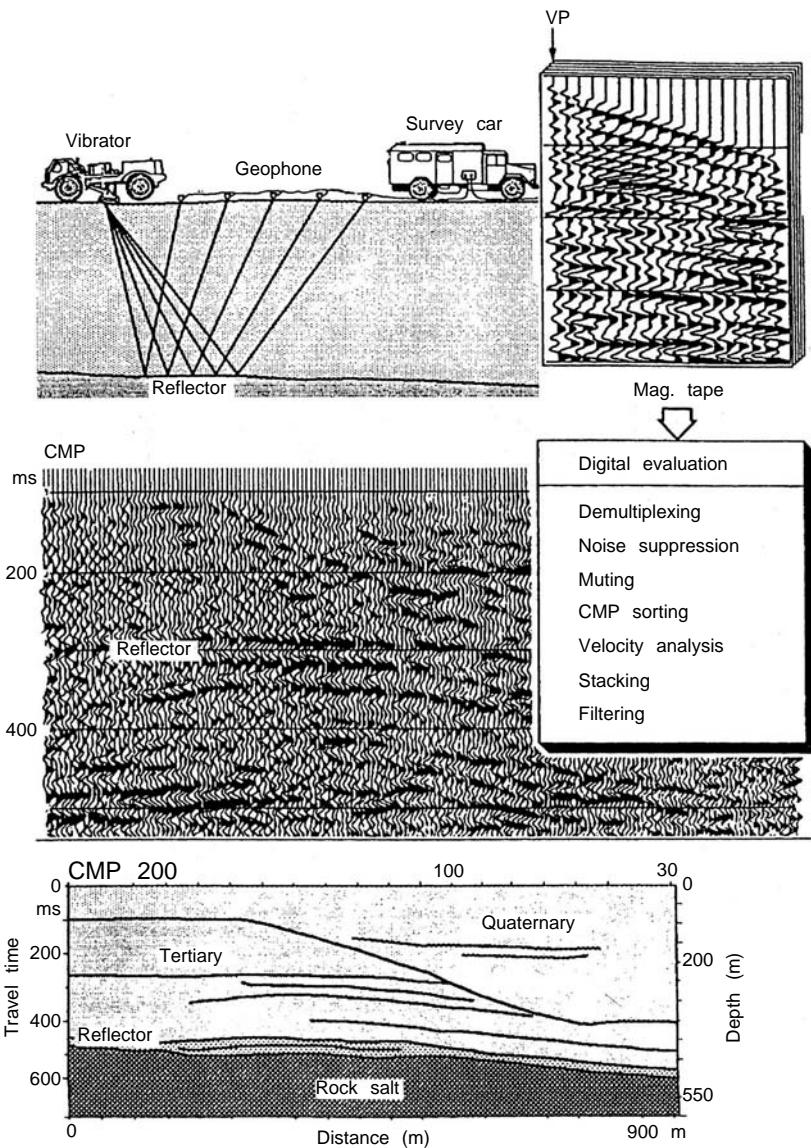

FIGURE 15.3 A diagram of seismic reflection data collection, processing, and interpretation. (From Vogelsang, D. 1995. *Environmental Geophysics: A Practical Guide*. Springer-Verlag, Berlin, 173 p. With permission.)

and measure the resulting seismic signal at multiple receivers called geophones (Figure 15.3). The measured signals are then processed for amplitudes and travel times for refracted and reflected seismic energy.

A portion of the incident seismic energy is reflected when it encounters a contrast in seismic impedance, which equals density (ρ) times seismic velocity (V), and the amount of reflected energy is proportional to the degree of contrast. The time (t) for reflected seismic energy to reach the surface from a single flat interface is:

$$t = \sqrt{\frac{4d^2}{V^2} + \frac{x^2}{V^2}} \quad (15.8)$$

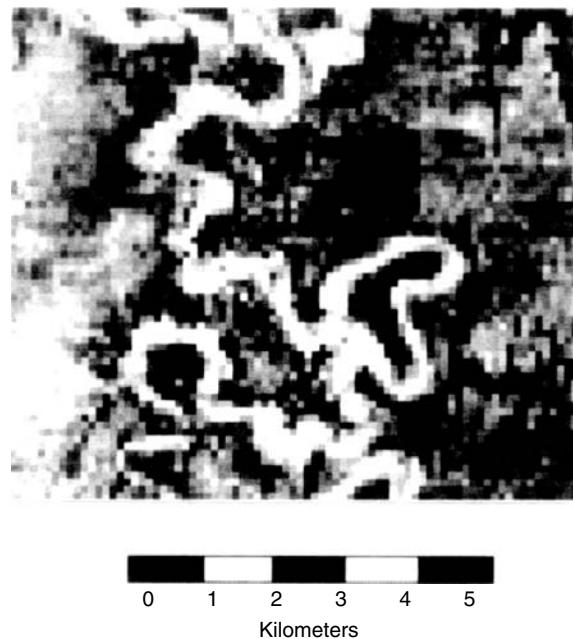

FIGURE 15.4 A horizontal slice through a 3D processed seismic reflection survey from the Gulf of Thailand that illustrates a buried meandering river channel. (Data courtesy of the Stanford Exploration Project.)

where d is the depth to the interface. The first term under the square root represents the time for a normal incidence reflection (source and receiver at same location), while the second term represents parabolic moveout due to offset x between source and receiver. More complex formulations for multiple dipping and curved interfaces can be found in introductory geophysics texts (e.g., Telford et al., 1990). Surface seismic reflection data can be processed by adjusting the velocity for a *common midpoint gather* to flatten the observed hyperbolic shape of the reflector, which is called a *normal moveout correction*.

Through this correction, the measured times are corrected from their offset positions back to a normal incidence position (no offset). The data are then stacked across each corrected common midpoint gather to estimate the seismic velocity structure at the midpoint of the plane between source and receiver locations (see Figure 15.3). This method does not account for interfaces that dip out of the plane, so the energy reflected from out of the image plane will appear at incorrect locations. As a result, the best approach is to collect and process surface seismic data in three dimensions. An excellent example of the type of information that can be obtained by 3D analysis of surface seismic data is the clear evidence of an old meandering channel that can be observed in the processed data from the Gulf of Thailand (Figure 15.4). The fundamentals of seismic reflection methods are described in more detail in Steeples and Miller (1990).

Seismic refraction surveys are collected with far offset receivers to measure energy that travels along an interface with a higher velocity at depth (Figure 15.5a). Refracted arrivals can be discerned from directly reflected arrivals by the slope of the distance versus time curve (Figure 15.5b). Direct reflected arrivals for a two-layer geologic setting will fall on a line that intersects the origin, while a line connecting refracted arrivals will have a positive zero-offset intercept. To ensure refracted energy is the first to arrive at the receivers, a refraction survey needs to be several times longer than the depth of investigation and velocity must increase with depth. The slope of the time versus distance line at the appropriate offset gives the reciprocal of the velocity of the deeper layer (Figure 15.5). In complex heterogeneous systems, detailed velocity analysis and ray tracing may be necessary to infer velocities from measured seismic data (Claerbout, 1992). More detailed descriptions of surface seismic surveys are covered in texts such as Telford et al. (1990).

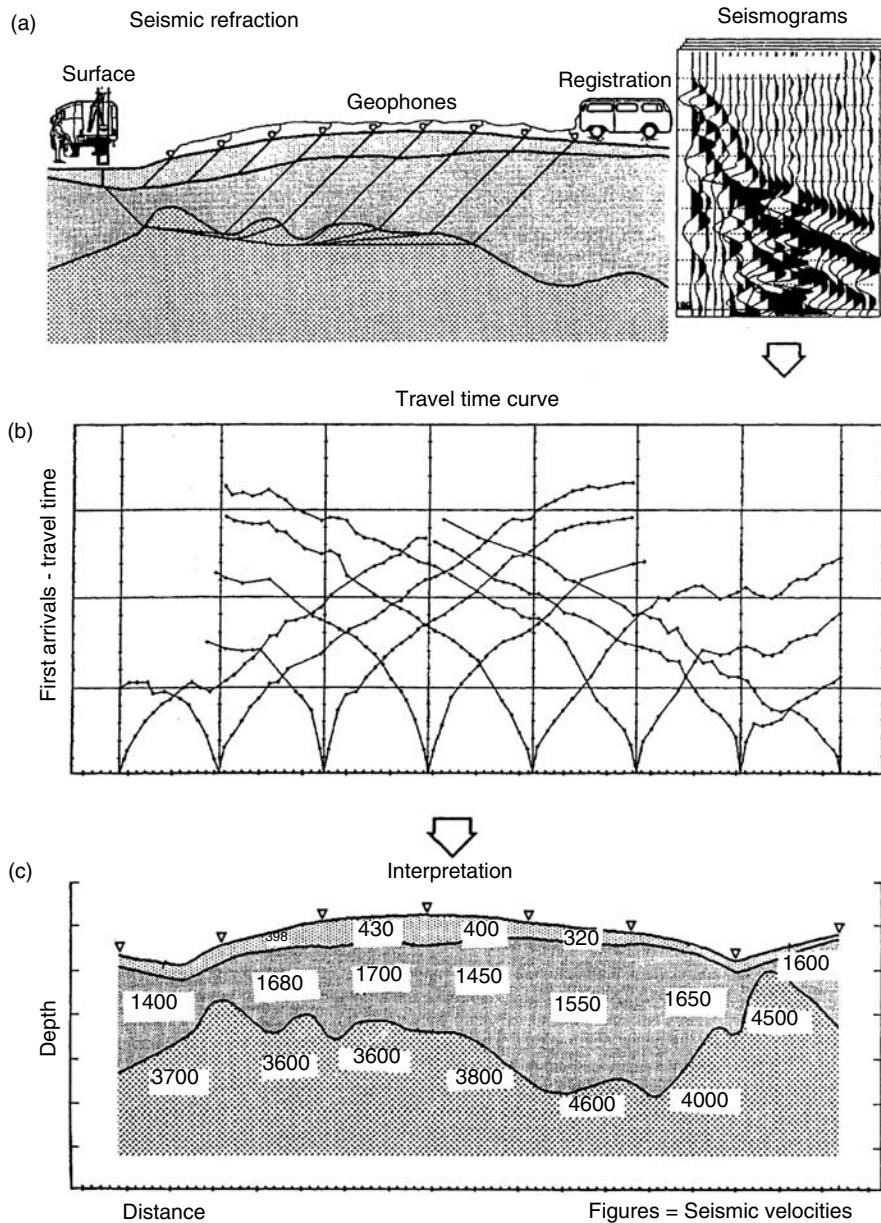

FIGURE 15.5 A diagram of a seismic refraction survey with the corresponding distance versus time plot for direct, reflected, and refracted waves. (From Vogelsang, D. 1995. *Environmental Geophysics: A Practical Guide*. Springer-Verlag, Berlin, 173 p. With permission.)

15.4 Ground-Penetrating Radar

Ground-penetrating radar (GPR) methods typically involve generating high-frequency electromagnetic waves (typically 10–1500 MHz) at a source antenna directed toward the ground and measuring the energy after it has moved through the subsurface at a receiver antenna. There is a trade-off between the high resolution obtained with high-frequency methods and the corresponding rapid signal *attenuation*. Preliminary surveys are often conducted with low-frequency radar antennas (50–100 MHz) that have

deeper signal penetration, with detailed higher frequency (200–900 MHz) surveys conducted in selected regions where higher resolution information about shallow properties is needed. The propagated direct wave (in cross-well GPR) or the reflected wave (in surface GPR) is measured at a receiver antenna. Surface GPR data are generally collected with a single spacing between antennas to provide nearly normal incidence reflections, although more information can be obtained using multiple offsets around each central point of interest, called common midpoint gathers, as described in Section 15.3.1. In both cases, multiple traces should be collected at each measurement point and stacked (or averaged) to improve the signal-to-noise ratio. Normal incidence reflection surveys have the benefit of rapid collection, since antennas can be towed across the surface at a constant rate while a signal is generated at a specified delay. This allows large regions to be rapidly surveyed and variable towing rates can be compensated using a timing mark at specified locations in a survey grid. A global positioning system (GPS) is a valuable addition to large radar surveys to continuously monitor the location of the radar system and map topography. Topographic data is necessary to correct the interpreted GPR depths to elevations above a reference, and lateral location information allows for rapid surveys of irregularly gridded regions.

Collecting traces in common midpoint gathers provides a suite of data that can be processed using surface seismic methods, yet the survey is more difficult to obtain because radar systems with multiple antennas are not readily available. The measured wavefields are processed for the first arrival traveltime and wave amplitudes. These wave attributes can then be processed using normal moveout corrections and mapped into depth versus amplitude plots which can be compared to lithological and moisture content variations in cores across the survey region. Tools that are commonly used to process seismic data such as frequency filtering, time-dependent gain, and migration can be used to improve interpretation of GPR data as described by Knoll et al. (1991) for the Cape Cod Aquifer. Rea and Knight (1998) estimated the near horizontal *variogram* (correlation vs. offset plot) of processed radar data from a gravel pit in southwestern British Columbia and compared this to the modeled variogram of a digitized image of a cliff face at the site. They found good agreement between both the direction of maximum correlation and the estimated correlation length determined from the two types of data. They then used this approach to infer the paleoflow direction of a buried channel and the correlation length in that direction from a three-dimensional GPR survey (Figure 15.6) over this site.

The subsurface propagation of electromagnetic energy depends on the electrical properties of the ground, commonly described using the relative dielectric permittivity ϵ_r in the electromagnetic wave equation

$$\nabla^2 E + i\mu\omega\sigma E + \omega^2 \epsilon^* \mu E = 0 \quad (15.9)$$

where E is the electrical field vector {Volts/m}; $i = \sqrt{-1}$; μ is the magnetic permeability {Henry/m}; ω is the angular frequency {radian/sec} = $2\pi\nu$ (ν = frequency in Hz); σ is the electrical conductivity {Siemen/m}; and ϵ^* is the complex dielectric permittivity of the media {Farad/m}.

The full electromagnetic wave equation is not generally used because of its complexity and uncertainty in all the parameters (i.e., μ , σ , ϵ^*). Instead, the imaginary portion of the dielectric permittivity is generally ignored, unless the goal is to describe electromagnetic wave attenuation, while the real portion of the relative dielectric permittivity is used to describe radar propagation velocities using

$$V = \frac{c}{\sqrt{\epsilon_r}} \quad (15.10)$$

where V is the electromagnetic wave velocity {m/nsec}; c is the free space light velocity (0.3 m/nsec); ϵ_r is the relative dielectric permittivity = (ϵ/ϵ_0) {dimensionless ratio}; ϵ is the real portion of the media dielectric permittivity; and ϵ_0 is the real portion of the free space dielectric permittivity (8.854×10^{-12} Farad/m). This approach has been successful in low electrical loss materials such as dry sand, which allow reasonable radar penetration depths.

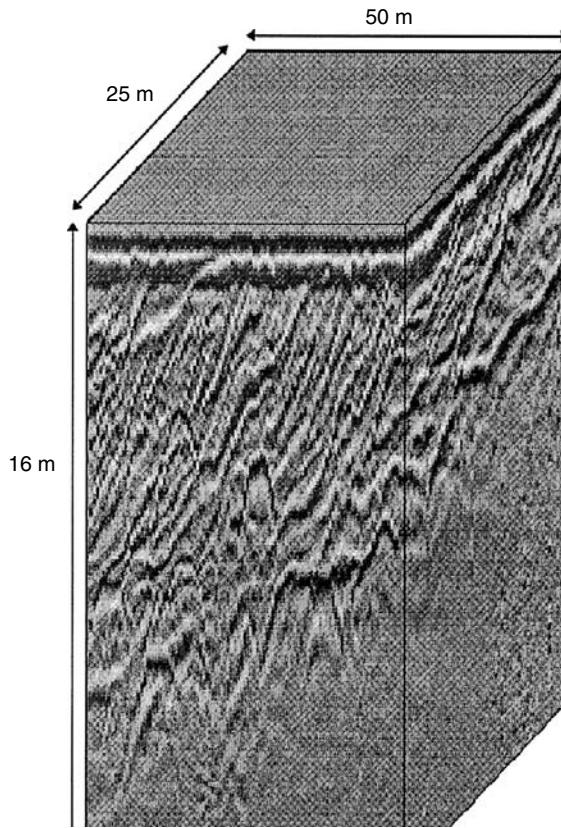

FIGURE 15.6 A 3D GPR survey conducted with 100 MHz antennas over dipping foreset beds in southwestern British Columbia. (From Rea, J. and Knight, R. 1998. *Water Resour. Res.* 34(3).)

The relative dielectric permittivity represents the ability of an electric field to polarize a material and is dependent on properties of both the solid and fluid. This property is inversely proportional to frequency, especially in saturated sediments (Telford et al., 1990). Some typical values are plotted in Figure 15.7 for high-frequency (> 100 MHz) measurements.

The large contrast between the dielectric permittivity of water and that of dry sediment can be used to infer the saturation of sediments from radar measurements. In this sense, it is possible to dynamically image wetting fronts, which would provide information about the hysteretic nature of unsaturated flow (e.g., Binley et al., 2001; Alumbaugh et al., 2002; Lunt et al., 2005). The capillary fringe often appears as a dominant reflector in radar records because of the large vertical gradient in saturation at this depth (Kim et al., 2000). The reflector depth should only be interpreted as the water table in coarse-grained sediments, as the capillary fringe will be significantly shallower than the water table in fine-grained sediments. A detailed GPR survey of the Cape Cod Aquifer imaged the capillary fringe as well as lithologic variability in the saturated zone (Figure 15.8) (Knoll et al., 1991). The GPR penetration depth is reduced in the saturated zone as a large portion of the incident energy is reflected from the capillary fringe due to the contrast in dielectric constant. At other sites, low-frequency radar (25 to 200 MHz) has provided deeper penetration and has been used to image lithologic contrasts in the saturated zone, although the trade-off for increased depth is decreased spatial resolution.

GPR has significant potential to image lithologic variations in the unsaturated zone due to the different water retention properties of sediments (Van Dam et al., 2003). Thus, lithologic heterogeneity may be detected by comparing the results of two radar surveys made under different moisture conditions. Although the dielectric permittivity of clay is different from sand with the same moisture content

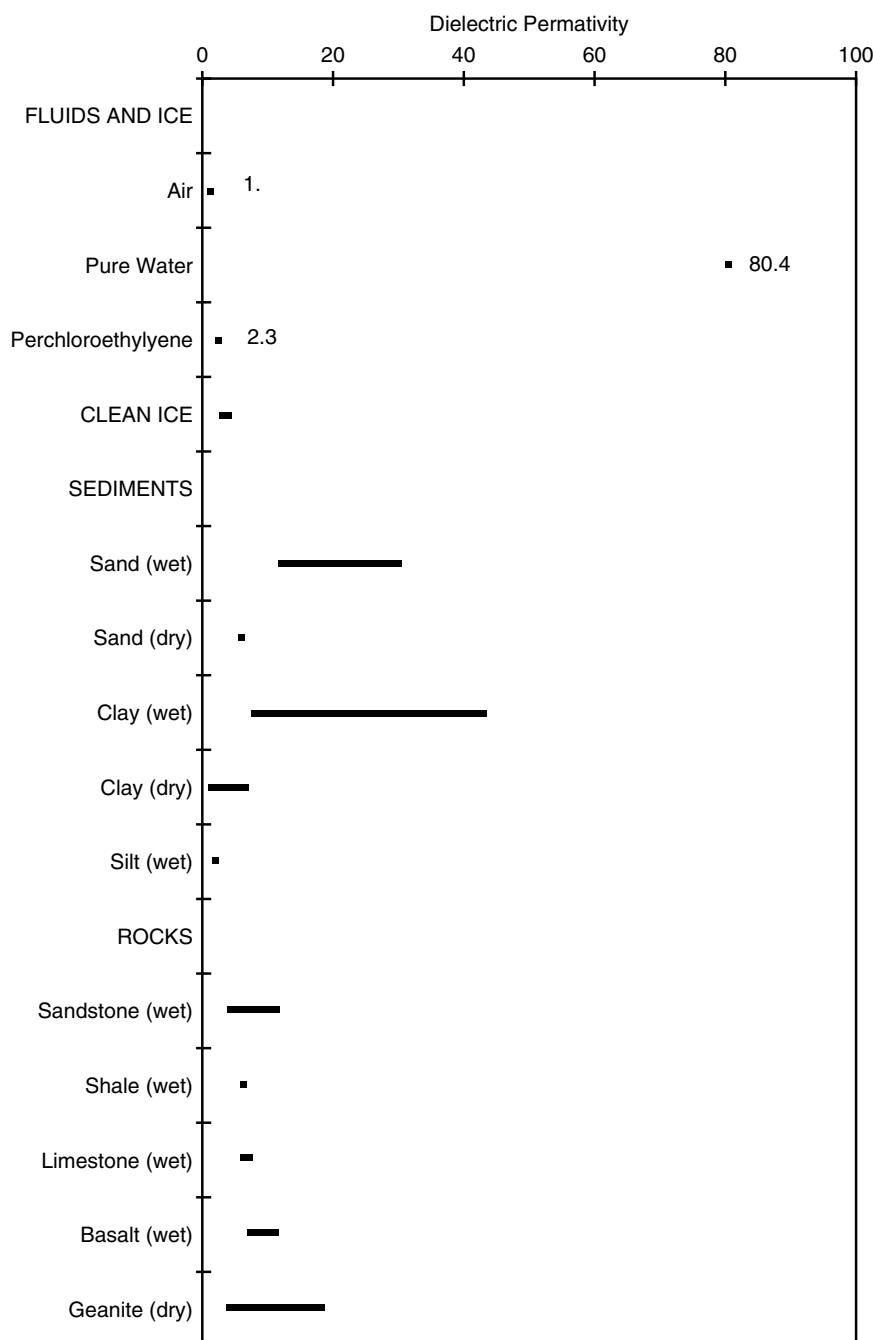

FIGURE 15.7 Plot of relative dielectric permittivity values of various materials. (Data from Placzek, G. and Haeni, F. P. 1995. FIGURE 15.8 A single line of processed radar data from a 3D survey over the Cape Cod Aquifer. The land surface and capillary fringe (labeled as water table) are noted on the plot. (From Knoll, M. D., Haeni, F. P., and Knight, R. J. 1991. G. E. Mallard and D. E. Aronson, eds., U.S. Geological Survey toxic substances hydrology program — Proceedings of the technical meeting, March 11–15, 1991, Monterey, CA. With permission.)

(Figure 15.7), the change is more pronounced after a wetting front has passed through regions with different clay content as zones with higher clay content will have a higher moisture content in this case due to stronger capillary forces in the small pore spaces. Greaves et al. (1996) interpreted variations in moisture content from the high-quality multichannel radar data collected at the Chalk River site, Ontario, which were processed by Fisher et al. (1992) (Figure 15.9). The clarity of this processed data shows the ability of multichannel GPR surveys to infer heterogeneities in lithology and water content.

15.5 Cross-Well Tomography

Cross-well tomography is a high-resolution approach to image heterogeneities between pairs of wells. The philosophy of cross-well tomography is similar to that of the computed axial tomography (CAT) scan, except that seismic or radar waves are used to image the subsurface rather than using X-rays to image the human body. The resolution of cross-well tomography is much lower than what is obtained from medical imaging techniques because much lower frequencies are used for seismic imaging (1–20 KHz) and radar imaging (50–1500 MHz), and the coverage is limited to planes between well pairs, whereas three-dimensional coverage is available in a CAT scan.

Cross-well radar surveys provide the opportunity to image subsurface features with higher resolution and more control over the path of energy between source and receiver than surface radar surveys. In the cross-well radar configuration, the transmitted radar signal is measured in a receiver well, thus cross-well tomography can estimate both the attenuation and velocity of electromagnetic energy throughout the plane between wells (Olhoeft, 1988; Johnson et al., 2005). Radar signals are strongly attenuated by clays and saline fluids, thus limiting their use in these environments. This attenuation, however, can be used to identify such zones using short offset cross-well surveys in regions where clay lenses are embedded in a sand matrix.

Cross-well seismic tests involve generating sound waves at specified depth intervals in one well, while hydrophones or geophones measure the propagated wavefield at multiple depths in nearby wells. A variety of sources can be used including (1) a weight drop, (2) a hydraulic pulse generator, (3) an air pulse, or (4) a piezoelectric bender bar. Piezoelectric sources provide a high-quality, frequency-controlled signal by applying an electrical impulse to material that expands due to this charge. The received wavefield is analyzed for key events, such as the compressional- and shear-wave arrival times at each receiver (Telford et al., 1990) or reflections (Lazaratos et al., 1993).

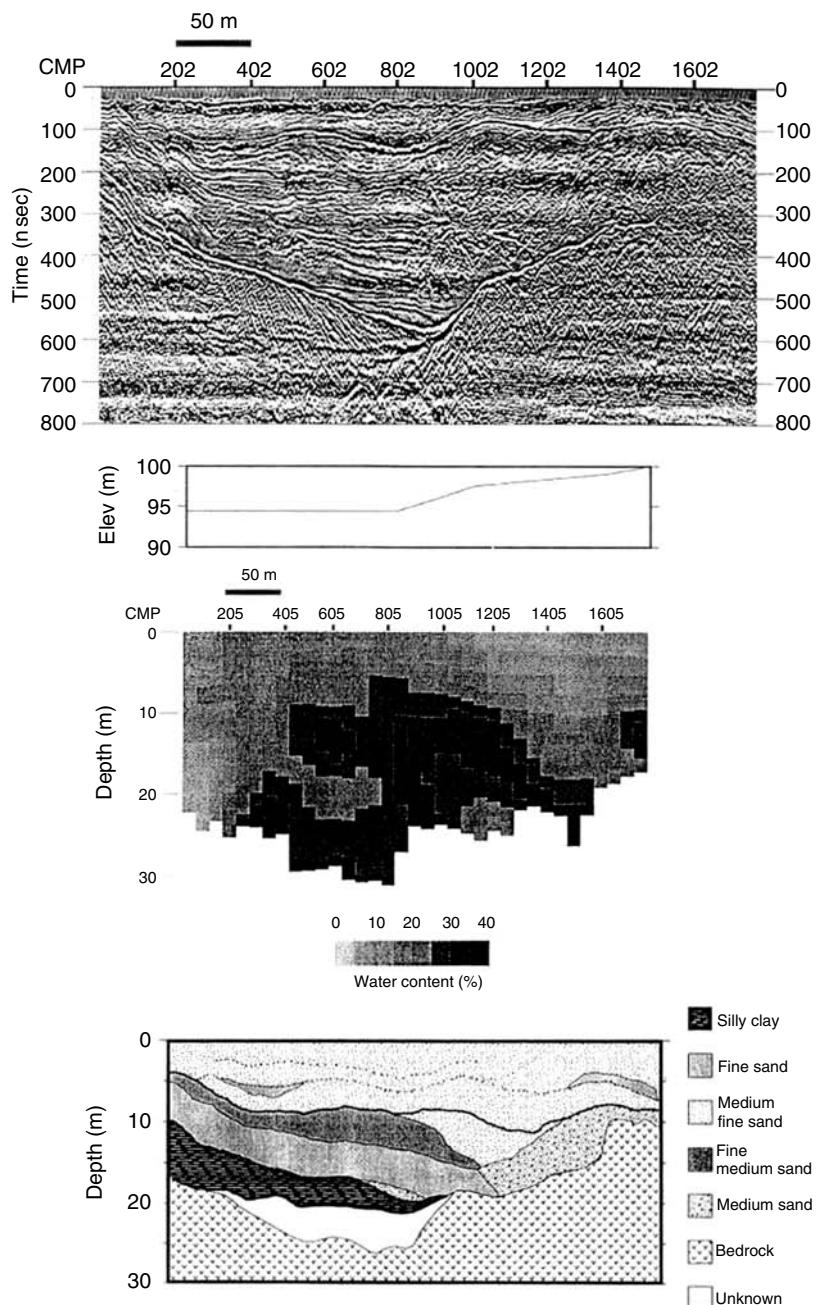

FIGURE 15.9 Plot of processed multiple offset GPR data collected at the Chalk River test site along with interpretations of water content and lithology for the surveyed region. (From Greaves, R. J., Lesmes, D. P., Le, J. M., and Toksoz, M. N. 1996. *Geophysics* 61(3):683–695. With permission. Original presentation in Fisher, E., McMechan, G., and Annan, A. P. 1992. *Geophysics* 57:495–504.)

Cross-well tomography fills a gap between sparse well logs and low-resolution surface geophysical estimates (Harris et al., 1996). These geophysical methods involve estimating seismic or radar properties that best reproduce aspects of the measured wavefield through wave propagation simulations. The best possible vertical resolution is a quarter wavelength (λ), which can be roughly calculated using the dominant frequency (f) of the source as $\lambda = V/f$, where V is the average seismic or radar velocity. This indicates that cross-well seismic tomography has the potential to image lithologic heterogeneities at scales from 10 cm to several meters, for typical sediment velocities (1000–2500 m/sec) (Telford et al., 1990; Kearey and Brooks, 1991) and source frequencies (1–10 KHz), while radar has resolution of less than 1 cm to more than 1 m for typical sediment velocities (0.05–0.15 m/nsec) and antenna frequencies (25 and 1500 MHz).

One seismic tomography approach involves simulating wave propagation through a homogeneous media with embedded scattering objects using the elastic wave equation

$$\rho \frac{\partial^2 \Delta}{\partial t^2} = (\lambda + 2\mu) \nabla^2 \Delta \quad (15.11)$$

where the compressional-wave velocity $\alpha^2 = (\lambda + 2\mu)/\rho$, Δ is the dilatation, or change in volume per unit volume due to strain, λ is Lame's constant, μ is the shear modulus, and ρ is the bulk density. Diffraction tomography provides one method of approximating wave propagation through a background model with embedded point objects, thus heterogeneous media can be split up into different levels of heterogeneities (Harris and Wang, 1996). Reiter and Rodi (1996) presented a nonlinear waveform tomography method that relaxes some of the assumptions necessary for diffraction tomography, however this approach is highly computationally intensive.

15.5.1 Traveletime Tomography

Rather than simulating the dynamics of wave propagation, this approach assumes that waves are of infinite frequency and thus can be represented using rays, which is fairly reasonable for high-frequency cross-well tomography. In this case the goal of the estimation problem is to minimize the absolute or squared difference between measured and simulated traveltimes for a particular type of seismic wave, such as a compressional wave. The wave equation can be simplified to the travelttime equation using the ray theory approximation

$$t_i = \int_{C_i} S(x, z) d\ell \quad i = 1, \dots, M \text{ rays} \quad (15.12)$$

where the travelttime (t_i) for source–receiver pair (i) is approximated as the integral of slowness (S) = (1/velocity) along the simulated ray path (C_i), and () is the increment of path length along the i th ray. Rays can be traced using a numerical approximation of Snell's law (which was originally derived for optics)

$$\frac{\sin \phi_1}{V_1} = \frac{\sin \phi_2}{V_2} = \frac{\sin \phi_i}{V_i} = \frac{\sin \phi_{i+1}}{V_{i+1}} \quad (15.13)$$

where ϕ_i is the incidence angle between the ray in zone i and the normal to an interface separating zone i from zone $i + 1$, and V_i is the seismic velocity in zone i . The top portion of Figure 15.5 illustrates an example from surface seismic characterization, in which refraction (or bending) of rays as they travel through progressively higher velocity regions with depth. The travelttime equation is nonlinear as both the ray path and the slowness field are unknown, thus we cannot directly invert this equation to estimate the slowness field. For each iteration, the travelttime equation can be linearized by iteratively tracing ray paths

through a known background slowness field (S_0) to calculate slowness perturbations (ΔS).

$$S = S_0 + \Delta S \quad (15.14)$$

The slowness estimate from the previous iteration is used for the known background field (S_0), except on the first iteration when an arbitrary starting model is used. A critical decision for tomographic inversions is the appropriate parameterization of the slowness model ($S(x, z)$). The most common parameterization for cross-well tomography has been rectangular constant-velocity pixels (S_j) as this simplifies the estimation problem. The solution to the traveltime equation reduces to a linear set of equations that relate traveltimes (Δt_i) to slowness perturbations in each of j pixels (ΔS_j).

$$\Delta t_i = \sum_{j=1}^N \Delta S_j \ell_{ij} \quad i = 1, \dots, M \text{ rays} \quad (15.15)$$

where the matrix (ℓ_{ij}) has elements of ray path length in each pixel when the slowness field is defined using rectangular pixels.

The slowness perturbations (ΔS_j) are calculated by inverting Equation 15.15 using an algorithm such as the simultaneous iterative reconstruction technique (McMechan et al., 1987). This algorithm simultaneously back-projects the traveltime residuals along the estimated ray paths and averages the result to determine the slowness perturbation to assign to each cell.

The slowness field can be parameterized in different ways depending on the goal of the inversion. The most common parameterization for tomography is a field of rectangular pixels, which are assigned slowness values using Equations 15.12 through 15.15. An alternative approach was presented by Michelena and Harris (1991) who parameterized the slowness inversion using “natural pixels” that account for the data collection geometry in cross-well tomography. These natural pixels are rectangular elements aligned in the direction of wave propagation. This approach can account for the sensitivity of the measured signal at a receiver to some average of the properties along a rectangular or ellipsoidal beam between wells.

For cases where the goal of the geophysical survey is identification of lithologic zones (e.g., sand, gravel, and clay), better results may be obtained by limiting the number of possible slowness values to the number of major lithologies identified in cores. For example, Hyndman and Harris (1996) parameterized a cross-well inversion using a small number of velocity values to estimate the geometry of the primary lithologies of the shallow Kesterson Aquifer in California’s San Joaquin Valley. This approach, called the multiple population inversion (MPI), converts traveltimes between all available well pairs for the spatial distribution of a small number of seismic slowness populations. This can provide more information about the dominant scale of subsurface heterogeneity than common parameterizations that provide smooth slowness fields. The lithologies and hydraulic parameters for the estimated populations can then be inferred from core data and hydraulic testing, or a co-inversion can be used to simultaneously estimate all parameters of interest as discussed in the next section of this chapter.

The MPI method iteratively assigns pixels to slowness populations based on the histogram of slowness perturbations, which are calculated by inverting Equation 15.15. By constraining the number of slowness values, this method is less susceptible to ray-based inversion artifacts and can resolve finer-scale sedimentary structures than methods that smooth the slowness field. Hyndman and Harris (1996) showed that the MPI converges to an equal or smaller average travelttime residual than obtained with an approach based on nonzonal parameterization for both a 2D synthetic aquifer, and for a 3D aquifer case from the Central Valley of California.

This approach reduced the artifacts commonly observed in ray-based inversions without smoothing the estimated field, which is the common method of reducing such artifacts. As tomography is an iterative estimation approach, the zonal slowness model can be used as the background model for an unconstrained velocity inversion. At the Kesterson site, this provided an updated seismic slowness estimate that preserved much of the structure of the zonal slowness estimates with finer-scale resolution (Figure 15.10). These

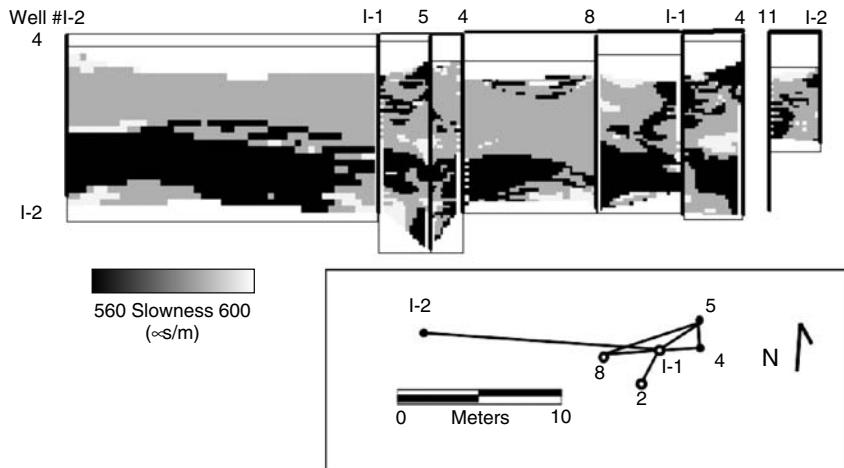

FIGURE 15.10 Location map for the Kesterson Aquifer site along with seismic velocity tomograms estimated by Hyndman and Harris. The low slowness zones were identified as low hydraulic conductivity regions. Note that well I-2 is the injection well, and I-6 is the extraction well, which is approximately the same distance from well 4 to well I-2, but to the right of well 4 along the approximate path from I-2 to 4. Well I-6 data are shown in Figure 15.11 (Modified from Hyndman, D. W. and Harris, J. M. 1996. *Geophysics* 61(6):1728–1737. With permission.)

Kesterson tomograms are used in later sections of this chapter for hydraulic and transport property estimation in three dimensions.

15.5.2 Attenuation Tomography

Traveltime tomography uses only one attribute of the measured wavefield, while attenuation tomography attempts to reproduce wave amplitudes due to wave propagation along the paths predicted by traveltome tomography. One philosophy of attenuation tomography is that the bulk of the seismic or radar energy travels near the ray paths predicted for traveltome tomography, thus the amplitude attenuation can also be described along such paths. Thus the attenuation coefficients can be iteratively updated to best reproduce some aspect of the amplitudes measured at the receivers. For example, Quan and Harris (1997) demonstrated an approach that used the observed frequency downshift in a window around the first arrival to estimate attenuation coefficients for an oil reservoir in Texas. If high-quality signals are measured, significant information can be gained about the lithologic heterogeneities through analysis of both attenuation and traveltome tomography results. Another approach to attenuation tomography is to minimize the difference between the simulated and measured amplitudes of the first arrival peak or energy in the first peak. Johnson et al. (2005) parameterized a radar tomography problem using fresnel zones, and calculated the attenuation in this region based on the difference in energy in the first half cycle of the received signal.

15.6 Combining Geophysical and Tracer Data

Geophysical and hydrogeologic data can be combined to provide aquifer property estimates over a range of spatial scales. Methods that estimate aquifer properties can benefit from different sampling scales for each type of data. Lithologic cores provide point values, while well-test data provide local information around a well. Cross-well seismic and radar tomography provides dense spatial information for a cross section between wells, while surface geophysical surveys can provide 3D information about variability in shallow lithologies and fluid saturation. Measured hydraulic heads and tracer concentrations are indirectly related to hydraulic conductivity through the groundwater flow and advection-dispersion equations. The scale measured by each type of data is different but overlapping, which provides a suite of information about spatial variability that could not be fully obtained using any single type of data alone. These independent data types complement each other because they contain information about a range of important aquifer scales.

15.6.1 Geostatistical Methods

Geostatistical methods provide one set of tools to combine geophysical and hydrogeologic data. These methods interpolate between available data points using weights that represent modeled spatial correlation structures and the uncertainty in the different measurement methods. Weights are assigned through a covariance matrix that incorporates the inferred spatial correlation of each variable and the interrelationships between variables. An excellent summary of basic geostatistical concepts is provided by Isaaks and Srivastava (1989) and a suite of powerful geostatistical computer codes is available in Deutsch and Journel (1997).

Geophysical surveys provide a good source of soft information for geostatistical estimation methods. Several geostatistical methods have been developed that use surface seismic and radar datasets to provide information about the heterogeneous structure of aquifers and reservoirs. The simplest approach is to *cokrig* the different datasets based on the inferred correlation structures of each variable and cross-correlation between datasets. The benefit of adding high-resolution seismic data to well-log data has been demonstrated in a number of studies. For example, Araktingi and Bashore (1992) cokriged 3D surface seismic velocity estimates with porosity measurements and found that even poor-quality seismic estimates provided information about reservoir properties. However, traditional cokriging cannot incorporate nonlinear and potentially non-unique relations between a parameter of interest and the accompanying soft geophysical estimates.

Sequential Gaussian co-simulation (Deutsch and Journel, 1997) provides an additional simple geostatistical method of developing hydraulic conductivity realizations based on hydraulic conductivity measurements as hard data and the slowness estimates as soft data. Sequential Gaussian simulation honors the values at all seismic tomogram locations, as well as the sample probability distribution and variograms of the tomographic slowness estimates. For the Kesterson Aquifer in California's San Joaquin Valley (Hyndman et al. 2000) found a correlation coefficient of +0.74 between slowness and natural log hydraulic measurements, which establishes the level of control the seismic data has in the geostatistical simulation (Figure 15.11). If this coefficient were +1.0 the seismic data would have a perfect positive linear correlation to log conductivity, with large slowness values indicating large $\ln(K)$ values. If this coefficient were 0.0, the seismic data would have no linear correlation to log conductivity and would thus have no influence on the $\ln(K)$ estimates. One limitation of this approach is the reliance on a linear relation between parameters.

Figure 15.11 demonstrates the value of adding seismic information to the conductivity estimation problem in cases where significant correlation is observed between slowness and log conductivity. The log conductivity field in Figure 15.11a is a randomly chosen realization generated using sequential Gaussian simulation of log hydraulic conductivity data alone, which results in the corresponding simulated concentration histories. Figure 15.11b shows a log conductivity realization generated using sequential Gaussian co-simulation for the same random path that was used to generate Figure 15.11a. For this realization, a slowness realization conditioned on the estimated seismic tomography planes (Figure 15.10) was used as soft data and hydraulic conductivity measurements were hard data. Thus to obtain the conductivity estimates first involved generating a slowness realization using sequential Gaussian simulation, then this field was updated using sequential Gaussian co-simulation to constrain the regions that are near conductivity measurements.

In the Kesterson case, Hyndman et al. (2000) illustrated that the slowness estimates improved the concentration histories at all wells, except for at well 8, relative to the simulations through the estimate based on conductivity data alone (Figure 15.11a). This improvement would likely be more pronounced if fewer conductivity measurements were available. In addition, the simulation with conductivity data alone required estimates of the correlation structure, which in this case were derived from the seismic estimates. Thus the simulations with conductivity alone would have been poorer if no seismic data were available to help infer the correlation structure of subsurface lithologies.

Bayesian geostatistics provides a more flexible alternative to traditional cokriging for incorporating "soft" geophysical data. Carty and Rubin (1995) developed a conditional log hydraulic conductivity

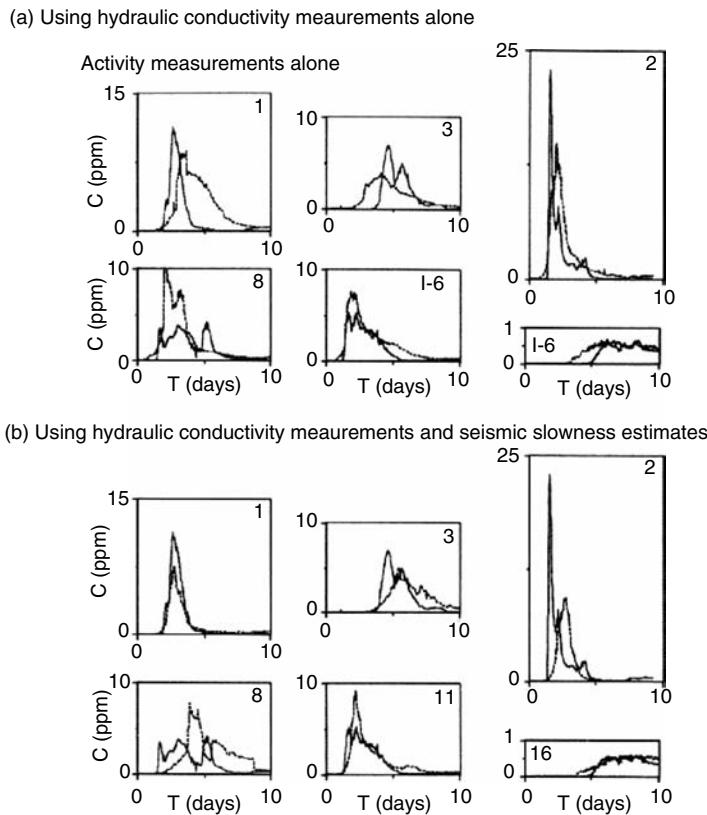

FIGURE 15.11 Comparison of observed (solid) and simulated (dashed) tracer concentration histories for the shallow Kesterson Aquifer, simulated through conductivity realizations (a) generated using conductivity measurements alone, and (b) generated using sequential co-simulation with hard conductivity data and a soft seismic slowness field based on estimates from seismic tomography (see Figure 15.10). (From Hyndman, D. W., Gorelick, S. M., and Harris, J. M. 2000. *Water Resour. Res.* 36(8):2121–2132. With permission.)

distribution based on seismic and lithologic data for a synthetic case study. They first estimated interval seismic velocities using *normal moveout corrections* (described in Section 15.3.1 of this chapter). Then they converted these interval velocities into a prior lithology indicator probability field, which represents the likelihood of each lithology across the survey region, using calibration curves that represented the relation between seismic velocity from well logs and lithology from core samples. This prior distribution was then conditioned on lithology logs from wells to provide an updated probability field. The log hydraulic conductivity pdf was then developed by weighting the conductivity probability distribution function (pdf) for each lithology by the indicator lithology pdf. The results of this study indicate that the best hydraulic conductivity estimates are obtained when both seismic and lithologic information are used. Hubbard et al. (1997) developed a similar *stochastic* technique that estimates binary permeability and saturation fields from GPR data based on petrophysical relationships from Knoll et al. (1995). In their numerical example, the GPR data dramatically improved the estimates relative to those based only on borehole data even with significant measurement error. In a field example at the Oyster, Virginia site, Hubbard et al. (2001) applied a Bayesian inversion approach to estimate hydraulic conductivity with prior estimates developed using borehole flowmeters, and posterior updates based on cross-well radar tomography. See 14-8 and Figure 14.18, along with the associated discussion in Chapter 14 of this volume for more information on this approach and example.

Other geostatistical techniques develop a covariance matrix between measurements and properties of interest through approximations of an appropriate governing equation. For example, hydraulic head can

be related to hydraulic conductivity using a first-order approximation of the steady-state groundwater flow equation (Hoeksema and Kitanidis, 1984), and solute tracer arrival times can be related to conductivity through a first-order approximation of the advection-dispersion equation (Harvey and Gorelick, 1995). The conductivity estimates obtained from such methods can be combined with high resolution seismic velocity estimates from inversion methods like those discussed in Section 15.3 of this chapter. For example, Rubin et al. (1992) and Carty et al. (1993) demonstrated the value of seismic velocity estimates given an assumed relation between seismic velocity and permeability (Marion et al., 1992). They showed that seismic information significantly enhanced estimates of hydraulic properties even in synthetic cases where random error was added to the seismic velocity values, when information about the relation between properties is available. For some sites, it may be possible to infer a relation between seismic and hydraulic properties using core data, which then allows the use of such stochastic methods to estimate the distribution of hydraulic properties across a region. Knowledge of the relationship between seismic or radar velocity and hydrogeologic properties (lithology or permeability), however, is generally unknown at the field scale.

Conditional indicator simulation can be used to combine a wide variety of datasets including geologic knowledge, seismic estimates, geophysical logs, and local lithologic and hydraulic conductivity measurements. This approach involves modeling the spatial correlation structure (i.e., variogram) for several sets of property ranges separated by indicator values, and developing realizations of a property that honor the correlation structure and are conditioned to all measured values. McKenna and Poeter (1995) classified the *hydrofacies* of a site using indicator seismic velocity thresholds. These thresholds were determined using discriminant analysis in a four-dimensional space representing borehole logs (sonic, neutron, electrical conductivity, and natural gamma). This approach allowed for a nonlinear and non-unique relation between hydraulic conductivity and seismic velocity. The concept behind this analysis is to group locations with similar lithologies as indicated by the combination of log responses at each location. Inverse flow modeling was then used to estimate the likely range of hydraulic conductivity for each hydrofacies and eliminate realizations that did not honor the hydraulic head data. This approach was used to delineate the hydrofacies of a fluvial deposit near Golden, Colorado, where the combined analysis of seismic, hydraulic, and geologic data reduced the uncertainty in the hydraulic conductivity estimates. Poeter and McKenna (1995) stressed the importance of incorporating hydraulic data to constrain the conductivity estimates. Using geologic and geophysical data (hydrofacies classification) from wells alone, they found that some of the geostatistical realizations were implausible.

15.6.2 Zonal Inversion Methods

Another approach to combining geophysical and hydrogeologic data involves inferring the large-scale zonation of lithologies and effective hydrogeologic properties that are consistent with seismic, tracer, and hydraulic data. The split inversion method (SIM) was introduced by Hyndman et al. (1994) to co-invert independently collected datasets (e.g., cross-well seismic traveltimes and tracer concentration histories) for the zonation of lithologies, effective hydraulic conductivity values for each zone, and an effective dispersivity for the region. The motivation for the approach is that the combined analysis of seismic energy and tracer concentrations, which have independently sampled portions of the same environment, should provide better estimates of the geometry of subsurface lithologies and effective zonal properties than obtained with either dataset alone. The SIM does not rely on knowledge of the relationship between seismic velocity and hydraulic conductivity, although it assumes some relationship exists for large-scale lithologic zones.

The ability to represent nonlinear and non-unique relations between these properties was illustrated by the accurate estimates obtained by Hyndman et al. (1994) for two synthetic aquifers with the same seismic profile (a heterogeneous high seismic velocity matrix with embedded low seismic velocity zones) but different hydraulic conductivity profiles. The low velocity zones in one aquifer represented low conductivity zones, while these zones in another aquifer represented both high and low conductivity zones. Thus seismic information alone did not provide enough information to discern the lithologic zonation or

hydrogeologic properties, yet the combined use of seismic and tracer data allowed for accurate estimates of both the zonation of lithologies and the hydrogeologic properties of the zones.

The SIM was also applied to the Kesterson Aquifer by Hyndman and Gorelick (1996). The first stage of this approach was to estimate the seismic slowness for the available cross sections between wells as discussed at the end of Section 15.5.1. The correlation structure of the estimated seismic tomograms was then modeled to provide horizontal and vertical slowness variograms for the region. These were used to develop multiple 3D conditional seismic slowness realizations (e.g., Figure 15.12) for a region surrounding the tomograms using sequential Gaussian simulation (Deutsch and Journel, 1992). The SIM was then used to split each slowness realization into three lithologic classes (e.g., Figure 15.13) and to estimate

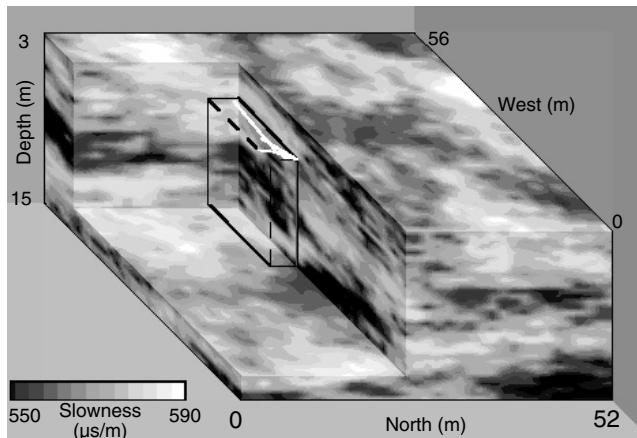

FIGURE 15.12 Three-dimensional seismic slowness realization for the shallow Kesterson Aquifer obtained using sequential simulation conditioned to the seismic tomograms in Figure 15.10. (From Hyndman, D. W. and Gorelick, S. M. 1996. *Water Resour. Res.* 32(9):2659–2670. With permission.)

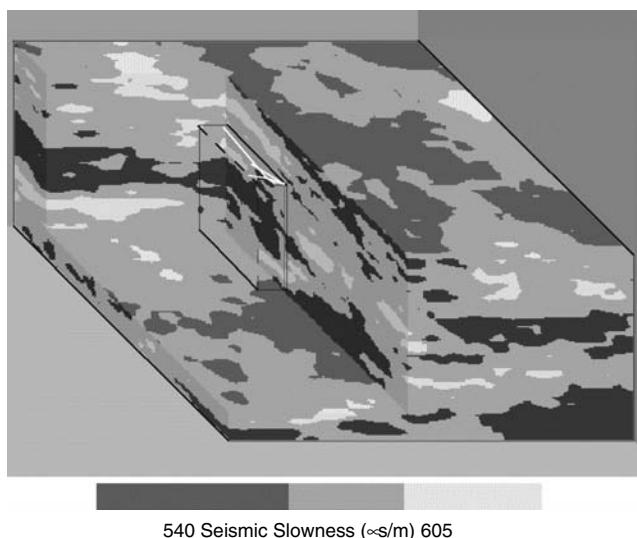

FIGURE 15.13 Zonation of hydraulic conductivity estimates obtained using the split inversion method (SIM). For this slowness realization (Figure 15.12), the estimated slowness splits are 569.4 and 587.8 s/m, and the hydraulic conductivity values are: 1.4×10^{-4} m/sec for the black regions; 3.6×10^{-4} m/sec for the gray regions; and 5.0×10^{-4} m/sec for the white regions. (From Hyndman, D. W. and Gorelick, S. M. 1996. *Water Resour. Res.* 32(9):2659–2670. With permission.)

both the effective hydraulic conductivity for each lithology and a single dispersivity value for the entire model domain. The objective function of this inversion was to minimize the squared residual between measured and simulated tracer arrival time quantiles, and drawdown during the tracer test. This study clearly illustrated the value of seismic tomography for estimating the hydraulic conductivity structure of a heterogeneous aquifer. The seismic slowness estimates provided information about the geometry of lithologic zones and the horizontal and vertical correlation structure of the aquifer lithologies. The drawdown measured during the tracer test provided information about the average regional hydraulic conductivity at the site, while the tracer concentrations provided information about the continuity of hydraulic conductivity across the region of the test.

15.6.3 Estimating the Relation between Geophysical and Hydrogeologic Properties

A major difficulty with incorporating geophysical data into hydrogeologic estimation methods is the uncertain and potentially non-unique relation between estimated geophysical properties (e.g., seismic velocity) and hydrogeologic properties (e.g., hydraulic conductivity). There is no reason to expect a fundamental relation between these properties as seismic velocities do not directly depend on the ability of sediment to transmit fluids. For particular frequencies of seismic energy, however, some researchers have found that fluid flow is important to the stiffness of the media, which is related to seismic velocity and attenuation (Bourbie et al., 1987). The effect of fluid moving through pores to accommodate the stress imposed by a sound wave was explored by Dvorkin et al. (1995) as an alternative to the Biot theory.

A primary goal in the field of rock physics (or petrophysics) is identifying relations between rock/sediment properties and measured geophysical signals to enable better predictions of properties in field settings. Petrophysics research has demonstrated empirical relations between seismic velocity and both porosity and clay content (Mavko et al., 2003). For example, Marion et al. (1992) developed a conceptual mixing model for the relationship between seismic velocity and porosity that involved sand-clay mixtures. The porosity had a minimum when the clay content was large enough to fill in the voids between sand grains, which resulted in a maximum seismic velocity. The porosity increased from this minimum toward both end member lithologies (sand and clay), with a corresponding reduction in the seismic velocity as the velocity of sound is lower through water than it is through sand or clay. Marion's model described one possible process leading to a relation between porosity and velocity. However, laboratory slowness estimates are often weakly correlated to the longer wavelength slowness estimates from the field because of factors such as frequency-dependent dispersion. It is thus difficult to extend the results of empirical laboratory studies to field scale with a wide variety of heterogeneous depositional environments.

Field-scale relationships between seismic slowness and hydraulic conductivity can be inferred by combining cross-well seismic tomography with hydraulic and tracer measurements in a joint estimation approach. The goal of this approach is to find a relation between seismic and hydraulic properties that minimizes the residual between simulated and measured hydraulic head and tracer concentration residuals. The concept is similar to that described above for the SIM, but for this approach the decision variables are parameters of the relation between seismic slowness and hydraulic conductivity. Hyndman et al. (2000) developed this approach to reduce computation time by reducing the number of decision variables adjusted in the estimation approach. The Kesterson field site was again used to test this approach, and the results were compared with the SIM results. For the Kesterson site a linear relation between slowness and the log of hydraulic conductivity appeared to be adequate based on: (1) laboratory measurements of hydraulic conductivity and seismic velocity, (2) the correlation between field cross-well slowness estimates and the hydraulic conductivity estimates in neighboring wells, which was used as an *a priori* relation for this iterative estimation approach, and (3) the zonal conductivity estimates from the split inversion method relative to the tomographic slowness values (see Figure 15.13).

A linear relation was not initially expected for the Kesterson Aquifer because of the nonlinear laboratory mixing relation of Marion et al. (1992). Even though the Marion model describes mixing of sand and clay, which are the predominant lithologies in the Kesterson region, the shallow aquifer examined in this study does not have the 100% clay end member, and the mixing process is likely quite different from

complete laboratory mixing. Estimating the relation between geophysical and hydrogeologic properties is a highly site- and scale-specific endeavor since no general relation is expected. The slowness (S in $\mu\text{s}/\text{m}$) at this site was positively correlated to log hydraulic conductivity (K in m/sec) for the shallow Kesterson Aquifer. The fit to the tracer and hydraulic data was significantly enhanced by the addition of the seismic data relative to those obtained using sequential simulation to interpolate between hydraulic conductivity measurements alone. This approach determined the likely conductivity structure of the shallow Kesterson Aquifer and explored the range of likely relations between slowness and conductivity at the field scale.

All the approaches described above indicated that geophysical information has the potential to increase the resolution of hydraulic property estimates. Changes in subsurface lithology are likely to cause a change in both geophysical and hydraulic properties at some scale, thus combining these different datasets provides better estimates than can be obtained with only one dataset. The primary difficulty in direct incorporation of these different datasets is the uncertain link between the measured properties. Different relations are expected for different depositional environments, and these relations may be nonlinear or non-unique if they are measurable at all. Moysey et al. (2005) presented an approach to develop field-scale petrophysical relationships using Monte Carlo simulation.

Other geophysical measurements could also be inverted to provide additional information about the hydraulic and lithologic properties of aquifers. For example, seismic attenuation is thought to be correlated to hydraulic conductivity. In all cases, high-quality data are necessary to perform detailed estimates of aquifer properties. This includes accurate surveys of well geometry for all cross-well surveys, since even small location errors may be larger than the variations in the property of interest between the wells. Hydraulic and tracer test data should be sampled with high spatial and temporal resolution to measure the fine scale variations in flow and transport that can be critical to solute transport predictions.

15.7 Dynamic Imaging of Tracer and Contaminant Plumes

A range of recent studies have used geophysical surveys to examine tracer or contaminant plumes. Static images of contaminant plumes provide valuable information which would be difficult or impossible to gather using well data alone. If a site has a conductive plume, as can occur from biodegradation of organic contaminants, the plume geometry can potentially be mapped using surface radar techniques (Sauck et al., 1998; Atekwana et al., 2000). Such plume maps could be used optimally design contaminant capture or remediation schemes.

Surface and cross-well radar have the potential to image the location of nonaqueous phase contaminant plumes (for nonpolar contaminants with permittivities very different from that of clean water), as was done in the Borden Aquifer (Greenhouse et al., 1993; Brewster and Annan, 1994). GPR reflections were observed as the dense nonaqueous phase liquid (DNAPL) pooled on successively deeper low-permeability lithologies. The late time GPR profiles illustrated the average increase in GPR velocity due to the introduction of the low dielectric constant DNAPL into the test region. The dynamic imaging of a tracer that influences the radar propagation velocity or attenuation can provide high resolution estimates of DNAPL saturation, which can be used to estimate the hydraulic conductivity structure of the aquifer and enhance our knowledge about transport processes in heterogeneous aquifer environments. Unfortunately, there has been limited success using geophysics to identify the location of NAPL plumes in the subsurface.

Dynamic geophysical imaging holds promise for estimating both changes in water content or concentrations of conductive or nonpolar solutes. Electrical resistivity tomography has been applied to image fractured rock (Slater et al., 1997), engineered barriers (Daily and Ramirez, 2000), and tracer transport through sediments (Mohrlock and Dietrich, 2001; Kemna et al., 2002; Singha and Gorelick, 2005). Such methods have defined the center of mass for tracer plumes, and provided information about solute plume geometry.

Cross-well radar tomography can also be used to dynamically image the transport of conductive tracer plumes. Attenuation difference tomography was used to successfully image the transport of a conductive

tracer plume through a highly heterogeneous test site in Boise Idaho (Barrash et al., 2003; Goldstein et al., 2003). This type of test provides the necessary data for fully coupled hydrogeophysical inversions, as the estimates of plume shape can be converted to estimates of solute velocity, which are closely related to the hydraulic properties of interest. Dynamic cross-well radar tomography was also used to image the properties of fractured rock at the U.S. Geological Survey Fractured Rock Hydrology Research Site in Grafton County, New Hampshire (Day-Lewis et al., 2002, 2003). Sequential imaging of the saline plume at this site allowed these researchers to identify preferential fracture flowpaths and estimate the peak tracer arrival times on planes between well pairs used for tomography. Such time-lapse geophysical imaging methods have the potential to provide insight into dynamic flow and transport processes through various coupled inversion methods.

Glossary

Aquifer Properties Characteristics of an aquifer that control the transport of fluid and solutes.

Attenuation Reduction in signal amplitude due to energy loss (because of reflection, dispersion, etc.).

Cokriging Interpolating between a series of measured values based on multiple types of data and the modeled spatial correlation structures of each data type.

Common Midpoint Gather A collection of geophysical data with source and receiver at different locations along a line, each equidistant from a central midpoint. If subsurface reflectors are flat and layered with homogeneous seismic properties in each layer, each trace sampled from the common midpoint gather will be reflected from the same point, which will be directly below the chosen common midpoint.

Converging Iteratively approaching a value or solution with successively smaller changes between iterations.

Global Minimum The smallest value of an objective function for all parameter combinations.

Hydrofacies Lithologies categorized by their flow and transport properties.

Inversion Iterative adjustment of model parameters to minimize the difference between simulated and observed values (e.g., hydraulic head or tracer concentrations).

Non-uniqueness For optimization problems, this condition indicates that multiple sets of parameters provide similar minimum objective values, thus no global minimum exists and the optimal parameter set cannot be determined using the provided data alone.

Normal Moveout Correction (NMO) Adjusting seismic or radar velocity estimates to flatten the parabolic appearance of reflectors due to offset between sources and receivers.

Objective Function A mathematical function that is minimized or maximized (i.e., the residual between measured and simulated head and concentration values for parameter estimation, or total cost for managing aquifer pumping).

Offset Horizontal distance between a source and a receiver.

Optimization Finding parameters that achieve the optimal objective value (minimum or maximum).

Pump Tests or Slug Tests Methods of estimating hydraulic conductivity near a well by pumping water into or out of the well and measuring the hydraulic response. A slug test involves rapid removal or addition of a small volume of water (or a solid slug that displaces water), while a pump test involves continuous pumping of water for a period of time.

Reflection Energy that bounces back from a surface due to a change in physical properties, such as seismic impedance in the case of sound waves.

Refraction Energy that bends according to changes in the velocity of sound waves in adjacent media. The angle can be described according to Snell's law, which is included in the text of this chapter.

Regression Iteratively adjusting the parameters of a model to minimize (or in some cases maximize) the objective value.

Simulation-Optimization Methods These methods estimate optimal parameter values by applying an optimization package, such as one based on nonlinear least-squares regression, to physically

based models of groundwater flow and solute transport to obtain the most desirable system response.

Slowness 1/seismic velocity. This terminology is used because the traveltime equation is solved using slowness.

Solute A dissolved substance (e.g., a contaminant or a tracer in groundwater).

Spatial Moments Statistical representations for the location, spread, and shape of a solute plume. In normalized forms, the zeroth moment defines the total mass, the first moment defines the location of the center of mass, and the second moment defines the spread of the plume.

Stacking Averaging multiple radar or seismic traces collected from the same location to improve the signal-to-noise ratio.

Travelttime Tomography Estimating the seismic velocity structure between wells based on the time for a type of wave (e.g., a compressional- or P-wave) to travel from the source to the receiver.

16.1 Introduction

Hydrogeologic applications often require the estimation of functions from data. For example:

Interpolation From observations of water elevation at a number of wells, draw the contour map of the water table in an aquifer.

Inverse Problems Estimate transmissivity from head observations and other information.

Most applications involve quantities that vary in space but the methods may also apply to quantities that vary in time. A variety of methods have been developed to address such problems in hydrogeology but also elsewhere, interpolation and inverse problems being ubiquitous. Methods include splines (de Boor, 1978), objective analysis (Thiebaux and Pedder, 1987), and the like. There are considerable formal similarities among available methods (Cressie, 1993), but even formally equivalent methods may differ in

emphasis or in how they are applied and understood. The focus here is on *geostatistics* (Matheron, 1971), a practical methodology popular in hydrology and other geophysical sciences.

We will put in a nutshell results useful in solving interpolation and inverse problems. The presentation assumes familiarity with linear algebra and probability theory.

16.2 Preliminaries

16.2.1 Model

A model of variability is essential for the solution of interpolation problems. The unknown function, denoted as z , is a function of variable \mathbf{x} (space and time coordinates). A practical and versatile model is:

$$z(\mathbf{x}) = c(\mathbf{x}) + \underbrace{\sum_{k=1}^p f_k(\mathbf{x})\beta_k}_{\text{deterministic}} + \underbrace{\varepsilon(\mathbf{x})}_{\text{random}} \quad (16.1)$$

where $c(\mathbf{x})$ and $f_1(\mathbf{x}), \dots, f_p(\mathbf{x})$ are known functions. The bold letter \mathbf{x} represents an array of point coordinates. The coefficients β_1, \dots, β_p are unknown. The term $\varepsilon(\mathbf{x})$ is a *random function* with zero expected value.

The *deterministic part*, known also as the *mean*, or *drift*, or the *trend*, represents information about large-scale trends, zones, and other features that can be represented through deterministic functions. This part may include parameters β to be “fitted” from the data. However, a crucial requirement is that the number of β coefficients must be much smaller than the number of observations. The *random part* represents erratic, complex, and usually small-scale variability about which we know too little to model through deterministic functions but enough to describe through statistics (or probabilistic averages). In addition to stating that the expected value of ε is zero, we specify a covariance function, variogram, or generalized covariance function. These statistics furnish information about the variance and the degree of continuity of ε and are needed to obtain estimates with error bars.

16.2.2 Stochastic Approach

The objective is to find a function z , a hydrogeologic variable, given limited information. If nothing were known about z , the search should be over an ensemble that includes all functions. As more information becomes available, many of these functions are eliminated or become less likely. The stochastic approach involves assigning probabilities to these functions that form the ensemble.

Geostatistical estimation is for convenience broken into two phases:

Structural analysis. The search is narrowed down to functions that share certain characteristics, collectively known as *structure*, such as continuity and smoothness, scale of variability, etc. Information about the structure is represented here through equations for the deterministic part and the covariance function of the stochastic part (Equation 16.1).

Conditioning. The search is further narrowed by eliminating functions that are not consistent with observations.

16.2.3 Least Squares

Consider the interpolation problem: estimate the value of z at a location \mathbf{x}_0 from observations at locations $\mathbf{x}_1, \dots, \mathbf{x}_n$. One approach is to fit parameters β_1, \dots, β_p , and $z(\mathbf{x}_0)$ from data $z(\mathbf{x}_1), \dots, z(\mathbf{x}_n)$ using Equation 16.1 and a weighted least squares criterion. Using this intuitive and time-honored approach, one obtains an estimate and its mean square error of estimation. It turns out that formally this is equivalent to the methods of linear geostatistics. However, in implementation, there are considerable

differences between some trend analysis approaches (traditionally associated with least squares fitting) and geostatistics, including:

- Trend analysis attempts to capture the structure of the function through an elaborate deterministic part, whereas the random part is represented as lacking spatial correlation. However, the deterministic part is not well suited to represent information about small-scale and erratic variability. In geostatistics, such variability may be represented through the structure of the random part that is appropriately parameterized through a covariance function.
- In geostatistics, a central issue is the selection of the covariance function or the variogram, which is accomplished in the phase that is known as structural analysis.
- In geostatistics, because one is not really interested in estimating the β coefficients, one may use simplified versions of the covariance function, which is what variograms and generalized covariance functions are. One can also use algorithms that are well suited for interpolation.

16.3 Ordinary Kriging

16.3.1 Interpolation

In many applications, it is appropriate to adopt the simplest and most conservative representation of the mean, which is as an unknown constant, that is, referring to Equation 16.1,

$$z(\mathbf{x}) = \beta + \varepsilon(\mathbf{x}) \quad (16.2)$$

The information about the function structure is described only through the *variogram* (used instead of the traditional term *semivariogram*) defined as:

$$\gamma(\mathbf{x} - \mathbf{x}') = \frac{1}{2} E[(z(\mathbf{x}) - z(\mathbf{x}'))^2] \quad (16.3)$$

where E denotes a probabilistic average or expected value. *Ordinary kriging*, the most common geostatistical method, gives an estimate and its mean square error of estimation of z at any location \mathbf{x}_0 given the variogram γ and n observations $z(\mathbf{x}_1), z(\mathbf{x}_2), \dots, z(\mathbf{x}_n)$. To infer the unmeasured value of z at a location \mathbf{x}_0 , a *linear estimator* is adopted, that is, formula:

$$\hat{z}_0 = \sum_{i=1}^n \lambda_i z(\mathbf{x}_i) \quad (16.4)$$

The weights $\lambda_1, \dots, \lambda_n$ are chosen based on the requirements of (1) *unbiasedness*, that is, the expected value of the estimation error $\hat{z}_0 - z(\mathbf{x}_0)$ must be zero and (2) *best* or minimum variance estimation, that is, the expected value of the square error must be as small as possible. These requirements result in a system of $n + 1$ linear equations with $n + 1$ unknowns, known as the kriging system:

$$\begin{aligned} - \sum_{j=1}^n \lambda_j \gamma(\mathbf{x}_i - \mathbf{x}_j) + v &= -\gamma(\mathbf{x}_i - \mathbf{x}_0), \quad i = 1, 2, \dots, n \\ \sum_{j=1}^n \lambda_j &= 1 \end{aligned} \quad (16.5)$$

where ν is a Lagrange multiplier. The mean square error of estimation is given by the formula:

$$\sigma_0^2 = E[(\hat{z}_0 - z(\mathbf{x}_0))^2] = -\nu + \sum_{j=1}^n \lambda_j \gamma(\mathbf{x}_j - \mathbf{x}_0) \quad (16.6)$$

Often, the reliability of the estimate is presented in the form of a 95% *confidence interval*. This is the interval that contains the actual value of $z(\mathbf{x}_0)$ with probability 0.95. Under normality, that is, Gaussian distribution of the estimation errors (a common implicit assumption in linear estimation), the confidence interval is approximately $[\hat{z}_0 - 2\sigma_0, \hat{z}_0 + 2\sigma_0]$.

In the *global neighborhood* approach, all observations are used. In the *local neighborhood* approach, one uses a subset of all observations; one may use a fixed number of observations that are closest to the point \mathbf{x}_0 , all observations within a certain radius, or a combination of these strategies. The global neighborhood approach is recommended except in special cases such as when there is a large number of observations. If the local neighborhood approach is used for interpolation, care should be taken to avoid introducing inadvertent discontinuities in the estimate.

16.3.2 Function Estimate

An expression for the estimate at any point \mathbf{x} that is useful in interpolation and graphing a function is the following:

$$\hat{z}(\mathbf{x}) = - \sum_{i=1}^n \gamma(\mathbf{x} - \mathbf{x}_i) \xi_i + \hat{\beta} \quad (16.7)$$

where the ξ coefficients and $\hat{\beta}$ are found from the solution of a single system of $n+1$ equations with $n+1$ unknowns:

$$\begin{aligned} - \sum_{j=1}^n \gamma(\mathbf{x}_i - \mathbf{x}_j) \xi_j + \hat{\beta} &= z(\mathbf{x}_i), \quad \text{for } i = 1, \dots, n \\ \sum_{j=1}^n \xi_j &= 0 \end{aligned} \quad (16.8)$$

This approach is useful when performing kriging on a fine grid, and expression 16.7 reveals how the form of the estimate depends on the form of the variogram.

The conditional covariance function R_c (i.e., the covariance function given the data) is not stationary and may be obtained explicitly as follows:

1. Form matrix of coefficients of system 16.8

$$\begin{bmatrix} Q & X \\ X^T & 0 \end{bmatrix} \quad (16.9)$$

where Q is matrix n by n with $Q_{ij} = -\gamma(\mathbf{x}_i - \mathbf{x}_j)$, X is n by 1 with $X_i = 1$, and exponent T denotes matrix transpose.

2. Compute matrix inverse

$$\begin{bmatrix} Q & X \\ X^T & 0 \end{bmatrix}^{-1} = \begin{bmatrix} P & a \\ a^T & B \end{bmatrix}$$

where P is n by n , a is n by 1, and B is a scalar.

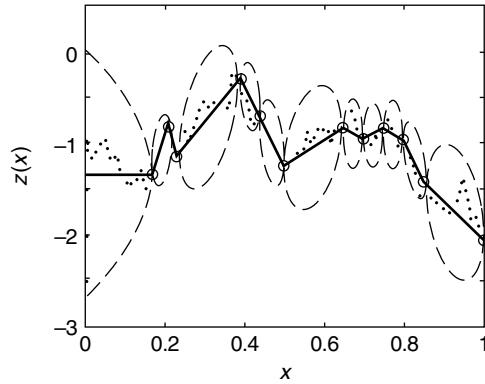

FIGURE 16.1 Best estimate (solid line), 95% confidence interval (dashed lines), vs. actual (fine dotted line) z function.

3. The conditional covariance function is given from:

$$R_c(\mathbf{x}, \mathbf{x}') = -\gamma(\mathbf{x} - \mathbf{x}') - \sum_{i=1}^n \sum_{j=1}^n \gamma(\mathbf{x} - \mathbf{x}_i) P_{ij} \gamma(\mathbf{x}_j - \mathbf{x}') - B + \sum_{j=1}^n a_j \gamma(\mathbf{x}_j - \mathbf{x}') + \sum_{i=1}^n \gamma(\mathbf{x} - \mathbf{x}_i) a_i \quad (16.10)$$

The mean square error is given from this formula by setting $\mathbf{x}' = \mathbf{x}$.

For illustration, the true function $z(\mathbf{x})$, the best estimate $\hat{z}(\mathbf{x})$, and the 95% confidence interval are shown in Figure 16.1, for a hypothetical case of a function of one variable. The data are indicated by small open circles and the variogram $\gamma(h) = 1.4$ h was used for estimation. The best estimate reproduces the observations and is a simplified version of the actual function. The 95% confidence interval is indicative of the potential error (difference between estimate and actual function).

16.3.3 Conditional Realizations

It is often useful to generate a large number of equally likely (given the available information) possible solutions perform probabilistic risk analysis. These solutions are called *conditional realizations* or conditional sample functions or conditional simulations. The average of the ensemble of all conditional realizations is equal to the best estimate and the covariance is equal to the conditional covariance function. We focus on the prevalent case of Gaussian realizations.

16.3.3.1 Point Simulation

Step 1. Generate an unconditional realization $z(\mathbf{x}; k)$, with zero mean, consistent with the assumed variogram (where the index k is used to remind that there are many possible solutions). This is a technical issue (Mantoglou and Wilson, 1982; Tompson et al., 1989; Dykaar and Kitanidis, 1992; Gutjahr et al., 1994; Robin et al., 1993) that goes beyond the scope of this chapter.

Step 2. Generate a conditional realization $z_c(\mathbf{x}_0; k)$ at a given point \mathbf{x}_0 ,

$$z_c(\mathbf{x}_0; k) = z(\mathbf{x}_0; k) + \sum_{j=1}^n \lambda_j (z(\mathbf{x}_j) - z(\mathbf{x}_j; k)) \quad (16.11)$$

where $z(\mathbf{x}_i)$ is actual observation and the λ coefficients are the same as that were used to obtain the best estimate.

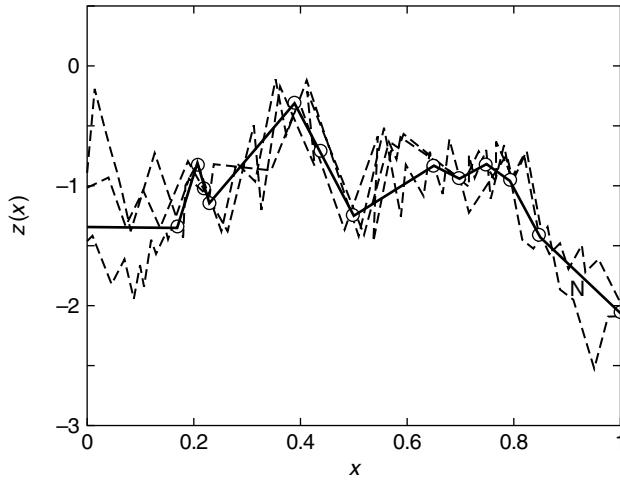

FIGURE 16.2 Three conditional realizations (discontinuous lines) and the best estimate (solid line).

16.3.3.2 Function Simulation

The functional form of $z_c(\mathbf{x}; k)$ is developed similarly as the best estimate in Section 16.3.2. First, generate an unconditional realization $z(\mathbf{x}; k)$, with zero mean. Then

$$z_c(\mathbf{x}; k) = - \sum_{j=1}^n \gamma(\mathbf{x} - \mathbf{x}_j) \xi_j + \hat{\beta} + z(\mathbf{x}; k) \quad (16.12)$$

where the ξ and $\hat{\beta}$ coefficients are found from system:

$$\begin{aligned} - \sum_{j=1}^n \gamma(\mathbf{x}_i - \mathbf{x}_j) \xi_j + \hat{\beta} &= z(\mathbf{x}_i) - z(\mathbf{x}_i; k), \quad \text{for } i = 1, \dots, n \\ \sum_{j=1}^n \xi_j &= 0 \end{aligned} \quad (16.13)$$

For illustration, three conditional realizations (out of many possible) of function $z(\mathbf{x})$ are shown together with the best estimate $\hat{z}(\mathbf{x})$ in Figure 16.2 for the same case as Figure 16.1. The conditional realizations have the structure described by the variogram and also reproduce the observations. Each conditional realization is equally likely to be the sought-after function. The average of all realizations is the estimate, which is a smooth function as shown in Figure 16.2. At any point \mathbf{x} , 95% of the conditional realizations should fall within the confidence interval (see Cressie, 1993; Kitanidis, 1996).

16.4 Variogram

16.4.1 Variogram Model

To perform ordinary kriging, an expression for the variogram is needed. In the isotropic case, the variogram γ is a function of separation distance only, $h = \|\mathbf{x} - \mathbf{x}'\|$, not the direction of the separation vector $\mathbf{x} - \mathbf{x}'$

TABLE 16.1 Common Variogram Models

Model	Expression, $\gamma(h)$	Parameters
Gaussian	$\sigma^2 \left(1 - \exp \left(-\frac{h^2}{L^2} \right) \right)$	$\sigma^2 > 0, L > 0$
Exponential	$\sigma^2 \left(1 - \exp \left(-\frac{h}{\ell} \right) \right)$	$\sigma^2 > 0, \ell > 0$
Spherical	$\begin{cases} \left(\frac{3}{2} \frac{h}{\alpha} - \frac{1}{2} \frac{h^3}{\alpha^3} \right) \sigma^2, & \text{for } 0 \leq h \leq \alpha \\ \sigma^2, & \text{for } h > \alpha \end{cases}$	$\sigma^2 > 0, \alpha > 0$
Nugget	$\begin{cases} C_0, & h > 0 \\ 0, & h = 0 \end{cases}$	$C_0 > 0$
Linear	$\theta \cdot h$	$\theta > 0$
Power	$\theta \cdot h^s$	$\theta > 0, 2 > s > 0$

between locations \mathbf{x} and \mathbf{x}' . For example, in three dimensions,

$$\mathbf{x} = \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \mathbf{x}_3 \end{bmatrix}, \quad \mathbf{x}' = \begin{bmatrix} \mathbf{x}'_1 \\ \mathbf{x}'_2 \\ \mathbf{x}'_3 \end{bmatrix}, \quad h = \sqrt{(\mathbf{x}_1 - \mathbf{x}'_1)^2 + (\mathbf{x}_2 - \mathbf{x}'_2)^2 + (\mathbf{x}_3 - \mathbf{x}'_3)^2} \quad (16.14)$$

We will consider the isotropic case first.

The variogram model must satisfy some mathematical requirements. In practice, the expression for the variogram is formed by combining a small number of simple mathematically acceptable expressions. Table 16.1 contains the most used isotropic variogram models.

By adding variograms from Table 16.1, one can obtain other mathematically acceptable variograms, for example, combining the linear and nugget effect variograms:

$$\gamma(h) = \begin{cases} C_0 + \theta h & h > 0 \\ 0, & h = 0 \end{cases} \quad (16.15)$$

with two parameters, $C_0 \geq 0$ and $\theta \geq 0$. This way, one can construct a model that adequately and parsimoniously (i.e., without unnecessary terms and parameters) represents information about the structure of z .

In many applications, due to geologic stratification, hydrodynamic mechanisms, and the like, the spatial structure may depend on direction as well as on distance. The simplest approach (Cressie, 1993; Kitanidis, 1997, describe more general cases) is to align the axes with the principal axes of anisotropy (e.g., parallel and perpendicular to layering) and to use as h :

$$h = \sqrt{\left(\frac{\mathbf{x}_1 - \mathbf{x}'_1}{l_1} \right)^2 + \left(\frac{\mathbf{x}_2 - \mathbf{x}'_2}{l_2} \right)^2 + \left(\frac{\mathbf{x}_3 - \mathbf{x}'_3}{l_3} \right)^2}$$

where l_1, l_2, l_3 are length parameters.

16.4.2 Variogram Selection

The variogram represents information about the structure of the function z and consequently should be consistent with (1) prior information and (2) the observations.

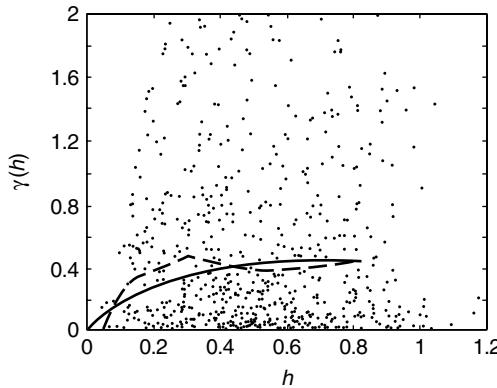

FIGURE 16.3 Raw (dots), experimental (dashed line), and model (solid line) variograms.

Prior information, sometimes referred to as “soft data,” is knowledge about the unknown that is additional to the observations. Prior information includes the experience and judgment of the analyst. In any specific application, there is always some prior information to the extent that even without observations one should be able to judge whether a variogram makes sense. Prior information is also important because certain features of the variogram cannot be established from the observations, no matter how dense. For example, if prior information suggests that function z should be smooth, then the Gaussian variogram (see Table 16.1) may be appropriate. If one expects that due to function “nonstationarity” (as when the likelihood of change in the hydrogeologic environment or geochemical regime increases rapidly with the distance) the estimate should not depend on measurements far away, one should choose a linear variogram. Certain decisions are easy to justify in the context of specific applications but, because here we deal with general methodologies, we will focus on the estimation of the variogram from data.

The process of developing a variogram from the data involves a number of steps and iterations. A variogram is selected tentatively based on an examination of the *experimental variogram*, as well as other information. The variogram is then calibrated (if it includes adjustable parameters) and tested on the basis of observations (or “hard data” or just “data”) using *residuals*.

16.4.3 Experimental Variogram

For all $n(n - 1)/2$ measurement pairs, plot the square difference $\frac{1}{2}[z(\mathbf{x}_i) - z(\mathbf{x}'_i)]^2$ against the separation distance $h = \|\mathbf{x}_i - \mathbf{x}'_i\|$. The plotting produces a cloud of points known as the *raw variogram*; the *experimental variogram* is a relatively regular line through this scatter plot (see Figure 16.3).

In the prevalent approach, the axis of separation distance is divided into consecutive intervals: the k th interval is denoted $[h_k^\ell, h_k^u]$ and contains N_k pairs of measurements $[z(\mathbf{x}_i), z(\mathbf{x}'_i)]$.

Compute:

$$\hat{\gamma}(h_k) = \frac{1}{2N_k} \sum_{i=1}^{N_k} [z(\mathbf{x}_i) - z(\mathbf{x}'_i)]^2 \quad (16.16)$$

where index i refers to a pair of measurements $z(\mathbf{x}_i)$ and $z(\mathbf{x}'_i)$ which meet the requirement

$$h_k^\ell < \|\mathbf{x}_i - \mathbf{x}'_i\| \leq h_k^u \quad (16.17)$$

The k th interval is represented by a single point h_k . Take h_k equal to the average value,

$$h_k = \frac{1}{N_k} \sum_{i=1}^{N_k} \|\mathbf{x}_i - \mathbf{x}'_i\| \quad (16.18)$$

Next, these points $[h_k, \hat{\gamma}(h_k)]$ are connected to form the experimental variogram (see Figure 16.3). Numerous modifications to this basic approach have been proposed to improve its robustness or to account for other effects (Cressie, 1993).

The appearance of the experimental variogram is affected by the choice of intervals. By choosing longer intervals, one averages over more points in each interval thus reducing jaggedness in the experimental variogram; however, one may sacrifice resolution, that is, “straighten” the variogram. One must use judgment in selecting the intervals to achieve reasonable trade-offs between the objectives of reducing jaggedness and preserving resolution. It usually suffices to use three to six intervals, and it makes sense to use shorter intervals where the points of the raw variogram are less spread out (in the vertical direction).

An experimental variogram that depends on orientation and is thus useful in identifying anisotropy is the so-called directional variogram (Journel and Huijbregts, 1978).

The experimental variogram, though it may provide a reasonable preliminary estimate of the variogram as shown in Figure 16.3, has its limitations (Armstrong, 1984) and should not monopolize the analysis. The selection of the variogram to be used in kriging should rely on the examination of the residuals.

16.4.4 Residuals

Arrange the n measurements in a given sequence. Calculate the kriging estimate of z at the second point, \mathbf{x}_2 , given only the first measurement, \mathbf{x}_1 : $\hat{z}_2 = z(\mathbf{x}_1)$ and $\sigma_2^2 = 2\gamma(\mathbf{x}_1 - \mathbf{x}_2)$. Calculate the actual error.

$$\delta_2 = z(\mathbf{x}_2) - \hat{z}_2 \quad (16.19)$$

and normalize by the standard error

$$\varepsilon_2 = \frac{\delta_2}{\sigma_2} \quad (16.20)$$

Use the same procedure to construct the other residuals. For the k th measurement location, estimate through kriging the value of z using only the first $k - 1$ measurements and normalize by the standard error. Thus,

$$\delta_k = z(\mathbf{x}_k) - \hat{z}_k, \quad \text{for } k = 2, \dots, n \quad (16.21)$$

$$\varepsilon_k = \frac{\delta_k}{\sigma_k}, \quad \text{for } k = 2, \dots, n \quad (16.22)$$

Using the actual data, the variogram model, and kriging, one thus computes the actual (or *experimental*) residuals, which are $n - 1$ δ or ε values.

According to the probabilistic model, the ε residuals satisfy:

$$E[\varepsilon_k] = 0, \quad k = 2, \dots, n \quad (16.23)$$

$$E[\varepsilon_k \varepsilon_\ell] = \begin{cases} 1, & \text{if } k = \ell, \\ 0, & \text{if } k \neq \ell, \end{cases} \quad k, \ell = 2, \dots, n \quad (16.24)$$

and are called *orthonormal* (Kitanidis, 1991, 1997).

16.4.5 Variogram Testing

Model validation means testing the agreement of the model with the data. In simple terms, a validation test is like an experiment with the following steps:

1. Predict the outcome to the experiment using the theory
2. Observe the actual outcome of the experiment
3. Compare the predicted and observed outcomes

The following tests are suggested to evaluate the model.

16.4.5.1 Q_1 Statistic

Experiment: Compute the average of the orthonormal residuals:

$$Q_1 = \frac{1}{n-1} \sum_{k=2}^n \varepsilon_k \quad (16.25)$$

Model Prediction: The model predicts that Q_1 is normally distributed with mean 0 and variance $1/(n-1)$.

Experimental Observation: Measure the experimental value of Q_1 (from the actual data).

Compare Model with Experiment: Agreement between the model and the data means that the experimental value of Q_1 is close to zero.

A reasonable rule is to reject the model if:

$$|Q_1| > \frac{2}{\sqrt{n-1}} \quad (16.26)$$

This rule involves a 5% probability that the correct model may be rejected.

16.4.5.2 Q_2 Statistic

The same procedure is followed with

$$Q_2 = \frac{1}{n-1} \sum_{k=2}^n \varepsilon_k^2 \quad (16.27)$$

Agreement between model and data means that the experimental value of Q_2 is near 1.

For $n > 40$, one may use (see Kitanidis, 1997, for procedure for smaller n): reject the model if

$$|Q_2 - 1| > 2.8/\sqrt{n-1} \quad (16.28)$$

16.4.5.3 Normality

The ε residuals should follow an approximately Gaussian distribution, because BLUE method makes most sense when estimation errors are approximately normal. Plotting the experimental $\varepsilon_2, \dots, \varepsilon_n$ on normal probability paper one may visually detect departures from normality, or one may perform goodness-of-fit tests (e.g., Shapiro and Wilk, 1965).

16.4.5.4 No Correlation

Finally, the experimental ε residuals should be uncorrelated, that is, they should have the pure nugget effect variogram,

$$\gamma(\mathbf{x}_i - \mathbf{x}_j) = \begin{cases} 1, & \text{for } \mathbf{x}_i \neq \mathbf{x}_j \\ 0, & \text{for } \mathbf{x}_i = \mathbf{x}_j \end{cases} \quad (16.29)$$

One may thus perform a variogram analysis and test the hypothesis that the experimental variogram of $\varepsilon_2, \dots, \varepsilon_n$ is indeed this γ . One can also plot the signs of the residuals seeking regular patterns that would contradict the model, which predicts that the residuals are uncorrelated.

16.4.6 Variogram Calibration

A measure of how close the model reproduces or fits the data is given by:

$$cR = Q_2 \exp \left(\frac{1}{n-1} \sum_{i=2}^n \ell n(\sigma_i^2) \right) \quad (16.30)$$

where σ_i^2 was defined in Section 16.4.4.

This quantity and Q_2 can be used to calibrate a variogram, that is, to estimate its parameters (Kitanidis, 1991). Consider, for example, that the model of Equation 16.15 has been selected but its parameters C_0 and θ need to be estimated from the data. Select the values $C_0 \geq 0$ and $\theta \geq 0$ that minimize

$$cR = \exp \left(\frac{1}{n-1} \sum_{i=2}^n \ell n(\sigma_i^2) \right) \quad (16.31)$$

subject to the constraint

$$\frac{1}{n-1} \sum_{i=2}^n \varepsilon_i^2 = 1 \quad (16.32)$$

This method is related to more general methods of statistics (Rao, 1973; Corbeil and Searle, 1976; Kitanidis, 1983). Also, such a parameter estimation method is sometimes referred to as a “cross-validation” method.

16.4.7 Nonnegativity

Quite often z , the function of interest, is known to be nonnegative. For example, z may represent transmissivity or solute concentration. However, kriging does not account for this nonnegativity requirement. If the 95% confidence interval turns out unrealistic because it includes negative values, then the nonnegativity constraint needs to be enforced.

The simplest approach is to make a one-to-one variable transformation. The prevalent transformation is the logarithmic:

$$y(\mathbf{x}) = \ln(z(\mathbf{x})) \quad (16.33)$$

Then, we proceed to perform kriging on the transformed variable. After the result is obtained, we back-transform the best estimate and the 95% confidence intervals or the conditional realizations. The results are guaranteed to be nonnegative. Issues of interpretation are discussed in Kitanidis (1997).

16.5 Kriging Variants

Consider estimation when z conforms to the general model of Equation 16.1. This formulation allows us to account for structural information by appropriately selecting the deterministic part in Equation 16.1,

as the following two examples illustrate:

Example 16.1

If $z(\mathbf{x})$ is the (depth averaged) piezometric head in an aquifer where a linear trend surface is known to exist,

$$f_1 = 1, \quad f_2 = x_1, \quad f_3 = x_2 \quad (16.34)$$

where x_1 and x_2 are the two Cartesian coordinates of location \mathbf{x} .

Example 16.2

If z represents log conductivity and the domain includes two zones with different hydro-geologic properties, interzonal differences in the mean are accounted for through

$$f_1 = \begin{cases} 1, & \text{in zone 1,} \\ 0, & \text{in zone 2,} \end{cases} \quad f_2 = \begin{cases} 0, & \text{in zone 1} \\ 1, & \text{in zone 2} \end{cases} \quad (16.35)$$

The covariance function $R(\mathbf{x} - \mathbf{x}')$ of the random part is defined as

$$R(\mathbf{x} - \mathbf{x}') = E[\varepsilon(\mathbf{x})\varepsilon(\mathbf{x}')] \quad (16.36)$$

The estimate of z at location \mathbf{x}_0 is

$$\hat{z}_0 = c(\mathbf{x}_0) + \sum_{i=1}^n \lambda_i(z(\mathbf{x}_i) - c(\mathbf{x}_i)) \quad (16.37)$$

where the coefficients are found (using the previously mentioned unbiasedness and best requirements) from the kriging system of $n + p$ linear equations with $n + p$ unknowns:

$$\begin{aligned} \sum_{j=1}^n R(\mathbf{x}_i - \mathbf{x}_j) \lambda_j + \sum_{k=1}^p f_k(\mathbf{x}_i) v_k &= R(\mathbf{x}_i - \mathbf{x}_0), \quad i = 1, \dots, n \\ \sum_{j=1}^n f_k(\mathbf{x}_j) \lambda_j &= f_k(\mathbf{x}_0), \quad k = 1, \dots, p \end{aligned} \quad (16.38)$$

where v_1, \dots, v_p are Lagrange multipliers. The mean square error is

$$E[(\hat{z}_0 - z(\mathbf{x}_0))^2] = - \sum_{k=1}^p f_k(\mathbf{x}_0) v_k - \sum_{i=1}^n \lambda_i R(\mathbf{x}_i - \mathbf{x}_0) + R(0) \quad (16.39)$$

From the general case, the following special cases are obtained:

Ordinary Kriging: When $c(\mathbf{x}) = 0, p = 1, f_1 = 1$. The ordinary kriging equations are obtained if we set $-\gamma$ in place of R in Equation 16.38 and Equation 16.39.

Kriging with External Drift and Simple Kriging: When $c(\mathbf{x})$ is given and there are no terms with unknown β coefficients. The kriging system is n equations with n unknowns and the v coefficients vanish. The even more special case of $c(\mathbf{x}) = \text{constant}$, is known as simple kriging.

Universal Kriging: When $c(\mathbf{x})$ vanishes and there are p unknown drift coefficients. This is also equivalent to kriging with generalized covariances because one needs a simplified version of the actual covariance function (in ordinary kriging, one can use $-\gamma$ instead of the covariance function). Issues of covariance estimation are discussed in Kitanidis (1993), and also the method of Section 16.7.3 can be applied.

16.6 Cokriging

Consider the case of N correlated functions, $z_1(\mathbf{x}), \dots, z_N(\mathbf{x})$, such as log-transmissivity, head, and accretion rate. One may want to estimate one of these functions, say $z_1(\mathbf{x})$, from observations of $z_1(\mathbf{x}), \dots, z_N(\mathbf{x})$ functions. The BLUE approach, known as *cokriging*, is similar to the one in kriging: after describing the joint structure of the N functions, the best estimate is a linear function of the data with coefficients determined from the requirements of unbiasedness and minimum variance.

The joint structure is described by:

Mean functions:

$$E[z_k(\mathbf{x})] = m_k(\mathbf{x}), \quad k = 1, \dots, N \quad (16.40)$$

Each of the mean functions may be represented as the deterministic part in Equation 16.1.

Covariance (or autocovariance) functions:

$$E[(z_k(\mathbf{x}) - m_k(\mathbf{x}))(z_k(\mathbf{x}') - m_k(\mathbf{x}'))] = R_{kk}(\mathbf{x}, \mathbf{x}'), \quad k = 1, \dots, N \quad (16.41)$$

Cross-covariance functions:

$$E[(z_k(\mathbf{x}) - m_k(\mathbf{x}))(z_\ell(\mathbf{x}') - m_\ell(\mathbf{x}'))] = R_{k\ell}(\mathbf{x}, \mathbf{x}'), \quad \text{for } k, \ell = 1, \dots, N \text{ and } k \neq \ell \quad (16.42)$$

Mean and autocovariance functions describe the structure of individual functions. Cross-covariance functions describe the interdependence of pairs of functions.

The cokriging equations are incorporated into the general equations of the next section. Determination of the model (structural analysis) for a set of functions is a more advanced topic that cannot be covered here in detail. Nevertheless, the next section outlines a method for estimation of parameters of autocovariance and cross-covariance functions and examples of application of cokriging are given in Dagan (1985) and Hoeksema et al. (1989).

16.7 Generalized Linear Estimation Equations

All linear kriging and cokriging equations can be written in a unified way, using matrix notation, as follows.

16.7.1 Model

$$\mathbf{y} = \mathbf{c} + \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon} \quad (16.43)$$

where \mathbf{y} is the $n \times 1$ measurement vector, \mathbf{c} is known $n \times 1$ vector, \mathbf{X} is a known $n \times p$ matrix, $\boldsymbol{\beta}$ is a $p \times 1$ vector of parameters (“drift coefficients” in kriging), and $\boldsymbol{\epsilon}$ is a random vector with zero mean and covariance matrix $\mathbf{Q}_{yy}(\boldsymbol{\theta})$ (a function of some covariance parameters). Also,

$$\mathbf{s} = \mathbf{c}_s + \mathbf{X}_s\boldsymbol{\beta} + \boldsymbol{\epsilon}_s \quad (16.44)$$

where \mathbf{s} is the $m \times 1$ vector of unknowns, \mathbf{c}_s is known $m \times 1$ vector, \mathbf{X}_s is a known $m \times p$ matrix, and $\boldsymbol{\epsilon}_s$ is a random vector with zero mean, covariance matrix $\mathbf{Q}_{ss}(\boldsymbol{\theta})$, and cross-covariance to $\boldsymbol{\epsilon}$ that is $\mathbf{Q}_{sy}(\boldsymbol{\theta})$.

16.7.2 Blue

$$\hat{s} = c_s + \Lambda(y - c) \quad (16.45)$$

where:

$$\begin{bmatrix} Q_{yy} & X \\ X^T & 0 \end{bmatrix} \begin{bmatrix} \Lambda^T \\ M \end{bmatrix} \begin{bmatrix} Q_{ys} \\ X_s^T \end{bmatrix} \quad (16.46)$$

The estimation error covariance matrix is:

$$E[(\hat{s} - s)(\hat{s} - s)^T] = -X_s M + Q_{ss} - Q_{sy} \Lambda^T \quad (16.47)$$

16.7.3 Parameter Estimation

Select covariance parameters θ that minimize:

$$\left(|Q_{yy}| |X^T Q_{yy}^{-1} X| |X^T X|^{-1} \right)^{1/(n-p)} \quad (16.48)$$

while at the same time satisfying:

$$Q_2 = \frac{1}{n-p} y^T \left(Q_{yy}^{-1} - Q_{yy}^{-1} X (X^T Q_{yy}^{-1} X)^{-1} X^T Q_{yy}^{-1} \right) y = 1 \quad (16.49)$$

where $| |$ applied on a square matrix indicates matrix determinant. Note that this method, which is a generalization of the method of minimizing cR in ordinary kriging, is appropriate for finding the parameters of generalized covariance functions and variograms (which are needed in kriging or cokriging) and not necessarily of ordinary covariance functions (see Kitanidis, 1993).

16.8 Inverse Problems

16.8.1 Definition

To be successful in modeling groundwater flow and transport, one needs to obtain representative values of the required parameters, such as transmissivity, storage coefficient, conductivity, dispersivity, retardation factor, reaction rate, and so on. The task is particularly difficult when a parameter is known to vary in space but is not measured directly. For example, conductivity (or transmissivity) varies over the flow domain, but there are not enough direct observations to resolve its spatial variability.

The inverse problem of groundwater modeling is defined broadly as the estimation of parameters from observations of the system response. The quintessential problem is the determination of conductivity from observations of the hydraulic head. Usually, this goal is achieved through systematic adjustment of parameter values to match the observations (as illustrated in Carrera and Neuman, 1986; Cooley et al., 1986), hence the term *history matching* is also used. Many approaches have been proposed, and the literature on the subject is vast. There have been several literature reviews (Yeh, 1986; Carrera, 1987; Ginn and Cushman, 1990) and a book devoted to the subject (Sun, 1994).

In this chapter, the inverse problem is defined as:

Estimation of at least one spatial function $z(\mathbf{x})$ from observations of other quantities related to z through a mathematical model as well as direct measurements of z .

The method to be presented is an extension of the geostatistical methods for the solution of the interpolation problem. We will examine exclusively static estimation problems (where all observations are given at the same time, as opposed to methods where data are taken into account as they become available). The justification for the approach that follows is given in Kitanidis (1995).

16.8.2 Methodology

Consider that we want to estimate parameter $z(\mathbf{x})$, a spatial function such as the log conductivity. The function is represented through the model of Equation 16.1. After discretization, $z(\mathbf{x})$ is represented through an n by 1 vector \mathbf{s} . The mean of \mathbf{s} is

$$E[\mathbf{s}] = \mathbf{X}\boldsymbol{\beta} \quad (16.50)$$

where \mathbf{X} is a known $n \times p$ matrix, $\boldsymbol{\beta}$ are p unknown drift coefficients. Furthermore, \mathbf{s} has a covariance matrix

$$E[(\mathbf{s} - \mathbf{X}\boldsymbol{\beta})(\mathbf{s} - \mathbf{X}\boldsymbol{\beta})^T] = \mathbf{Q}(\theta) \quad (16.51)$$

that is considered a known function of parameters θ . If there are two or more spatially variable parameters that need to be estimated (such as log transmissivity and storage coefficient), this case is included in this formulation by considering \mathbf{s} as the aggregation of all spatially variable parameters. The objective is to find the best estimate of \mathbf{s} and to evaluate the error of estimation.

There may also be other unknown parameters, such as boundary conditions or the intensity of sources or sinks, but these will not be included here because we focus on the estimation of the spatial process and its structural parameters. The $\boldsymbol{\beta}$ and θ parameters are treated as unknown constants and are supposed to be few in number, certainly far fewer than the observations. The observations are related to the unknown spatial process and this relation is denoted through:

$$\mathbf{y} = \mathbf{h}(\mathbf{s}) + \mathbf{v} \quad (16.52)$$

where \mathbf{y} is the $m \times 1$ vector of observations. The observation error \mathbf{v} is random with normal distribution, zero mean, and covariance matrix \mathbf{R} that is fixed or a known function of an expanded set of parameters θ . The standard deviations of the measurement errors, which are the square root of the diagonal elements of \mathbf{R} , define how closely the observations should be reproduced.

An intuitive approach is to minimize the weighted least squares criterion:

$$(z - \mathbf{h}(\mathbf{s}))^T \mathbf{R}^{-1} (z - \mathbf{h}(\mathbf{s})) + (\mathbf{s} - \mathbf{X}\boldsymbol{\beta})^T \mathbf{Q}^{-1} (\mathbf{s} - \mathbf{X}\boldsymbol{\beta}) \quad (16.53)$$

where the first term represents the objective of reproducing the observations and the second term the objective of being consistent with the structure. The minimization should be with respect to \mathbf{s} and $\boldsymbol{\beta}$ vectors. The covariance parameters are to be imposed by the analyst based on prior information or inferred from the data through a process of cross-validation.

This approach is systematized into the two phases of a geostatistical approach:

1. Structural analysis, where the form of the mean and the covariance function are selected and the structural parameters are estimated.
2. Conditioning on the data, where vector \mathbf{s} is estimated.

The implementation of the second step is an iterative cokriging approach. We start with an estimate of \tilde{s} and we improve at each iteration. Find the derivative of \mathbf{h} about s at \tilde{s} :

$$\mathbf{H} = \frac{\partial \mathbf{h}}{\partial s} \Big|_{s=\tilde{s}} \quad (16.54)$$

Then, assuming that the actual s is close to \tilde{s} , approximate

$$\mathbf{y} = \mathbf{h}(\tilde{s}) + \mathbf{H}(s - \tilde{s}) + \mathbf{v} \quad (16.55)$$

Define

$$\Sigma = \mathbf{H} \mathbf{Q} \mathbf{H}^T + \mathbf{R}$$

Solve the cokriging system of equations:

$$\begin{bmatrix} \Sigma & \mathbf{H} \mathbf{X} \\ (\mathbf{H} \mathbf{X})^T & 0 \end{bmatrix} \begin{bmatrix} \Lambda^T \\ \mathbf{M} \end{bmatrix} = \begin{bmatrix} \mathbf{H} \mathbf{Q} \\ \mathbf{X}^T \end{bmatrix} \quad (16.56)$$

where Λ is an $m \times n$ matrix of coefficients and \mathbf{M} is a $p \times n$ matrix of multipliers. Then, the cokriging estimate is:

$$\hat{s} = \Lambda(\mathbf{y} - \mathbf{h}(\tilde{s}) + \mathbf{H}\tilde{s}) \quad (16.57)$$

If \hat{s} is practically equal to \tilde{s} , the algorithm has converged and the covariance matrix of estimation is

$$\mathbf{V} = -\mathbf{X} \mathbf{M} + \mathbf{Q} - \mathbf{Q} \mathbf{H}^T \Lambda^T \quad (16.58)$$

Otherwise \tilde{s} is set equal to \hat{s} and the procedure is repeated. Examples are found in Kitanidis (1995) and Yeh et al. (1996).

The cokriging equations assume that the covariance parameters, θ , are known and in some approaches are not estimated in any formal way. They can be estimated (Kitanidis, 1995) by minimizing the criterion:

$$\begin{aligned} L = & \ln |\Sigma| + \ln |\mathbf{X}^T \mathbf{H}^T \Sigma^{-1} \mathbf{H} \mathbf{X}| + (\mathbf{y} - \mathbf{h}(\hat{s}) + \mathbf{H}\hat{s})^T \\ & \times (\Sigma^{-1} - \Sigma^{-1} \mathbf{H} \mathbf{X} (\mathbf{X}^T \mathbf{H}^T \Sigma^{-1} \mathbf{H} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{H}^T \Sigma^{-1}) (\mathbf{y} - \mathbf{h}(\hat{s}) + \mathbf{H}\hat{s}) \end{aligned} \quad (16.59)$$

This approach is essentially a restricted maximum likelihood or cross-validation methodology. A variation to this approach is to minimize the sum of the first two terms subject to the constraint that the third term is equal to 1, which is the method of Section 12.7.3. The two approaches yield similar or identical results.

After the covariance parameters are updated, one may need to repeat the iterative procedure of estimating s .

The error computed in the iterative cokriging or “quasilinear” approach is valid provided that the final estimation error is small. In small-variance cases (Kitanidis and Vomvoris, 1983; Hoeksema and Kitanidis, 1984, 1985, 1989; Dagan, 1985; Rubin and Dagan, 1987a; Wagner and Gorelick, 1989), the observation Equation 16.52 is linearized only once, about the mean (deterministic part). Sometimes, Monte Carlo methods can be used instead of the usual linearization (Hoeksema and Clapp, 1990). The approach is effectively the same with the method of Carrera and Neuman (1986) in the conditioning step but differs in the step of estimating θ . Conceptually and in simple terms, the relation of this approach to the least squares approach (Cooley and Naff, 1990, for example) is that in least squares the spatial variability is accounted for by including sufficient terms in the deterministic part; the covariance matrix \mathbf{Q} is proportional to the identity matrix; and the problem is formulated to estimate the β coefficients.

16.8.3 Derivative Computation

Computationally, the greatest challenge in the application of this method with numerical models is the computation of the derivative matrix \mathbf{H} in Equation 16.54. The direct approach of varying one element of \mathbf{s} at a time is inefficient because usually there are many components in \mathbf{s} and few components in \mathbf{y} . More efficient “adjoint state” methods have been developed. This topic, although important, is beyond the scope of this chapter, and the reader is referred to Chavent et al. (1975), Neuman (1980), Townley and Wilson (1985), Carrera et al. (1990), and Sun (1994).

Glossary

BLUE: Acronym for Best Linear Unbiased Estimation. Any estimation procedure where the estimate depends linearly on the data, with weights selected so that the estimation error has zero mean and minimum variance.

Cokriging: A geostatistical estimation method where one function is estimated using measurements from another related function.

Conditional Realizations: Functions that are possible solutions to the problem of finding a function from observations. They are consistent with the structure and with the data.

Deterministic Part: Also known as mean, drift, or trend. The part of the function that is described through a deterministic expression, such as a polynomial or zones with uniform values.

Experimental: Indicates computed from data.

Experimental Variogram: An estimate of the variogram obtained from the data using a graphical procedure. It is usually shown as piecewise linear.

Generalized Covariance: The part of the covariance that matters in universal kriging.

Geostatistics: A method for the estimation of spatial variables. It is based on the theory of random functions.

Kriging: Denotes any “geostatistical” interpolation or averaging method.

Ordinary Kriging: BLUE for the case that the mean is an unknown constant and the variogram is specified.

Orthonormal: Normalized random variables, which are uncorrelated and have zero mean and unit variance.

Random Function: Defined through probabilistic averages. Also known as *stochastic process*.

Random Part: The part of the unknown function that is described as a random function with zero mean. Usually, the less “regular” part of the function.

Residuals: Differences between model predictions and data. Useful in model testing and in parameter estimation.

Structure: Common characteristics of an ensemble of functions. In this chapter, structure is quantified by expressions for the deterministic part and the covariance function of the random part.

Variogram: Used synonymously with semivariogram. A measure of spatial structure. The expected value of half the square difference expressed as a function of the separation.

Further Information

Cressie (1993) is a comprehensive reference on methods of statistical estimation of spatial functions. Journel and Huigbrechts (1978) and Rendu (1981) describe geostatistics as applied in mining, including methods for the estimation of volume averages. Isaaks and Srivastava (1989) is another reference on basic geostatistics. Software is found in Deutsch and Journel (1992). Kitanidis (1997) is an introduction to estimation of spatial functions with applications in hydrogeology. de Marsily (1986) has a chapter on geostatistics including universal kriging and cokriging. A two-part paper (ASCE, 1990) reviews applications of geostatistics in hydrogeology. Statistical groundwater mechanics are covered in Dagan (1989) and Gelhar (1993). Rivoirard (1994) covers nonlinear geostatistics. Sun (1994) covers inverse methods in hydrogeology including methods for estimation and sensitivity analysis (computation of derivatives) in steady and unsteady state. Cooley and Naff (1990) describe the least squares approach to inverse modeling.

17.1 Introduction

Webster's New Collegiate Dictionary defines the verb "contaminate" as a process by which a material is made "inferior or impure by admixture" or made "unfit for use by the introduction of unwholesome or undesirable elements". While both of these definitions are accurate, they do not fully represent the connotation with which the word is used. For purposes of this chapter, the term "contaminant" will generally refer to an undesirable constituent that is introduced directly or indirectly as a result of human activity. Furthermore, the identification of groundwater contaminants and their effects will require knowledge of pre-existing or background conditions.

Groundwater contaminants exist in many forms, and contaminant classification schemes can be based on any of several physicochemical characteristics. For example, contaminants may be classified based on their preference for association with the aqueous phase or with particles. Contaminant distinction based on phase preference is important as the phase(s) a contaminant associates with can affect its transport behavior and toxicology. Furthermore, the form taken by a contaminant can also affect

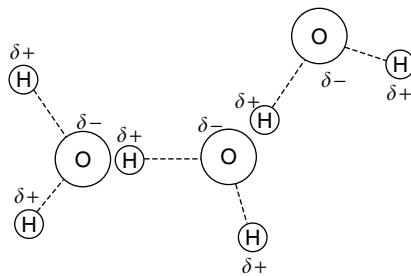

FIGURE 17.1 Schematic representation of the structure of the water molecule and resultant hydrogen bonding. The symbols $\delta+$ and $\delta-$ represent the positive and negative ends of the dipole, respectively. Alternatively, these symbols may be viewed as markers of areas of relatively low and high electron density, respectively.

the choice of treatment processes that may be implemented to remediate a contaminated area. In general, the physicochemical characteristics of groundwater contaminants and the surrounding aquifer will play critical roles in determining their fate, transport, and effects.

The goal of this chapter is to define the nature and behavior of groundwater contaminants. Important physicochemical characteristics will be defined and described in terms of their potential effects on contaminants. The major contaminant classes will be examined and examples of important contaminants within each class will be provided.

17.2 Physicochemical Characteristics of Water

Water molecules are comprised of two hydrogen atoms and one oxygen atom. The oxygen atom, being more electronegative than hydrogen, preferentially attracts electrons, thereby leading to a nonuniform electron distribution around the water molecule. Together with the two pairs of unbound electrons carried by the oxygen atom, the water molecule displays an asymmetrical structure (see Figure 17.1). The hydrogen atoms form covalent bonds with the oxygen atom at an angle of 105°.

The structure of water leads to several properties that are critical to its use as a resource and to the behavior of contaminants. Water is a highly polar molecule, with the negative end of the dipole being associated with the oxygen atom, and two strongly positive regions near the hydrogen atoms. One result of this structure is the ability of water molecules to attract each other through the formation of hydrogen bonds. These bonds, which are weak relative to covalent bonds, allow water to display properties that are somewhat anomalous based on its molecular size and composition. For example, water has a higher boiling point than hydrogen sulfide (H_2S) even though sulfur, which lies immediately below oxygen on the periodic table, is heavier than oxygen. As a result, water exists predominantly as a liquid at room temperature and pressure, whereas H_2S exists predominantly in the gas phase under the same conditions. The polarity of water is critical to its ability to function as a solvent. The dipolar nature of water allows it to associate with positively or negatively charged species; in turn, this property allows water to separate (dissociate) ionizable constituents, leading to dissolution.

The ability of water to function as a solvent is not limited to ionizable constituents. Essentially all compounds have measurable solubility in water. However, compounds that do not form ions will express affinity for water molecules via another mechanism. An important example is the ability of water to dissolve polar molecules. For example, if one examines the dipole moments of molecules in a homologous series of organic acids, decreasing polarity and aqueous solubility are observed as the molecule size increases. In essence, with the addition of each methyl group, the effects of the nonpolar group become less important as the electrons can distribute themselves over a larger molecule. Alternately, one could view the molecule as becoming more aliphatic as the chain length increases. Regardless of the viewpoint, the effect of polarity on water solubility is clear. In general terms, molecular solubility in water increases with polarity.

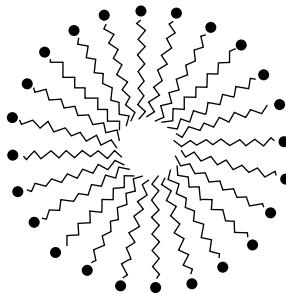

FIGURE 17.2 Two-dimensional schematic representation of a surfactant micelle in aqueous solution. The hydrophilic head is indicated by the filled circle (●); this end of the surfactant molecule will associate preferentially with the polar solvent (water). The nonpolar tails will be repelled by the water and allow the surfactant molecules to agglomerate into the micelles.

Natural or anthropogenic additions to water may also affect the solubility of constituents for water. For example, surfactants and detergents can dramatically increase the solubility of nonpolar compounds. In the case of surfactants, this can be accomplished through the formation of micelles, which exist as essentially a phase within a phase, often referred to as a “pseudo-phase” (see Figure 17.2). Micelles are agglomerations of organic molecules in which the polar ends of the surfactant molecules are directed outward, to associate with the bulk aqueous phase, and the relatively nonpolar ends of these molecules form the micelle core, yielding a relatively nonpolar region that promotes solubilization of nonpolar constituents. Detergents often serve as sequestering agents for Ca^{2+} and Mg^{2+} (the primary constituents of chemical hardness), thereby preventing interactions between hardness constituents and surfactants.

17.3 Factors Affecting Aqueous Solubility

The aqueous solubility of a contaminant compound will influence the transport, fate, and toxicity of that compound in a groundwater system. As such, it is important to define the characteristics of the system that can affect solubility. The primary factors that contribute to aqueous solubility are defined and reviewed below.

17.3.1 pH and Chemical Composition

Often referred to as a “master variable” in describing water composition, no single factor plays a more universal role in defining the characteristics of an aqueous system than pH. Water undergoes autoionization, resulting in the production of H^+ and OH^- .

In reality, ions such as H^+ and OH^- do not exist in solution, at least not as written. As described previously, ions are surrounded by water molecules. Therefore, the notation H^+ is really a shorthand representation for the hydrated proton that could be more accurately represented by $n(\text{H}_2\text{O})\text{H}^+$, where the coefficient n represents the number of waters of hydration. For purposes of this chapter, shorthand notation will be used to represent H^+ , OH^- , and all other ions. The strict definition of pH is as follows:

$$\text{pH} = -\log_{10}(\text{H}^+) \quad (17.2)$$

where (H^+) is defined as the activity of the hydrogen ion. For solutions of low ionic strength, activity may be closely approximated by molar concentration.

TABLE 17.1 Temperature Dependence of the Ion Product of Water (K_w)-Temperature (°C) pK_w

0	14.9435
5	14.7338
10	14.5346
15	14.3463
20	14.1669
24	14.0000
25	13.9965
30	13.8330
35	13.6801
40	13.5348
45	13.3960
50	13.2617
55	13.1369
60	13.0171

Note: Values as tabulated in the *CRC Handbook of Chemistry and Physics, 59th Edition*. 1978. CRC Press, Boca Raton, FL. With permission.

As the activity of molecular water (solvent) in aqueous solution is essentially constant, it is (by convention) excluded from the formal representation of the equilibrium constant for autoionization. Therefore, the equilibrium constant for reaction (17.1) is defined by:

$$K_w = (H^+)(OH^-) \quad (17.3)$$

K_w is also referred to as the ion product of water. For most acid-base reactions, equilibrium conditions in homogeneous aqueous solutions are established rapidly. However, it should be noted that the values of acid-dissociation constants, including K_w , are temperature-dependent (see Table 17.1). Under some circumstances, variations in K_w can have measurable consequences in a system. For example, in a typical mid-latitude groundwater system, with a characteristic temperature of roughly 13°C, the condition of neutrality (equal concentrations of H^+ and OH^-) will occur at a pH of approximately 7.2, whereas at room temperature, neutrality corresponds to pH = 7.0. In a physical sense, pH is a representation of the availability of hydrogen ions (protons) in solution; analytical determinations of pH are based on measurement of electrochemical potential using a hydrogen-ion selective electrode that has been previously calibrated using standard solutions.

Solution pH has a dramatic effect on the characteristics of solubilized compounds that can donate or accept protons (acids and bases, respectively). Some compounds have the ability to act as both acids and bases. Many examples of these so-called "amphoteric" compounds can be found, none more important than water itself. Since K_w has been accurately quantified as a function of temperature, knowledge of pH and temperature yields knowledge of both (H^+) and (OH^-).

The effect of pH on aqueous chemistry is not limited to the autoionization of the water molecule; pH will determine the speciation of all acids and bases in solution. An important example in groundwater chemistry is the distribution of carbonate species. Gaseous carbon dioxide (CO_2) will dissolve in water to yield aqueous CO_2 , followed by hydration to yield carbonic acid (H_2CO_3) that are often represented jointly by the fictitious species $H_2CO_3^*$. The equilibrium partitioning of gaseous and aqueous CO_2 are defined by Henry's law:

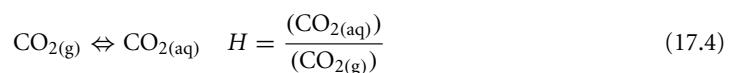

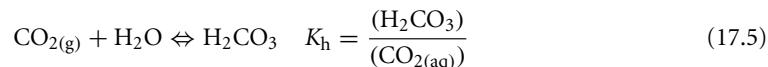

TABLE 17.2 Temperature Dependence of Equilibrium Constants for the Carbonate System

T (°C)	− log ₁₀ H	pK _{a,1}	pK _{a,2}
5	1.20	6.52	10.56
10	1.27	6.46	10.49
15	1.34	6.42	10.43
20	1.41	6.38	10.38
25	1.47	6.35	10.33
40	1.64	6.30	10.22

Source: Data from Larson, T. E. and Buswell, A. M. 1942. *Journal, AWWA*, **34**, 1664. With permission.

As activity (concentration) in the gas and liquid phases can be expressed in many units, many forms of Henry's law exist within the literature.

CO₂ hydration is defined by the following reaction:

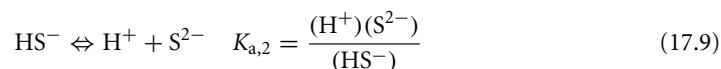

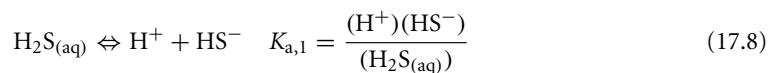

The equilibrium distribution of CO_{2(aq)} and H₂CO₃ is such that the vast majority of the dissolved CO₂ attributed to these species is found in the form of CO_{2(aq)}. However, the hydration reaction described by Equation 17.5 provides a direct link for CO₂ to the carbonate system. Therefore, the hypothetical compound H₂CO₃^{*} is used to represent the combination of these two compounds. Carbonic acid can donate two protons and is therefore referred to as a diprotic acid:

The equilibrium constants that describe these reactions are all functions of temperature. A compilation of these constants for the range of temperatures relevant to this subject can be found in Table 17.2. The information presented in Equations 17.4 through 17.7 and Table 17.2 reveal that with knowledge of pH and the concentration of any of the CO₂-based constituents, it is possible to quantify the concentrations (activities) of all CO₂-based constituents. As will be discussed later, the pH-dependence of the solubility of many metals in groundwater systems is closely related to the distribution of carbonate species.

Acid-base behavior determines the physicochemical characteristics of many other compounds. For example, H₂S is a relatively volatile, toxic compound. It is a product of some anaerobic biochemical processes, and can yield the sulfide ion (S²⁻), which can play an important role in determining the solubility and mobility of metals. The acid/base behavior of the diprotic acid H₂S can have important implications regarding the fate of sulfide, as well as many other aqueous constituents:

Dissociation of aqueous H₂S leads to the production of ionic species that have high solubilities relative to their parent compound. Furthermore, the sulfide ion (S²⁻) forms precipitates with many metals that have

TABLE 17.3 Acid Dissociation Constants for Common Ionizable Groundwater Constituents at 25°C

Compound (formula)	Conjugate Base (formula)	pK _a
Hydrochloric acid (HCl)	Chloride (Cl ⁻)	~−3
Sulfuric acid (H ₂ SO ₄)	Bisulfate (HSO ₄ ⁻)	~−3
Nitric acid (HNO ₃)	Nitrate (NO ₃ ⁻)	−1
Bisulfate (HSO ₄ ⁻)	Sulfate (SO ₄ ²⁻)	1.9
Phosphoric acid (H ₃ PO ₄)	Dihydrogen phosphate(H ₂ PO ₄ ⁻)	2.1
Acetic acid (CH ₃ COOH)	Acetate (CH ₃ COO ⁻)	4.7
Hydrogen sulfide (H ₂ S)	Bisulfide (HS ⁻)	7.1
Dihydrogen phosphate (H ₂ PO ₄ ⁻)	Hydrogen phosphate(HPO ₄ ²⁻)	7.2
Hydrogen cyanide (HCN)	Cyanide (CN ⁻)	9.2
Ammonium (NH ₄ ⁺)	Ammonia (NH ₃)	9.3
<i>o</i> -Silicic acid (Si(OH) ₄)	Silicate (SiO(OH) ₃ ⁻)	9.5

extremely low solubility in water. The acid-dissociation constants for the H₂S system are listed together with those of many other important acid/base pairs in Table 17.3. These constants reveal the importance of pH in determining the characteristics and behavior of many compounds that display acid–base behavior in aqueous systems, such as groundwater.

For many of the same reasons that the term “pH” is often used to describe hydrogen-ion activity, the more general term “pC” is often used to describe the activity of a given constituent, where pC is defined as the negative log₁₀ of the activity of that constituent. An important application for this term is in the development of pC–pH diagrams, which are used to illustrate acid–base behavior over a broad range of conditions. These diagrams are constructed based on knowledge of the equilibrium relationships for a given system and the total concentration of the compound(s) which display(s) acid/base behavior.

An example of such a diagram is given for the carbonate system in Figure 17.3 for water exposed to the ambient atmosphere at 25°C, a so-called “open” system. Under the circumstances described in Figure 17.3, the constraint of equilibrium with atmospheric CO₂ dictates that the concentration of H₂CO₃* be fixed at approximately 10^{−5} molar, regardless of pH. At a pH between the first and second dissociation constants (i.e., pK_{a,1} < pH < pK_{a,2}), the majority of the carbonate present in the system will be found in the form of bicarbonate ion (HCO₃⁻). At pH > pK_{a,2} carbonate ion (CO₃²⁻) will represent the predominant species. Under some circumstances, equilibration with atmospheric CO₂ cannot be assumed, as will often be the case with groundwater. Under these circumstances (i.e., a “closed” system), the pC–pH diagram will be defined by the acid/base equilibria presented in Table 17.2 and the total amount of inorganic carbon (dissolved carbonate species) in solution. Figure 17.4 provides an example of the pH dependence of carbonate composition for a “closed” system, wherein exposure of the water to the ambient atmosphere is prevented. Since acid/base equilibria are established rapidly in most cases,¹ pC–pH diagrams represent a powerful tool for evaluating speciation of aqueous constituents that display acid/base behavior. The details of the development of these and other pC–pH diagrams can be found in texts that deal with the subject of aquatic chemistry (e.g., Stumm and Morgan, 1996).

Other aqueous constituents are also subject to pH effects. Principal among these are the metals that generally exist in their oxidized forms in aqueous solutions containing measurable quantities of dissolved

¹Note that for acid/base distributions that rely on equilibration with a gas, the rate of equilibration between the gas and liquid phases will generally be much slower than the rate at which acid/base equilibria are reached in solution. Therefore, the assumption of the applicability of Henry’s law (which defines gas–liquid partitioning at equilibrium), may not always be valid.

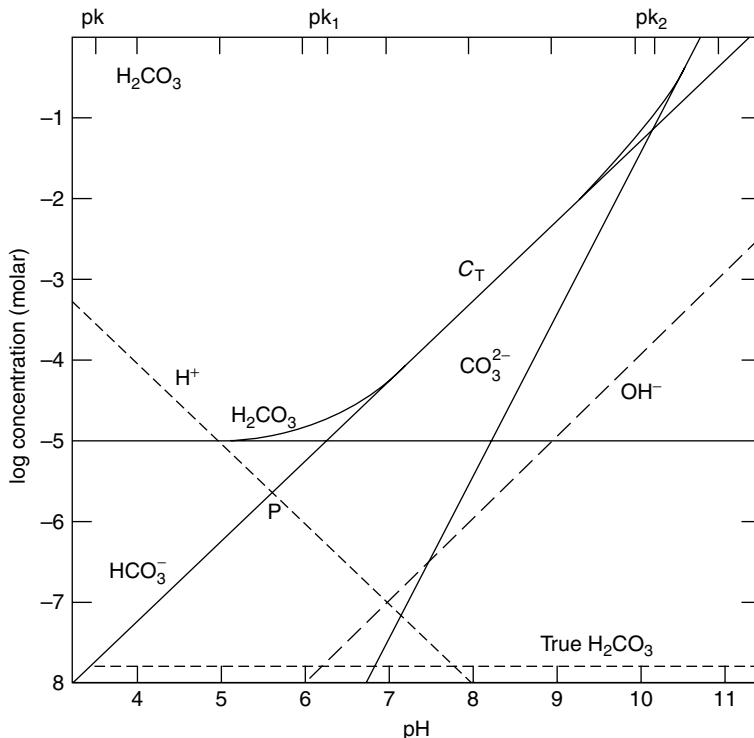

FIGURE 17.3 pC-pH diagram for the carbonate system under conditions of equilibrium with the atmosphere and 25°C. (From Stumm, W. and Morgan, J. J. 1981. *Aquatic Chemistry*, 2nd Edition, John Wiley & Sons, New York. With permission.)

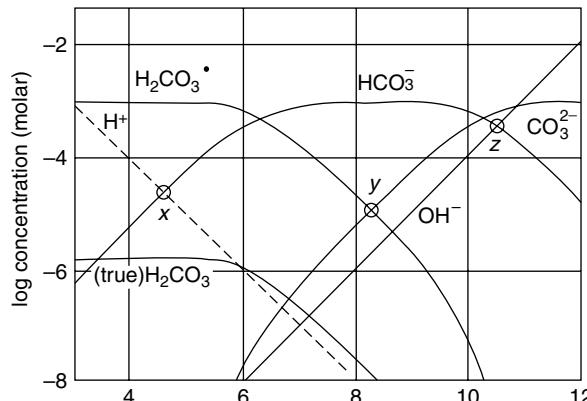

FIGURE 17.4 pC-pH diagram for the carbonate system without atmospheric exposure at 25°C. (From Stumm, W. and Morgan, J. J. 1981. *Aquatic Chemistry*, 2nd Edition, John Wiley & Sons, New York. With permission.)

oxygen. The majority of these compounds exist as polyvalent cations and related complexes. Important examples among background constituents include calcium and magnesium, which are found in the forms of Ca^{2+} and Mg^{2+} , respectively, and related complexes. Ca^{2+} and Mg^{2+} will both form complexes and precipitates with hydroxide, bicarbonate, and carbonate. These anionic constituents are referred to as ligands in the complexation and precipitations reactions. As the distribution of all three of these commonly found ligands are dependent on pH, the aqueous solubility of calcium and magnesium are also closely linked to pH. Similar logic can be used to describe the pH-dependent solubility behavior of many other

metals in solution. A detailed discussion of this topic is beyond the scope of this text, but good summaries can be found in textbooks relating to the subject of aquatic chemistry. An excellent compilation of the equilibrium constants for complex formation and precipitation can be found in the reference series by Martell and Smith (1974–1989).

As in the case of acid–base reactions, the reactions that result in formation of aqueous complexes in a homogeneous system (i.e., systems comprised only of an aqueous phase) are so rapid that in most circumstances equilibrium distributions can be assumed. However, the formation of precipitates and the reverse reaction (dissolution) involve at least two phases and equilibrium conditions do not always apply. Several factors contribute to the sometimes slow rates with which equilibria are achieved in these multiphase systems including transport limitations between phases and slow rates of crystallization among solids. Therefore, equilibrium calculations of solubility based on the presence of precipitates are not always valid and generally result in errors when compared to actual conditions.

The pC–pH diagram can also be used as a tool for evaluation of precipitate formation. One example of how pC–pH diagrams may be used for this purpose is the so-called predominance area diagram, which provides an indication of the conditions under which a particular solid phase (precipitate) is expected to predominate. These diagrams can be used to predict the form of a solid and the limits of solubility under aqueous conditions that will allow a metal to form precipitates with more than one ligand. An example of such a diagram is presented in Figure 17.5 for reduced iron, or Fe(II) at a total system concentration (C_t) of $10^{-5} M$. Fe(II) will form precipitates in the presence of both hydroxide and carbonate. As both ligands are likely to be present in groundwater systems, it is sometimes important to evaluate their combined effects on metal solubility. At pH < 10.5, the majority of precipitated Fe(II) in this example is expected to be present in the form of $\text{FeCO}_3(s)$. As pH increases above this value, more hydroxide ion becomes available and $\text{Fe(OH)}_2(s)$ is expected to predominate. Under either condition, it is likely that both forms of Fe(II) will be present, but one form will be expected to predominate. Figure 17.5 also defines the concentration of Fe(II) and related complexes that would be expected to be present in solution, in equilibrium with the solid phases, as a function of pH. The limit of solubility is defined by the lower borders of the solid regions within the predominance area diagram.

The characteristics and behavior of solids in solution are strongly related to pH; in particular, the net surface charge displayed by a particle in solution is largely determined by its composition and the solution

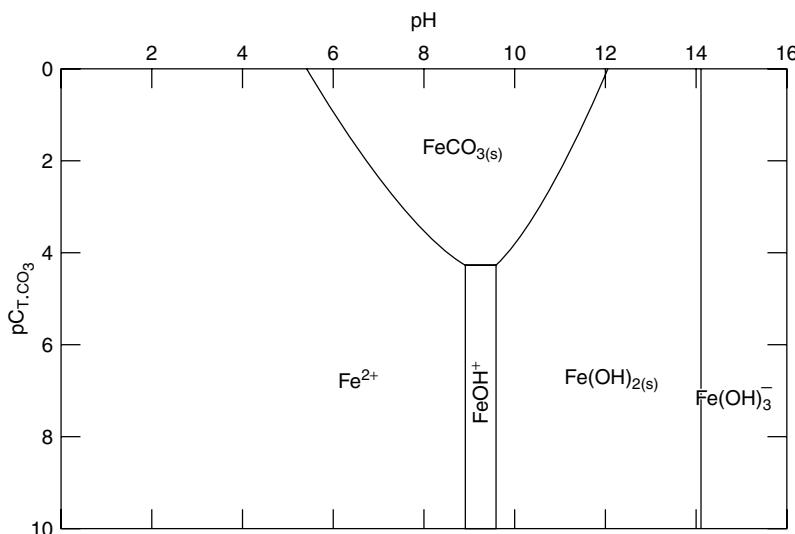

FIGURE 17.5 Predominance-area diagram for Fe(II) under conditions of exposure to carbonate and hydroxide, and with a total iron concentration of $10^{-5} M$. (From Snoeyink, V. L. and Jenkins, D. 1980. *Water Chemistry*, John Wiley & Sons, New York. With permission.)

pH. At least three mechanisms exist whereby solids generally express a surface charge in solutions. The first involves surface groups that display many of the same characteristics as dissolved constituents. For example, silica-based particles (e.g., sand) will have silanol groups; silanol groups display amphoteric behavior in aqueous solution:

The charge expressed by this surface group will be determined by the availability of protons to adsorb to the site. Therefore, the charge expressed by this surface group will depend on the pH of the solution to which it is exposed. Many other surface groups on particles express amphotericism; furthermore, this behavior is not limited to inorganic surface groups.

A similar mechanism by which particles obtain surface charge is the adsorption of ionic constituents. The similarity stems from the fact that the behavior of amphoteric groups may be viewed as the equivalent of adsorption or desorption of protons. Similarly, other ionic constituents generally adsorb to these sites resulting in a corresponding change of the surface charge.

A third mechanism by which particles express surface charge is isomorphous replacement of metals within crystal structures. For example, silica sand is commonly assumed to have a monomeric structure of SiO_2 ; however, imperfections in this structure, perhaps by the inclusion of metals with valence which is different than Si, results in a net surface charge.

Collectively, these processes allow particles in contact with liquid water to express a net surface charge. This charge is balanced by the migration of ions in solution to produce a region of local charge imbalance within the solution immediately adjacent to the particle : water interface. This region is often referred to as the electrical double-layer and plays an important role in governing the behavior of many constituents in groundwater systems.

The effect of pH in determining surface charge is profound. Titrimetric procedures exist whereby changes in surface charge may be quantified as a function of pH. These procedures allow for the determination of the zero point of charge (zpc), or the pH at which net surface charge is zero. A compilation of zpc values for some common particles is found in Table 17.4. At a pH above the zpc in a system where protons are the only adsorbable ion, the surface will express a net negative charge, whereas at a pH below the zpc, a net positive surface charge is expressed. From the values presented Table 17.4, it is evident that at near-neutral pH, most particles in solution express a net negative surface charge; however, important exceptions to this generalization can be found. This fact is important in that particles with like charges will express a repulsive electrostatic force, whereas those with opposite surface charge will experience

TABLE 17.4 Zero Points of Charge (pH_{zpc}) for Selected Inorganic Solids

Compound	pH_{zpc}
SiO_2	2.0

an attractive electrostatic force. The magnitude of the electrostatic forces between particles is a strong function of separation distance. Particles in suspension will experience other forces that also are strong functions of separation distance (e.g., London and van der Waal's forces). The sum of all such forces will govern the stability of particulate suspensions.

Surface charges expressed by particles and soil media must be considered in an evaluation of the fate and transport of ionic and particulate contaminants. The fate of particles in soils has been the subject of considerable numerical and experimental research dealing with the process of sand filtration. The results of these research efforts have generated numerical models that can accurately represent the movement of particles in soil media under some conditions. Those interested in modeling particle transport in groundwater systems should refer to the text by Clark (1996), which provides an excellent critical review of the pertinent literature on the subject.

17.3.2 Sorption to Solids

In the general case, compounds present in groundwater systems will have the opportunity to associate with the aqueous phase and the solid phase(s). The partitioning of a constituent among these phases will depend on the characteristics of the constituent and the phases themselves.

Two main categories of association among aqueous and solid phases exist. The first involves the accumulation of material at a water:solid interface and is termed adsorption. The second involves the intermingling of solute molecules with the molecules of the solid phase and is referred to as absorption. Absorption may be viewed as the dissolution of an aqueous constituent in a solid solvent. The distinction between the two processes is often vague and in a large number of cases, such a distinction is nearly impossible to make. Furthermore, in many cases both adsorption and absorption play a significant role in determining the partitioning behavior of groundwater constituents among the solid and liquid phases. For purposes of this chapter, these terms will be collectively referred to as sorption.

Three general types of sorption can be described for groundwater systems. All three involve the formation of bonds between the constituent and the solid phase. The first type, physisorption, involves the formation of relatively weak physical bonds such as those attributable to London and van der Waal's forces. Under some conditions, the interactions between a solute and a solid surface may be more accurately described as a chemical bond, with the process being referred to as chemisorption. In chemisorption, the bond strength between a solute and the solid surface may approach that of a covalent bond. The third type of interaction involves electrostatic interactions between surface groups and the solute; this type of surface:solution interaction plays a crucial role in ion exchange.

Physisorption and ion exchange (which may be viewed as a special case of physisorption) tend to be readily reversible processes, as the forces that are responsible for the attraction of a solute to the solid are relatively weak. In the case of ion exchange, the factors that govern the affinity of a solute for the solid phase are comparatively well-defined. For ions of similar size, the valence of the ion will govern the magnitude of the coulombic force between the surface and solute; ions of higher valence will show a greater affinity for the solid surface. For ions of similar valence, the hydrated radius of the ion will dictate solid affinity, with ions having small hydrated radii showing preference over those with large radii. Interestingly, hydrated radius is inversely related to (unhydrated) ionic radius for elements of the same family on the periodic table. Therefore, ion exchange selectivity order may be defined for a particular solid medium. A representative example of a selectivity order is presented below for some common cations:

This order implies that at similar concentrations, ions will replace those ions that lie to their right in the selectivity order. As an example, Ca^{2+} will replace Na^+ under most conditions. The specific selectivity order displayed by a soil medium may vary from that defined in Equation 17.11 due to situation-specific circumstances. Furthermore, the reader should recognize that when solute concentrations are not similar,

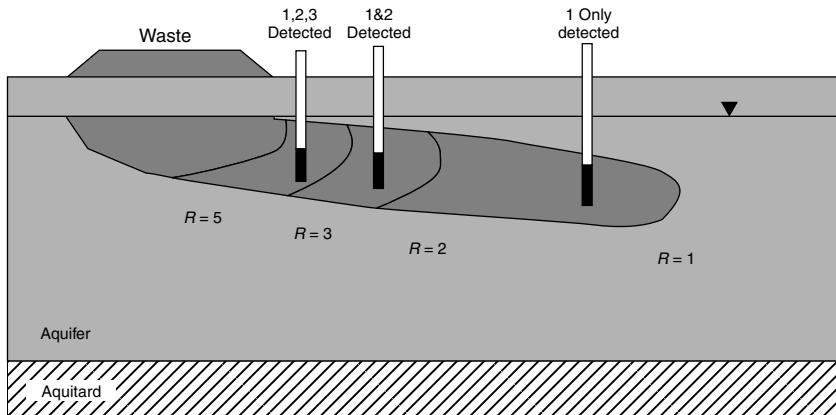

FIGURE 17.6 Schematic representation of the behavior of a mixture of pollutants (compounds 1, 2, 3, and 5) in a groundwater system. All pollutants are assumed to be introduced from the same spill and are assumed to be present initially in roughly equal amounts. The affinity of the constituents for the soil matrix is defined by the order $5 > 3 > 2 > 1$. (From US Environmental Protection Agency. 1989. *Transport and Fate of Contaminants in the Subsurface*, EPA/625/4-89/019. With permission.)

the tendency of ions with relatively high solution-phase concentration to replace ions associated with the solid phase will increase.

The importance of sorptive processes in determining the fate of groundwater contaminants may be illustrated by an example. Imagine a chemical spill comprised of four constituents: 1, 2, 3, and 5, all at similar concentrations. Furthermore, we will assume that all four constituents compete for the same sorption sites within the soil matrix and that the affinity of the constituents is defined by $5 > 3 > 2 > 1$. All four compounds will move through the soil medium by advection, but their movement will be retarded by interactions with soil surfaces. As constituent 5 shows the highest affinity for the soil matrix, it will be able to replace constituents 3, 2, and 1. Therefore, on average, constituent 5 will spend more time in association with the soil matrix than constituents 3, 2, or 1, and will therefore move through the matrix more slowly. A schematic representation of the movement of these constituents through this hypothetical system is provided in Figure 17.6. The separation of constituents 1, 2, 3, and 5 based on their affinity for the stationary soil matrix is referred to as chromatography. This process is used on a much smaller scale and under more controlled conditions in the family of chromatographic analytical procedures, which are extremely important in the analysis of groundwater contaminants. Important analytical techniques that employ these principles include gas chromatography (GC), liquid chromatography (LC), and ion chromatography (IC). Many variations on these processes exist.

17.3.3 $p\epsilon$

Much in the same way that pH is used as a master variable in describing the availability of protons, $p\epsilon$ is a master variable that is used to describe the availability of electrons for reaction. The analogy may also be carried further in that much as H^+ does not exist in solution, free electrons do not exist in solution. The mathematical definition of $p\epsilon$ is as follows:

$$p\epsilon = -\log_{10}(e^-) \quad (17.12)$$

In aqueous systems, $p\epsilon$ provides an indication of the tendency for electrons to be transferred. Under conditions of low $p\epsilon$, the activity of aqueous electrons is high, and there is significant pressure being exerted on aqueous constituents to undergo reduction. Conversely, under conditions of high $p\epsilon$, electron activity is low and the tendency is for oxidation reactions to be promoted. Oxidation and reduction

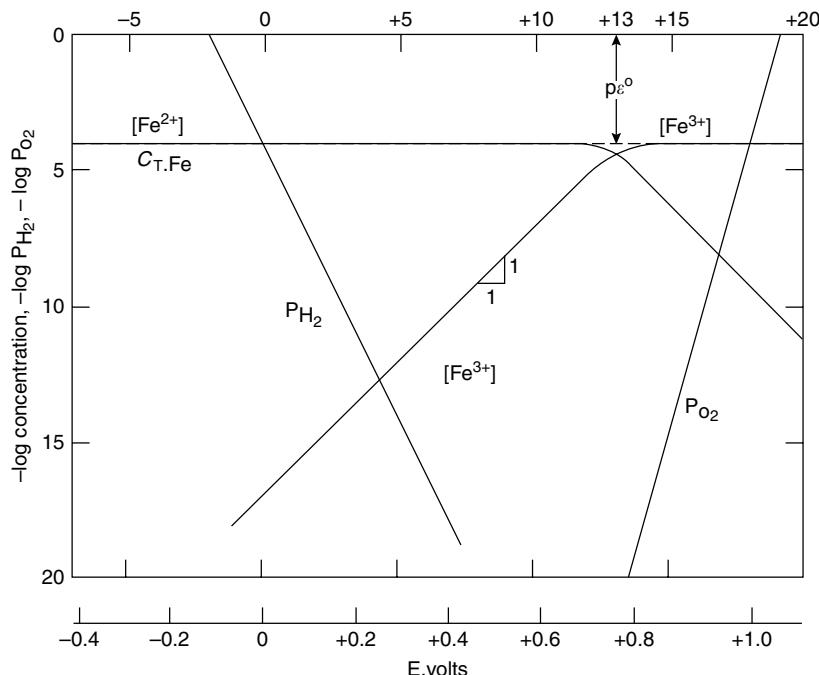

FIGURE 17.7 $p\epsilon$ - pC diagram for iron at a total dissolved iron concentration of $10^{-4} M$ and $pH = 2$. (From Snoeyink, V. L. and Jenkins, D. 1980. *Water Chemistry*, John Wiley & Sons, New York. With permission.)

reactions cannot take place in isolation (free electrons do not remain in solution for any significant period of time). Therefore, oxidation and reduction reactions must be coupled.

As in the case of pH, graphical tools exist to describe equilibrium conditions using $p\epsilon$ as a master variable. One such tool is the so-called $p\epsilon$ - pC diagram. Figure 17.7 provides an example of such a diagram for a system containing dissolved iron at a total iron concentration of $10^{-4} M$ and a pH of 2. Under conditions of low $p\epsilon$, the system will be characterized as a reducing environment. In the case of the Fe(II)/Fe(III) system, this suggests that Fe(II) will be the dominant form. When $p\epsilon$ increases, a more oxidizing environment will exist. For the iron system at pH = 2 and at $p\epsilon > 13$, Fe(III) is expected to be the predominant form.

The $p\epsilon$ - pC diagram is conceptually similar to the pC -pH diagram for description of acid/base equilibria. However, the $p\epsilon$ - pC diagram is somewhat limited in its ability to present these equilibria in the sense that only a single pH can be represented. Another graphical tool for presentation of redox equilibria is the $p\epsilon$ -pH diagram. Figure 17.8 provides an example of such a graph for the sulfur system at a total dissolved sulfur concentration of $10^{-2} M$ (Stumm and Morgan, 1981). This diagram provides an illustration of the conditions under which given sulfur species are expected to predominate. Though many similarities exist between pH and $p\epsilon$ and the equilibria they can be used to describe, a significant difference between equilibrium calculations based on acid/base transfer reactions and those corresponding to oxidation/reduction reactions is that whereas equilibrium conditions can often be assumed to apply for reactions involving proton transfer (i.e., acid/base reactions), the same cannot be said for reactions which involve electron transfer (i.e., oxidation/reduction reactions). Therefore, equilibrium calculations for redox reactions will not always yield an accurate representation of actual conditions in an aqueous system; however, these calculations do represent a powerful tool for defining the conditions one would expect to find if an infinite amount of time were allowed for the system to stabilize.

Compilations of aqueous redox chemical equilibria can be found in the literature. An excellent summary of the methods used to conduct redox equilibrium calculations and graphical representations of these equilibria can be found in Stumm and Morgan (1996).

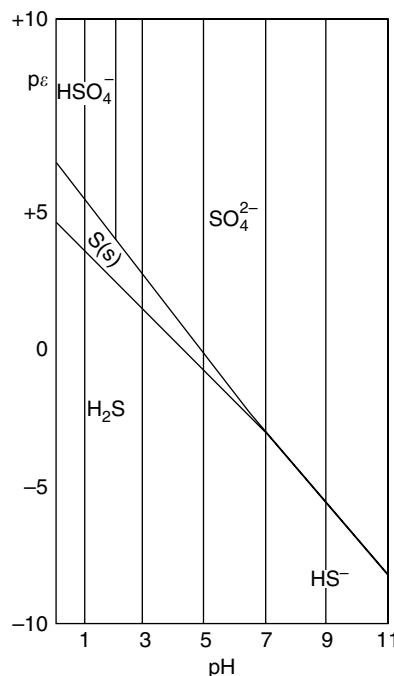

FIGURE 17.8 $p\epsilon$ -pH diagram for sulfur at a total sulfur concentration of 10^{-2} M . (From Stumm, W. and Morgan J. J. 1981. *Aquatic Chemistry, 2nd Edition*, John Wiley & Sons, New York. With permission.)

17.3.4 Temperature

Thermodynamic considerations play an important role in evaluating the rates and equilibria of chemical reactions. In general, reaction rates will increase with temperature due to the increased availability of thermal energy. This energy will promote collisions between molecules by increasing rates of diffusion and will reduce energy barriers to reaction progress. Equilibrium conditions are achieved in a system when the rates of forward and reverse reactions are equal. If a given reaction is endothermic (i.e., heat is “consumed” by the reaction), then an increase in temperature would be expected to promote the forward reaction and shift the equilibrium to the right (an increase in “product” formation). Examples of the effects of heat on groundwater contaminants include changes in the equilibria and kinetics of precipitation and dissolution of minerals, and changes in the rates by which biological transformation processes proceed.

In most groundwater situations involving *in situ* contamination, temperature can often be assumed to be constant at a value of 1–2°C greater than the annual average ambient air temperature for the region (Freeze and Cherry, 1979). For example, the groundwater temperature in the midwestern United States (at depths greater than approximately 10 m, where diurnal and seasonal variations in air temperature have minimal effect) can generally be assumed to be approximately 13°C. Under these conditions, the role of temperature in governing contaminant transport and behavior is more of a buffer than a variable. However, those who deal with groundwater contaminants should be aware of the potential for thermal effects to influence system behavior. For example, shallow contamination in areas subject to substantial variations in climate (i.e., within the frost zone) generally display variations in behavior as a function of the season. Similarly, other thermal sources and sinks within groundwater systems may play a role in determining the local behavior of contaminants. And finally, many remediation strategies call for removal of contaminants for *ex situ* treatment. Contaminants exposed to these conditions will obviously be subjected to a less stable thermal environment than those that remain *in situ*. Consequently, the behavior of groundwater contaminants may be different in the *ex situ* environment than *in situ*.

17.4 Inorganic Constituents

The compounds that comprise the inorganic fraction of groundwaters are heavily influenced by interactions between source water and soils. As source water moves through a soil, chemical reactions taking place at the soil : water interface will change the composition of both phases. In the previous section, the basic characteristics of these reactions were reviewed. Based on the working definition of “groundwater contaminants” provided in the introduction, the inorganic constituents of primary interest are those that have been introduced to a groundwater system as a result of human activity. Therefore, it is necessary to define background conditions in an unpolluted groundwater system to understand the importance of these reactions relative to inorganic groundwater contaminants.

17.4.1 Source Water Composition

The accumulation of atmospheric moisture as a result of evapotranspiration may be viewed as a large-scale distillation process. However, the composition of precipitation, in the form of rain or snow, is not accurately represented by the composition of distilled water one might find in a laboratory. In particular, rain and snow will react with atmospheric constituents to determine their composition prior to reaching the earth’s surface. A summary of measured compositions in rain and snow is provided in Table 17.5.

Many atmospheric gases display substantial solubility in water. The typical composition of gases in a “clear” atmosphere (which also must be defined in relative terms as a result of human activities) is summarized in Table 17.6. Normally, atmospheric precipitation can be assumed to be at equilibrium

TABLE 17.5 Measurements of the Chemical Composition of Rain and Snow

Constituent	Location				
	1	2	3	4	5
SiO ₂	0.0		1.2	0.3

with atmospheric gases, as defined by Henry's law. Of the constituents listed in Table 17.6, several play significant roles in determining the chemistry of rain and snow. Primary among these is carbon dioxide (CO_2). As described previously, CO_2 will dissolve in water to form carbonic acid, which can dissociate to form carbonic acid (H_2CO_3), bicarbonate (HCO_3^-), and carbonate (CO_3^{2-}) ions. The carbonate system plays an important role in governing groundwater composition through precipitation and complexation reactions. The carbonic acid cycle also plays a major role in determining the pH and buffering capacity of precipitation. Specifically, water at equilibrium with atmospheric CO_2 will have a pH of approximately 5.7. This value is often used as benchmark in the evaluation of the effects of atmospheric constituents that participate in the formation of acidic precipitation — precipitation with $\text{pH} < 5.7$ is often assumed to be under the influence of strong acids.

The influence of atmospheric composition on groundwater chemistry goes far beyond CO_2 . Examples of other atmospheric constituents that play important roles in the subsurface environment are provided below.

Oxygen (O_2) will dissolve in water to yield a liquid-phase concentration of approximately 8 to 10 mg/L, depending on altitude and temperature. In a groundwater system, the availability of oxygen (and other constituents) will play a major role in determining the extent and type (i.e., aerobic, anoxic, or anaerobic) of microbiological activity that can take place. Microbiologically mediated chemical transformations can play a significant role in determining groundwater composition; this fact is exploited in many soil and groundwater remediation strategies (see Chapter 31 and Chapter 36).

The oxides of nitrogen and sulfur (NO_x and SO_x), which are released to the atmosphere as a part of many natural processes (e.g., volcanic activity, microbiological activity), can react in the atmosphere to yield strong acids, such as HNO_3 and H_2SO_4 . In an unpolluted atmosphere, the concentrations of these constituents are relatively low and do not play an important role in determining precipitation chemistry.

TABLE 17.6 Typical Gas-Phase Composition in a “Clean” Atmosphere
(Based on a Total Pressure of 1.0 atm)

Gas	Partial Pressure (atm)
N_2	0.781
O_2	0.209
H_2O	0.028
Ar	0.0093
CO_2	0.0003
Ne	1.8×10^{-5}
He	5.2×10^{-6}
CH_4	1.5×10^{-6}
Kr	1.1×10^{-6}
CO	$(0.6-1) \times 10^{-6}$
SO_2	1×10^{-6}
N_2O	5×10^{-7}
H_2	5×10^{-7}
O_3	$(0.1-1.0) \times 10^{-7}$
Xe	8.7×10^{-8}
NO_2	$(0.05-2) \times 10^{-8}$
Rn	6×10^{-20}

Source: B. A. Mirtov, Gaseous composition of the atmosphere and its analysis. *Akad. Nauk. SSSR, Inst. Prikl. Geofiz. Moskva* (translated by the Israel Program for Scientific Translations, published in Washington, US Dept. of Commerce, Office of Technical Services, 1961, 209 pp. With permission.).

However, combustion of fossil fuels in mobile and stationary sources can result in large increases in atmospheric NO_x and SO_x concentration. The spatial scale on which these combustion processes are carried out allows them to influence rain and snow chemistry over geographic areas that span international boundaries.

Radon (Rn) is a noble gas, which means that its electron structure is such that it tends to be quite inert with respect to conventional chemical reactions. However, radon has several naturally occurring isotopes, some of which have unstable nuclear structures, and therefore express radioactivity. In the natural atmosphere, the concentration of Rn is quite low and does not play a significant role in determining precipitation chemistry.

Groundwater composition will not be strictly governed by the composition of atmospheric gases; the subsurface generally contains gases at partial pressures that are markedly different from those of the atmosphere. For example, locally intense microbiological activity can substantially alter the partial pressures of gases such as CO_2 and O_2 . The reader should be aware of the potential for subsurface conditions to change gas-phase composition, and the resulting composition of groundwater with which it comes into contact. However, atmospheric composition provides a reference point in the analysis of groundwater composition and contamination.

Rain and snow are also effective scavengers of atmospheric particulate matter. Naturally occurring dust particles and aerosols will contribute to the inorganic composition of rain and snow. These particles are probably responsible for the presence of metals such as sodium (Na), potassium (K), calcium (Ca), and magnesium (Mg) in precipitation.

In a “polluted” atmosphere, the concentrations of gaseous and particulate constituents may be markedly different from those of a clean atmosphere. For comparison, Table 17.7 provides a listing of atmospheric composition in a clean atmosphere and in a polluted atmosphere, based on the trace constituents. It is interesting to note that most of these compounds are formed and can be found in unpolluted air, but the concentrations of many oxidizing compounds (e.g., ozone), acid-forming gases (e.g., oxides of nitrogen and sulfur), and particles can be substantially higher in a polluted atmosphere than in an unpolluted atmosphere.

The nature of atmospheric contamination will be specific to an area. Therefore, the composition of a polluted atmosphere cannot be quantitatively generalized and local information is needed. However, for a given atmospheric composition, increases in atmospheric constituent concentrations attributable to anthropogenic activities can be expected to translate to parallel changes in rainwater and snow chemistry

TABLE 17.7 Typical Concentration Ranges of Trace Atmospheric Constituents in Clean and Polluted Atmospheres

Species (formula)	Concentration (ppbv)	
	Clean Troposphere	Polluted Troposphere
Sulfur Dioxide (SO_2)	1–10	20–200
Carbon Monoxide (CO)	120	1,000–10,000
Nitric Oxide (NO)	0.01–0.05	50–750
Nitrous Oxide (N_2O)	0.1–0.5	50–250
Ozone (O_3)	20–80	100–500
Nitric Acid (HNO_3)	0.02–0.3	3–50
Ammonia (NH_3)	1	10–25
Formaldehyde (HCHO)	0.4	20–50
Formic Acid (HCOOH)		1–10
Nitrous Acid (HNO_2)	0.001	1–8
Peroxyacetyl Nitrate ($\text{CH}_3\text{C}(\text{O})\text{O}_2\text{NO}_2$)		5–35
Non-Methane Hydrocarbons	500–1200

in downwind areas. Those who work in the groundwater arena should be aware of the link between groundwater behavior and the surrounding environment, including the atmosphere.

17.4.2 Source Water: Soil Interactions

Percolation of rainwater and snow into a soil formation is responsible for the existence of groundwater. As water moves through soil, a complex set of reactions take place that alter the chemical composition of both phases (solid and liquid). The general categories of reactions have already been reviewed: acid/base, complexation, precipitation/dissolution, and oxidation/reduction. The local implications of these reactions will depend on the specific compositions of the solid and liquid phases that come into contact. For example, many geologic formations consist largely of calcium- and magnesium-based minerals, such as limestone. Dissolved CO₂ (and other acids) will interact with these minerals to promote equilibration between the phases. This results in mineral dissolution and an increase in the liquid-phase concentration of the metals that make up the dissolved minerals. In groundwater systems, the presence of Ca²⁺ and Mg²⁺ are important not only in terms of the dietary needs they serve to people who consume water from a groundwater source, but also in terms of industrial applications. Chemical hardness, defined as the sum of the concentrations of all polyvalent cations in an aqueous system, is almost exclusively attributable to Ca²⁺ and Mg²⁺ in most groundwaters. The constituents of chemical hardness cause problems of fouling and scale formation in industrial systems, and form stable complexes with detergents, thereby increasing detergent usage. Mineral dissolution will also lead to increases in the concentrations of inorganic constituents.

A summary of the major, minor, and trace constituents, according to the designations defined by Freeze and Cherry (1979), in groundwater is provided in Table 17.8. As can be seen from this table, the ranges of constituent concentrations are quite broad. Not surprisingly, groundwater composition is highly variable between sites, and is largely determined by the differences in geology among the sites.

Inorganic groundwater contaminants may come in the form of increases in the concentrations of the constituents listed in Table 17.8 above their naturally occurring concentrations, or the introduction of constituents that otherwise would not be detectable in the system at all. A number of factors can contribute to the changes in solution chemistry in these systems, including changes in atmospheric composition, changes in soil chemistry, and human activities that directly alter the physical or chemical conditions of a soil matrix.

The introduction of strong acids (e.g., H₂SO₄ and HNO₃) to groundwater systems from atmospheric sources can have a profound effect on groundwater composition. These acids reduce the pH of source waters (rain and snow) and promote dissolution of the soil matrix. In contaminated soils, dissolution is not limited to naturally occurring minerals. For example, many military sites have extensive heavy-metal contamination in their soils as a result of firing range activities. The heavy metals at these sites are often dominated by lead (Pb), but other elements are also present including zinc (Zn), copper (Cu), and antimony (Sb). The solubility of these metals in their zero-valent states is quite limited. Therefore, for these metals to represent a potential source of groundwater contaminants, they must generally undergo oxidation. A number of mechanisms exist whereby these metals may be oxidized in a soil including microbiological activity, contact with chemical oxidants, and galvanic interactions with other metals. As a result of these and other processes, zero-valent metals are transformed, usually at slow rates, to their more mobile oxidized forms, where dissolution by aqueous constituents can become important.

Among heavy metals, lead has generally been the subject of the most extensive and comprehensive research, probably because of the large number of potential sources and its general ubiquity. Other examples of potential sources of lead in soils and groundwater include lead-based paints and leakage of lead-based fuels from underground storage tanks. While both of these products are now out of production in the United States, important reservoirs of contamination (or at least potential contamination) still exist. Furthermore, these compounds are still being produced in many areas of the world.

Another source of inorganic contamination is mining and related activities. In the past, a common mining technique involved the application of liquids to promote selective chemical extraction of valuable mineral constituents. These practices that are no longer in use *in situ*, sometimes created significant local

TABLE 17.8 Major, Minor, and Trace Constituents as defined by Freeze and Cherry (1979)

<i>Major Constituents (> 5 mg/L)</i>	
Bicarbonate	Magnesium
Calcium	Silicon
Chloride	Sodium
Carbonic acid	Sulfate
<i>Minor Constituents (0.01–10 mg/L)</i>	
Boron	Nitrate
Carbonate	Potassium
Fluoride	Strontium
Iron	
<i>Trace Constituents (< 0.1 mg/L)</i>	
Aluminum	Molybdenum
Antimony	Nickel
Arsenic	Niobium
Barium	Phosphate
Beryllium	Platinum

Indium	Uranium
Iodide	Vanadium
Lanthanum	Ytterbium
Lead	Yttrium
Lithium	Zinc
Manganese	Zirconium

soil and groundwater contamination problems, some of which are quite long-lasting, and still exist today. Modern mining techniques are substantially improved in terms of their potential to contaminate, but are not exempt from the ability to cause groundwater problems.

The presence of mineral acidity in the form of elevated proton activity (low-pH) leads to the dissolution of many precipitates, including those that involve hydroxide, carbonate, sulfide, and phosphate ligands. The mineral composition of many soils incorporates large amounts of these materials, which themselves act as buffers against changes in pH. Therefore, the presence of mineral acidity in soils and groundwater is somewhat unusual. However, processes do exist that can create locally low pH. One prominent example of such a process is the oxidation of pyrite (FeS_2) and other iron sulfide crystalline forms. As will be discussed below, the process is often linked to mining activities, and the resulting low-pH waters from these operations are commonly referred to as “acid mine drainage.” The stoichiometry of the process is described as follows:

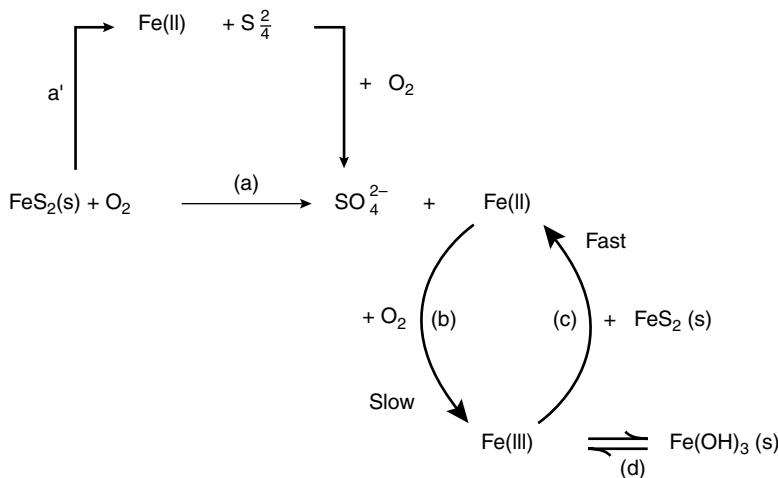

FIGURE 17.9 Mechanistic description of the processes responsible for pyrite oxidation, as hypothesized by Temple and Delchamps (1953).

Reactions 17.13 through 17.16 do not accurately represent the mechanism by which pyrite oxidation leads to acidification. Temple and Delchamps (1953) hypothesized the mechanism illustrated in Figure 17.9 to describe the process and its rate limitations. Under the low-pH conditions that would be expected in waters subject to these reactions, the rate of Fe^{2+} oxidation is extremely slow. However, several species of bacteria are known to catalyze this reaction, including *Thiobacillus thiooxidans*, *Thiobacillus ferrooxidans*, and *Ferrobacillus ferrooxidans*. These microorganisms, which are categorized as microaerophiles, require oxygen to catalyze Reaction 17.14, though they can survive under conditions of low oxygen concentration. The introduction of oxygen, often as a result of mining activities, initiates the process by dramatically increasing the rate of reaction (Equation 17.14). Once the process is started, the presence of oxygen is no longer a requirement for the development of mineral acidity. Therefore, sealing of mines that have experienced this problem does not represent an acceptable remediation approach.

The generation of acid mine drainage is often associated with coal mining activities as pyrite-bearing minerals are commonly found in conjunction with coal deposits. However, pyrite is also found in other mineral deposits, and similar acidification problems have been linked to acid mine drainage within copper and uranium mining facilities.

Another source of inorganic contamination is storage of salt for municipal operations, such as road deicing. Large salt piles, largely comprised of sodium chloride (NaCl), are often stored with little or no weather protection. Given the solubility of NaCl and related compounds in water, these situations provide a tremendous potential for salt introduction to a groundwater system. While the constituents of road salts do not generally represent an acute toxicity problem toward humans, they can increase salt concentrations to the point where a groundwater is not fit for human consumption. Additionally, the removal of sodium and potassium salts from groundwaters is difficult because they are so soluble in water. Their affinity for water makes them difficult and expensive to separate them from the aqueous phase.

17.5 Organic Constituents

17.5.1 Background Organics

In uncontaminated soil/groundwater systems, the predominant organic constituents are humic substances. These compounds, which represent the products of natural decay processes from plant and animal matter, do not have a well-defined chemical structure. Therefore, humic substances are identified

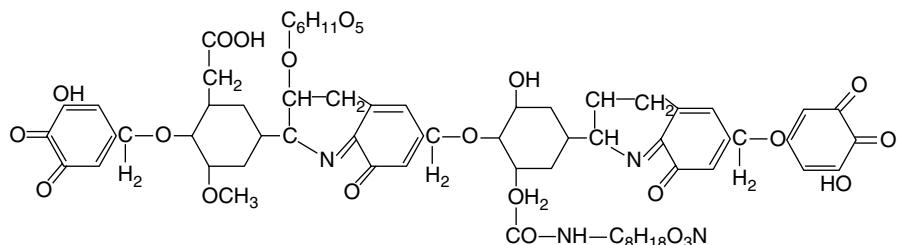

FIGURE 17.10 Representation of the structure of humic acid. (From Schnitzer, M. and Khan, S. U. 1972. *Humic Substances in the Environment*, Marcel Dekker, New York. With permission.)

and differentiated according to a broad set of operational definitions. Three classes of humic substances exist:

1. Fulvic acid — constituents that are soluble at any pH.
2. Humic acid — constituents that are insoluble at low-pH, but otherwise soluble.
3. Humin — constituents that are insoluble in water at any pH.

In most groundwaters, the concentrations of humic substances (humic and fulvic acids) are quite low, normally less than several milligrams per liter.

As humic substances are operationally defined, no unique structural representation of these compounds can be defined. Humic substances generally take the form of large heteroatomic organic polymers. The composition and structure of humic substances will differ depending on the source material and conditions under which they are generated. However, some generalizations have been developed regarding the functional groups that tend to exist within humic substances. For example, the structure presented in Figure 17.10 has been hypothesized to be representative of a monomer of a humic acid (Schnitzer and Khan, 1972). One of the most significant features of these hypothesized structural representations is the presence of oxygenated functional groups. These groups are believed to be largely responsible for the ability of humic substances to complex metals.

Many classes of synthetic organic compounds have been identified as groundwater contaminants, including pesticides, petroleum products, and (halogenated) solvents. Though it is not practical to list all possible organic groundwater contaminants, a number of their important characteristics can be illustrated with examples from the aforementioned categories.

The mobility of groundwater contaminants is largely determined by their affinity for soil particles. Generally speaking, contaminants with high affinity for soil particles preferentially associate with the soil matrix, and therefore move relatively slowly (see Figure 17.6). Among organic compounds, relative affinity for soil vs. water can be evaluated using the octanol : water partitioning coefficient (K_{ow}). K_{ow} provides a measure of the equilibrium distribution of a specific compound between octanol and water phases in direct contact. K_{ow} values for a wide variety of important compounds, including many pesticides are presented in Table 17.9. Large values of K_{ow} are indicative of compounds that are likely to preferentially associate with organic constituents (because of their relatively low polarity), such as those found in many soils; small values indicate a preference for the more polar aqueous phase. Common sources of hydrophobic organics, such as those listed in Table 17.9, include land application, either directly or by incorporation with soil amendments (such as process sludges) and surface spills.

17.5.2 Nonaqueous Phase Liquids

Compounds that display extremely low aqueous solubility can exist as a separate liquid phase in groundwater systems, if present in sufficient quantities. In groundwater systems, these contaminant phases are referred to as nonaqueous phase liquids (NAPLs), and their behavior will be fundamentally different from that of the bulk aqueous phase. In the case of a NAPL with density less than the surrounding water, the

TABLE 17.9 Octanol–Water Partition Coefficients (K_{ow}) for Selected Soil and Groundwater Contaminants

nonaqueous phase is referred to as a light NAPL (LNAPL), and will generally be found at or near the phreatic surface (see Figure 17.11). Fluctuations in the height of the phreatic surface can enhance LNAPL dispersion. LNAPL spills often are attributable to leaking underground fuel tanks (LUFTs) used for storage of petroleum hydrocarbons. Cleanup activities focus on location of the LNAPL phase and removal, by pumping if possible. Hydrocarbons that cannot be recovered by these methods may be subjected to other remediation methods, including soil vapor extraction, *in situ* bioremediation, or a combination.

Low-solubility organic compounds with density greater than water can exist as a dense NAPL (DNAPL) phase; their behavior in the subsurface environment is fundamentally different from that of LNAPLs. DNAPL compounds, because of their high density, tend to sink in groundwater systems. Often these compounds have lower viscosity than water — as a result, they tend to sink according to a pattern known as viscous fingering (see Figure 17.12). As they sink, they leave a trail of residual DNAPL compounds among the solids (soil particles) and liquid (water) in their wake. A DNAPL phase will continue to sink until it completely disperses among the soil and water phases, or it reaches an impermeable boundary, such as a clay lens or bedrock (see Figure 17.12). DNAPL pools can be extremely difficult to locate and are often difficult (or impossible) to remediate using existing technologies. Furthermore, as DNAPLs are often comprised of halogenated solvents, microbiological activity is slow to bring about changes in their molecular structure, and the products of microbial degradation involving these compounds are sometimes more toxic than their parent compounds. Possibly the most common examples of DNAPL compounds are trichloroethylene (TCE) and perchloroethylene (PCE). As in the case of LNAPLs, the source of DNAPL spills is often leakage or failure of underground storage tanks.

17.5.3 High-Profile Organic Contaminants

Within roughly the last decade, several important classes of organic groundwater contaminants have been identified. The discoveries of these contaminants have been attributed to improvements in analytical capabilities, changes in industrial practices, as well as changes in efforts to identify and quantify contaminants in groundwater settings.

The text below describes two high-profile groups of contaminants that have emerged as potentially serious threats to groundwater supplies. These two classes of compounds have physical, chemical, and

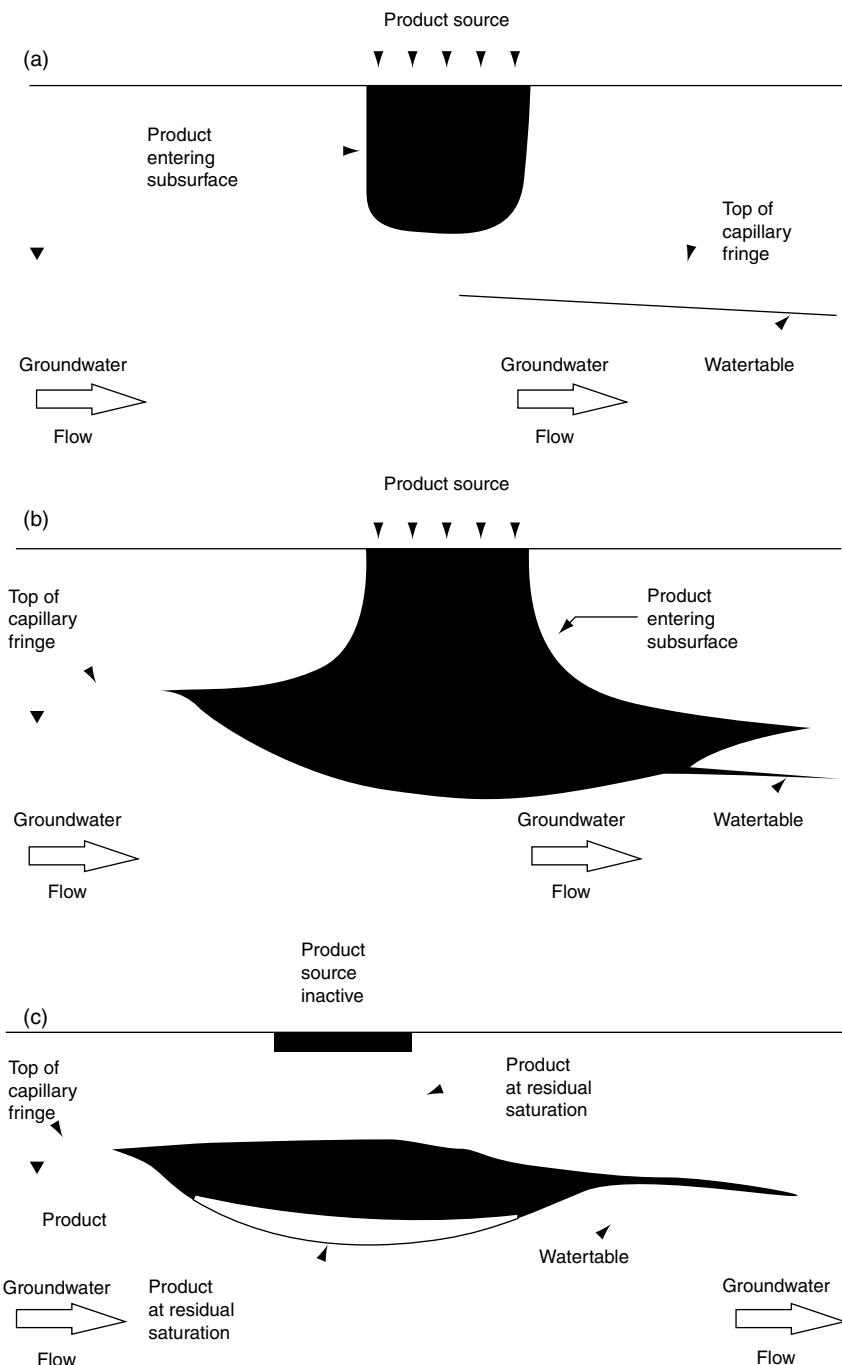

FIGURE 17.11 Schematic illustration of the behavior of LNAPL compounds. Under some conditions (a), the mass of an LNAPL spill is insufficient to allow penetration to the capillary fringe. With additional compound introduction (b), LNAPL product will reach the water table and begin to spread, though the compound will not penetrate far beyond the phreatic surface. If the source of LNAPL is eliminated (c), removal of LNAPL will allow for “rebound” of the water table. (From US Environmental Protection Agency. 1989. *Transport and Fate of Contaminants in the Subsurface*, EPA/625/4-89/019. With permission.)

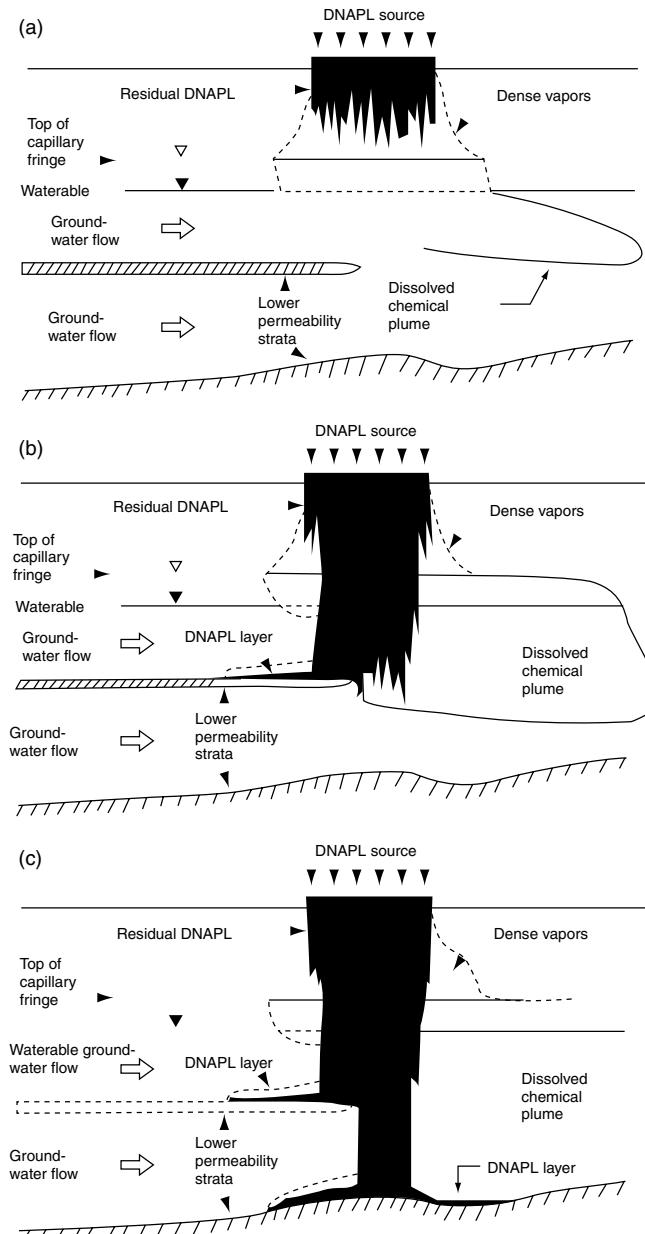

FIGURE 17.12 Schematic illustration of the behavior of DNAPL compounds. Under some conditions (a), the mass of a DNAPL spill is insufficient to allow penetration of the intact DNAPL to the capillary fringe; vertical movement of the DNAPL is by viscous fingering. With additional input of the compound (b) and (c), DNAPL product will reach the water table and continue to move vertically until it reaches an impermeable boundary. (From U.S. Environmental Protection Agency. 1989. *Transport and Fate of Contaminants in the Subsurface*, EPA/625/4-89/019. With permission.)

toxicological characteristics that have created important problems relative to the actions that can be taken to address groundwater contamination problems involving them.

17.5.3.1 N-Nitrosamines

These represent a family of compounds that are believed to be extremely potent carcinogens in humans. Notable among these compounds is *N*-nitrosodimethylamine (NDMA). NDMA is a common

contaminant in the manufacture of some rocket fuels, and has been discovered at high concentrations in the vicinity of some rocket fuel production facilities (Mitch et al., 2003). However, NDMA is also found in many food items and in tobacco smoke. NDMA can also be formed as a by-product of halogen-based water and wastewater disinfection processes; therefore, groundwater contamination by NDMA has been observed in the vicinity of groundwater recharge zones, where halogenated wastewater effluents are used as the water source for recharge.

Two general classes of reaction mechanism have been identified as sources of NDMA formation: nitrosation and oxidation of unsymmetrical dimethylhydrazine. Several reaction pathways have been identified that fit into these reaction mechanisms.

The US EPA has defined a cleanup level of 0.7 ng/L for NDMA in groundwater, based on a 10^{-6} increased lifetime cancer risk. However, no Federal regulatory standard for NDMA has been identified (Najm and Trussell, 2001). Treatment of NDMA-contaminated water is complicated by the physico-chemical characteristics of the compound. In particular, NDMA has a water solubility of roughly 4 g/L, a relatively low Henry's law constant (2.6×10^{-4} atm M^{-1} at 20°C), and is fairly hydrophilic. Therefore, it is not amenable to treatment by conventional processes such as gas–liquid transfer, or sorption. To date, the most effective treatment strategy appears to be UV-based photolysis (Mitch et al., 2003).

17.5.3.2 Fuel Oxygenates

The 1990 amendments to the Clean Air Act mandated use of fuel oxygenates as a means of reducing air pollution (CO and O₃ formation potential) in urban areas (Shih et al., 2004). Based on these amendments, fuels sold in many urban areas for automobiles were reformulated or oxygenated by the addition of ethers or alcohols. Although no specific fuel oxygenate was specified or mandated by regulation, methyl *tert*-butyl ether (MTBE) is the most widely used compound in the United States because of low cost and generally favorable engineering characteristics (Shih et al., 2004; Deeb et al., 2003).

MTBE is highly soluble in water, it has a relatively low Henry's law constant, and it has a low affinity for most soils. Therefore, it is not easily removed from water by conventional physico/chemical treatment processes, and it tends to migrate rapidly in aquifers. MTBE and related compounds have low taste and odor thresholds; therefore, groundwater contamination at low concentrations can result in the loss of water potability (Froines et al., 1998). MTBE has been linked to several other acute health problems, including potential adverse effects within the central nervous system and the respiratory system. It has been identified as a carcinogen in rats and mice and has been identified as a possible human carcinogen; however, the issue of carcinogenicity in humans remains unresolved, as conflicting reports appear in the literature.

The greatest source of MTBE contamination in groundwater supplies is believed to be LUFTs (Shih et al., 2004). Leaks from underground fuel tanks are quite common, and the tanks themselves are often located in close proximity to wells used for public water supplies. Complicating this situation is the fact that the characteristics of MTBE (and other fuel oxygenates) are such that they tend to migrate faster and farther than most other petroleum-derived fuel constituents in the subsurface environment.

17.6 Radionuclides

17.6.1 Radioactive Decay

Each chemical element in the periodic table has a fixed number of protons, but can exist with a variety of neutrons. Elemental isotopes are nuclei with the same number of protons, but different numbers of neutrons. Radionuclides are typically written with the chemical symbol and a superscript to the left of the symbol that denotes the atomic mass (total number of protons and neutrons) of that isotope. For example, ¹²C and ¹⁴C are isotopes of the element carbon; each has 6 protons, but are associated with 6 and 8 neutrons, respectively. Elements that undergo radioactive decay as a result of an unstable nuclear structure are referred to as radionuclides. As part of the decay process, radionuclides release ionizing radiation in the form of alpha particles (α), beta particles (β), and gamma radiation (γ).

Alpha particles are composed of two protons and two neutrons. They interact with matter through electrostatic interactions between their positive charge and the negative charge of orbital electrons in the medium through which they travel. Because of this, α particles deposit large amounts of energy in a very small travel distance; the mean travel distance of a 4.7 million electron volt (MeV) α particle, such as that emitted from ^{237}Np , is only 3.3 cm through air (Knoll, 1989).

Beta decay results in the production of high-energy electrons or positrons. Interactions of β particles result in deposition of the β particle energy in the medium through which it travels. Beta particles can also undergo electron-nuclear reactions as well. Beta particles lose energy at a lower rate as compared to α particles, and therefore have greater penetrating power. Positrons are the antiparticle of the electron. Once a positron has deposited its energy in the medium, it will undergo an annihilation reaction with an electron, producing two 0.511 MeV photons. Electrons are expelled from the nucleus in the conversion of a neutron to a proton, while a positron is emitted for a proton to neutron conversion. Weakly interacting particles known as (anti)neutrinos are also produced in β decay, but are not the focus of this discussion as they have an extremely small interaction probability with matter.

Gamma rays are high-energy photons released by excited nuclei as they transition from an excited state in a radioactive decay process. The γ photons are usually emitted in conjunction with an α or β decay process, and interact primarily with atomic electrons through photoelectric absorption, Compton scattering, and pair production. Unlike α and β particles, which slow down gradually via Coulombic forces, γ radiation interacts by partial or complete energy transfer to atomic electrons in sudden, discrete interactions. As γ rays deposit energy in a medium, they transfer energy to atomic electrons, producing high-energy electrons in the medium that interact in the same manner as β decay high-energy electrons (Knoll, 1989). Gamma radiation has a much larger penetrating power relative to α or β radiation; the mean free path of a 0.66 MeV photon, such as that emitted by ^{137}Cs , is approximately 100 m in air.

Each of the types of radiation described above is known as ionizing radiation. That is, they are capable of transferring enough energy to atomic electrons to allow the electrons to escape from the atom. As radiation interacts with the medium through which it travels, it creates a path of excitation (promotion of electron to a higher energy shell) and ionization in its wake.

The rate of radioactive decay of a group of atoms is proportional to the number of atoms of that isotope that are present in the group. This principle can be represented mathematically by defining a decay constant, λ , as the proportionality constant for decay. Equation 17.17 relates the time rate of change of the number of nuclei to the decay constant.

$$\frac{dN}{dt} = -\lambda N \quad (17.17)$$

This equation yields a simple analytical solution shown in Equation 17.18.

$$N = N_0 e^{-\lambda t} \quad (17.18)$$

Using Equation 17.18, it is possible to determine the amount of time for half of a radionuclide to decay, as indicated by Equation 17.19. This time is referred to as the half-life of an isotope, $t_{1/2}$.

$$t_{1/2} = \frac{\ln(2)}{\lambda} \quad (17.19)$$

As an element decays, the parent nucleus is transformed into a daughter nucleus, which may or may not be stable. If the daughter nucleus is unstable, it can then be considered a parent nucleus with an associated stable or unstable daughter nucleus. In this way, decay chains from a parent nucleus can involve numerous decays and radioactive emissions.

17.6.2 Definitions and Units

With these equations defined, it is necessary to understand the units that are commonly used to describe radionuclide activity. The activity, A , of a radioactive substance is defined as the number of decays of that radionuclide per unit time; the mathematical definition of activity is shown in Equation 17.20.

$$A = \lambda N \quad (17.20)$$

Activity is typically reported in units of Curies (Ci), where each Ci is defined as 3.7×10^{10} disintegrations per second. The SI unit for activity is the Becquerel (Bq), defined as one disintegration per second. It is important to note that a short half-life (high λ) radionuclide produces much higher activity relative to a long half-life (low λ) radionuclide when they are present in equimolar concentrations.

It is sometimes necessary to be able to calculate the amount of energy deposited in a medium exposed to radiation to analyze ionizing radiation effects. The amount of energy deposited per unit mass is referred to as dose, D , and is measured in Grays (Gy). A Gray is defined as one Joule of energy deposited per kg of material and is equivalent to 100 rads (radiation absorbed dose).

The biological damage done by ionizing radiation to organisms (e.g., humans) is called the dose equivalent, H , and is related to the dose by a quality factor, Q (see Equation 17.21).

$$H = DQ \quad (17.21)$$

Dose equivalent is measured in Sieverts (Sv) using the product of the quality factor and dose in Grays (rems, or roentgen equivalent man, are also dose equivalent units where one rem is 0.01 Sv). The quality factor is related to the linear energy transfer (LET) of the radiation passing through the organism. High LET radiation does greater damage than lower LET radiation, and this is reflected by a higher quality factor for external α and β radiation as compared to γ radiation. Radiation energy is typically reported in units of millions of electron volts (MeV), while LET is typically given in units of kiloelectron volts per centimeter.

17.6.3 Important Radionuclides and Their Sources

There exist a variety of sources of radionuclides that can be dissolved in groundwater. Sources are typically categorized as natural or anthropogenic. Natural sources of radionuclides include formation in the atmosphere caused by cosmic irradiation, and presence in mineral deposits of long-lived radioisotopes of heavy elements and their associated daughters. Anthropogenic sources include nuclear power plants, nuclear weapons explosions and testing, medical, research, industrial, and pharmaceutical radionuclide applications, and mining wastes. A number of specific radionuclides are known to represent potential problems in groundwater systems. Each is described below.

17.6.3.1 Radon (^{222}Rn)

The only long-lived isotope of radon is ^{222}Rn , which undergoes α decay with a half-life of 3.82 d. This radionuclide is produced by decay of ^{226}Ra , and is often associated with deposits that have significant uranium concentrations (^{226}Ra and ^{222}Rn are part of the ^{238}U decay chain). ^{222}Rn represents a significant health concern in some homes, entering as a dissolved species in drinking water or directly from soil as a gas. Additional radiation is emitted from daughter products of ^{222}Rn as it decays to a stable element. ^{222}Rn is a naturally occurring radioisotope, and can be significant for uranium mining in terms of worker safety and waste disposal (Fetter, 1993).

17.6.3.2 Radium (^{226}Ra and ^{228}Ra)

^{226}Ra ($t_{1/2} = 1600$ yr) is a daughter of ^{230}Th , part of the ^{238}U decay chain, and decays subsequently to ^{222}Rn . As ^{228}Ra ($t_{1/2} = 5.8$ yr) is a daughter of ^{232}Th , both radium radionuclides are associated with uranium- and thorium-containing deposits. Radium is more soluble than either thorium or uranium,

and can therefore be transported in higher concentrations with an associated higher activity, particularly when considering the relatively short $t_{1/2}$ of ^{228}Ra . As radium is associated with uranium deposits, it is therefore a potentially important problem in mining wastes (Freeze and Cherry, 1979).

17.6.3.3 Uranium (^{238}U and ^{235}U)

Uranium in mineral deposits is composed of 99.3% ^{238}U ($t_{1/2} = 4.5 \times 10^9$ yr) and 0.7% ^{235}U ($t_{1/2} = 7.1 \times 10^8$ yr). As ^{235}U is fissile (split by low-energy neutrons), it is used as fuel for nuclear power reactors worldwide. Both uranium isotopes are long-lived and part of long decay chains. Each has numerous radioactive daughter nuclei that produce emissions before decaying to stable states. Uranium is typically mined in open pits or underground and concentrated to 65 to 70% uranium via flotation, dissolution, and solvent extraction processes. Further purification to U_3O_8 and enrichment to increase the fraction of the ^{235}U isotope can achieve desired levels of ^{235}U , with 3 to 4% being typical for nuclear power reactors (Choppin et al., 1995).

17.6.3.4 Neptunium (^{237}Np)

^{237}Np can be found in nuclear waste as the product of nuclear reactions (in a nuclear power reactor) converting ^{238}U to ^{237}U , which then β decays to ^{237}Np . It has a $t_{1/2}$ of 2.2×10^6 yr and undergoes α decay to ^{233}Pa , with associated daughter decays from that element and others. ^{237}Np is of great concern in high-level and spent nuclear fuel disposal as it is only slightly sorbed (i.e., high mobility) in many groundwater environments and has a long half-life (USDOE, 1995).

17.6.3.5 Tritium (^3H)

Tritium undergoes β decay with a half-life of 12.43 yr, producing ^3He as a daughter element. As tritium can combine with hydrogen and oxygen to form tritiated water, it poses a significant threat in terms of groundwater transport. Tritium is especially useful in delineating groundwater recharge occurring since the 1963 spike of tritium released by the United States and Soviet Union prior to the implementation of an above-ground testing treaty (Fritz et al., 1991). Tritium concentrations in natural waters have increased nearly tenfold since the advent of the nuclear age (Fetter, 1993). Tritium is formed naturally in the atmosphere when high-energy neutrons bombard ^{14}N , producing ^{12}C and ^3H . It is also produced in large quantities at nuclear power plants, and in nuclear weapons testing and production.

17.6.3.6 Carbon (^{14}C)

Like tritium, ^{14}C can be used for dating purposes, in this case for organic material. It decays by β emission to ^{14}N , and has a $t_{1/2}$ of 5715 yr. ^{14}C labeling of organic compounds is often done to provide sensitive detection methods for experiments with organic compounds. As it can be oxidized to soluble or gaseous $^{14}\text{CO}_2$, or form a variety of organic compounds, ^{14}C can pose a significant transport threat as a radionuclide. It can be produced naturally in the atmosphere when low-energy neutrons bombard ^{14}N , producing ^{14}C and ^1H . Anthropogenic sources include nuclear power plants, nuclear weapons testing, and research laboratories.

17.6.3.7 Fission Fragments (^{90}Sr , ^{99}Tc , ^{129}I , and ^{137}Cs)

Fission fragments are radioactive materials produced by fission of heavy isotopes such as ^{235}U . The fission reaction typically splits the heavy atom into two (sometimes three) lighter isotopes, with associated neutron, neutrino, and γ radiation emissions as well. The lighter isotopes are produced primarily in the atomic mass range of 80 to 155. Although a variety of fission fragments are produced, ^{90}Sr , ^{99}Tc , ^{129}I , and ^{137}Cs are of primary concern due to the significant amounts that are produced and their relatively long half-lives.

^{90}Sr decays by β emission to ^{90}Y with a $t_{1/2}$ of 29.1 yr. ^{90}Y then decays to stable ^{90}Zr via β emission. Strontium is a prominent fission fragment with no associated γ emissions. In high-level nuclear waste and spent fuel, it is one of the highest activity radioisotopes for the first 200 yr after fission ceases. It can be particularly dangerous when ingested by humans because it is known to accumulate in or near the bones, resulting in greater irradiation of sensitive bone marrow.

^{99}Tc undergoes β decay to ^{99}Ru with a $t_{1/2}$ of 2.1×10^5 yr. In addition to being a fission fragment, ^{99}Tc is also associated with medical and research wastes where it is used in diagnostic testing. ^{129}I is an important fission fragment as it β decays to stable ^{129}Xe with a long $t_{1/2}$ of 1.7×10^7 yr. It is also used in medical diagnostic tests and can therefore be found in low-level waste as well as spent fuel.

^{137}Cs emits γ and β radiation while decaying to stable ^{137}Ba and has a $t_{1/2}$ of 30.3 yr. Along with ^{90}Sr , ^{137}Cs is one of the high-activity isotopes in high-level nuclear waste for the first 200 yr after fission ceases.

17.6.4 Radioactive Waste Disposal

There are four different classes of radioactive wastes defined in United States regulations. *High-Level Waste* (HLW) is defined as radioactive waste produced in the reprocessing of nuclear fuel to recover usable uranium and plutonium. *Spent Nuclear Fuel* (SNF) is nuclear fuel that has been removed from a power reactor but has not been reprocessed. *Transuranic Waste* (TRU) consists of wastes from nuclear power or weapons production operations with atomic number greater than 92 (uranium), being primarily α emitters with long half-lives; it is typically associated with nuclear weapons production, fuel fabrication, and reprocessing. *Low-Level Waste* (LLW) is high volume, low radioactivity waste produced by industry, consumer products, research and medical labs, government, and nuclear power plants (Tang and Saling, 1990).

The United States does not reprocess commercial nuclear fuel, although Japan and most of Europe have chosen this option. As a result, US wastes associated with the nuclear power industry are primarily in the form of SNF, but with significant amounts of HLW and TRU from government (defense) related activity. The following discussion will focus on radioactive waste disposal options being pursued in the United States, but different strategies are being considered all over the world.

17.6.4.1 HLW and SNF Disposal

Ultimate disposal of HLW and SNF is unlikely to occur in a timely fashion, though the ultimate responsibility lies with the Federal government to solve the problem. At present, three Federal agencies within the United States participate in the management and disposal of HLW and SNF: the US EPA, the US Nuclear Regulatory Commission, and the US Department of Energy. The policies that define the approach to be used for HLW disposal are defined in the Nuclear Waste Policy Act of 1982.

The current US plan for ultimate disposal (storage) of HLW and SNF is to place it in the deep geologic repository at Yucca Mountain in Nevada. The repository will rely on an engineered barrier system (EBS) combined with site characteristics (geology) to contain the waste. A deep repository has the advantages of providing the best safety, flexibility, retrievability, convenience, maintenance, and feasibility relative to other disposal options (Faure, 1991). The US Department of Energy is currently developing plans for construction of the repository at Yucca Mountain (DOE, 2005a). The entire HLW and SNF disposal plan is far behind schedule due to technical difficulties, public fear and protests, and resistance from the host state. Because of this, there are plans to place the waste temporarily in monitored, retrievable storage (MRS). Once the Yucca repository is complete, waste will be transferred from the MRS to the final repository.

17.6.4.2 TRU Disposal

Transuranic wastes have been held in interim storage since 1974 while an ultimate disposal solution was pursued. The wastes will be placed in the Waste Isolation Pilot Plant (WIPP), located in a salt bed repository in New Mexico. Site characterization was completed in 1978 and an environmental impact statement filed in 1980. Full construction started in 1984, and the site began operations in March 1999 (DOE, 2005b). TRU disposal plans are notable because it is the only successful radioactive waste disposal program in the United States that has not been significantly delayed or halted.

17.6.4.3 LLW Disposal

LLW disposal is the responsibility of the states, with technical assistance from the federal government. To alleviate some of the difficulty of each state constructing an LLW landfill, the states have formed compacts where numerous states can contribute waste to a single site. Much like federal HLW disposal efforts, the

states are well behind schedule in meeting their planned opening dates for disposal sites. Currently, three low-level radioactive waste disposal facilities are operating in the United States. These facilities are located at Barnwell, SC; Hanford, WA; and Clive, UT (NRC, 2004).

17.6.5 Remediation

Remediation of radionuclide contaminated sites can be a costly and difficult endeavor. The chemical behavior of an atom in the environment is dictated by its atomic structure (not nuclear structure). Therefore, different isotopes of the same element behave identically in terms of chemical reactions. The essential difference between isotopes is that unstable elements will undergo radioactive decay. Because of this, radionuclide remediation techniques consist of the same methods that are used for inorganics and have been described previously in this chapter.

A fundamental difference between radionuclide and inorganic wastes is that radionuclides do not require direct contact to cause damage to an organism; radiation provides its own transport mechanism to reach a target. Because of this, providing for public and worker safety at a site that is contaminated by radioactive wastes may be more difficult to accomplish than at sites without such contamination. In addition, remediation techniques can concentrate a radionuclide (e.g., ion exchange or activated carbon) to such an extent as to create a hazardous radiation field; appropriate shielding and transportation arrangements of the concentrate medium must be considered.

It is sometimes possible to use the unstable characteristics of radionuclides to facilitate remediation. For radionuclides with short half-lives, it may only be necessary to contain the waste for an appropriate period of time before the unstable nuclei have decayed below the background radiation. In this manner, it is possible to use the decay properties of the nucleus to facilitate safe disposal of some radionuclide wastes. The idea of transmutation (bombarding radioactive waste with neutrons or protons) has been proposed as a way to stabilize radioactive nuclei, but has been discarded primarily because of high costs associated with this process.

17.7 Particulates

The definition of a particle is arbitrary and will depend on the application. For purposes of this presentation, particulate matter will refer to constituents that exist as a distinct solid phase, either within or apart from the groundwater itself. Though no absolute distinction is possible to define particles based on size, constituents with a size of 10 nm or greater may be considered to display particle behavior in groundwater system. Figure 17.13 provides a graphical representation of the spectrum of particle sizes that may be found in groundwaters, some important examples, and an indication of the physicochemical processes by which these constituents may be separated from the aqueous phase.

Microorganisms play an important role as particulate contaminants in groundwater systems. Important categories of microbial groundwater contaminants include viruses, bacteria, and protozoan cysts. Based on the arbitrary definition given above, viruses are representative of the smallest particles that are likely to be present in groundwater systems. Their small size facilitates mobility in groundwater systems; however, even though viruses are smaller than the pore size openings common to groundwater systems, their movement in aquifers is not unimpeded by soil particles. Like all constituents in groundwater systems, movement is largely governed by association with soil grains. Viruses display surface characteristics (large surface:volume ratio, net surface charge) that allow them to associate with soil grains. In the general case, groundwater supplies are assumed to be subject to possible contamination by pathogenic viruses, and disinfection processes for public water supplies are designed to address this source of contamination. Virus movement within aquifers is strongly influenced by electrostatic interactions with soil surfaces and Brownian motion. Microorganisms from the other categories (e.g., bacteria and protozoan cysts) will also move in groundwater systems; however, their movement within an aquifer is likely to be largely influenced by size exclusion and inertial processes, in contrast with the phenomena that govern movement of virus

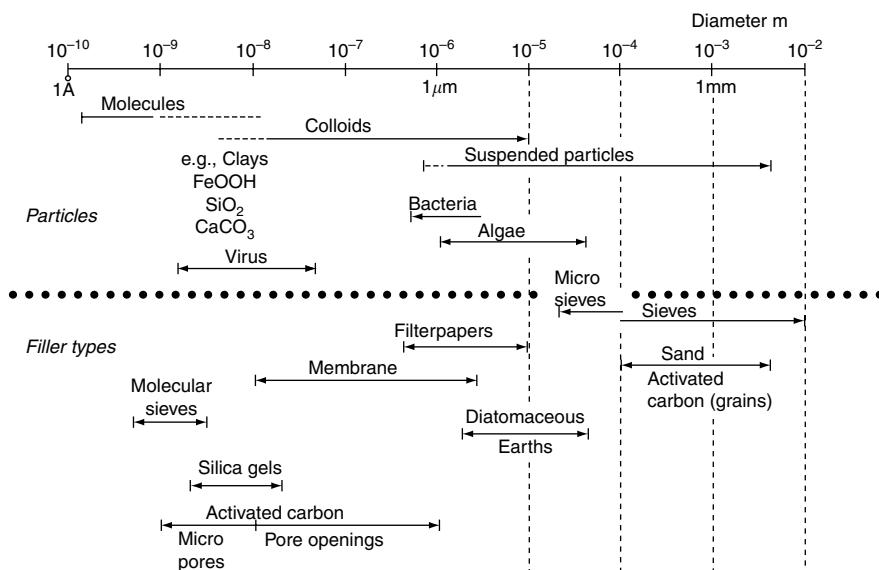

FIGURE 17.13 Spectrum of particle sizes that may be observed in natural waters, including groundwaters. Physical processes for separation of particles of a given size from the aqueous phase are also indicated. (From Stumm, W. 1977. *Environ. Sci. Technol.*, 11, 1066. With permission.)

particles. Groundwater supplies that are under the direct influence of surface waters are subject to more stringent disinfection requirements for potabilization due to the possible presence of protozoan cysts such as *Giardia lamblia* and *Cryptosporidium parvum*, which are generally more difficult to inactivate than either bacteria or viruses by conventional chemical disinfectants (e.g., chlorine).

Other, nonmicrobial colloidal particles can also exist and be transported in groundwater systems. Movement of these particles represents an important mechanism of transport for constituents that associate strongly with them. Important examples of compounds for which groundwater transport is enhanced by the presence of colloids include hydrophobic organic compounds, metals, and microorganisms.

Glossary

Acid/Base Reaction: A reaction in which proton transfer takes place.

Amphotericism: Ability of a solid surface or solute to display the characteristics of an acid or base.

Chemisorption: Association of solute (adsorbate) molecules with a solid (sorbent) as a result of relatively strong chemical bonds, similar in strength to covalent bonds.

Dense, Nonaqueous Phase Liquid (DNAPL): (Organic) liquids that are more dense than water, often being comprised of halogenated organic solvents.

Groundwater Contaminant: Groundwater constituent, often viewed as undesirable, introduced to the subsurface either directly or indirectly as a result of human activity.

High Level Waste (HLW): Radioactive waste produced in the reprocessing of nuclear fuel.

Humic Substances: Stable organic products of the natural decay of plants and animals.

Ion Exchange: Association of charged solutes (ions or complexes) with a solid (sorbent) as a result of electrostatic interactions.

Light Nonaqueous Phase Liquid (LNAPL): (Organic) liquids that are less dense than water, often being comprised of hydrocarbons or hydrocarbon mixtures, such as those that result from petroleum refining.

Low Level Waste (LLW): High volume, low radioactivity waste produced from many industrial and commercial processes.

Micelle: Pseudo-phase agglomeration of (organic) surfactant molecules in which polar “ends” of the surfactant molecules are directed outward and the nonpolar “ends” are directed inward.

Nonaqueous Phase Liquid (NAPL): Usually comprised of organic compounds having extremely low aqueous solubilities.

NO_x: Nitrogen oxides — common atmospheric constituents produced by a number of natural and anthropogenic processes, including combustion of fossil fuels.

Oxidation/Reduction (Redox) Reaction: Reaction in which electron transfer takes place.

Particle: Constituents that exist as a distinct solid phase within or apart from a solvent; oftentimes particles are operationally defined as constituents greater than a given size (e.g., 10 nm).

p ϵ : Negative log₁₀ of electron (e^-) activity; a representation of electron availability in solution.

pH: Negative log₁₀ of proton (H^+) activity; a representation of proton availability in solution.

Physisorption: Association of solute (adsorbate) molecules with a solid (sorbent) as a result of relatively weak physical bonds.

Polarity: A relative term describing the distribution of electrons (or electronic charge) around a molecule. Highly polar molecules generally contain atoms of widely varying electronegativity.

Radionuclides: Unstable elemental isotopes that release ionizing radiation.

SO_x: Sulfur oxides — common atmospheric constituents produced by a number of natural and anthropogenic processes, including combustion of fossil fuels.

Transuranic Waste (TRU): Wastes from nuclear power or weapons production having an atomic number greater than 92.

Zero Point of Charge (zpc): pH at which net surface charge is zero.

Further Information

Clark (1996) is a reference text in which transport phenomena are presented in terms of environmental processes. US EPA (1989) provides basic information on many of the fundamental phenomena that govern the fate and transport of subsurface contaminants. Freeze and Cherry (1979) is perhaps the most frequently cited reference text on the subject of groundwater, and includes an excellent presentation of many important aspects of groundwater chemistry. Martell and Smith (1974–1989) represents a critical evaluation of stability (equilibrium) constants for complexation and precipitation reactions involving organic and inorganic aqueous constituents. This series of six volumes represents the most comprehensive summary of data on the subject. Snoeyink and Jenkins (1980) is an intermediate-level text on the subject of aquatic chemistry. Stumm and Morgan (1996) is the third edition of this advanced text on the subject of aquatic chemistry and is perhaps the most frequently cited reference on the subject.

18.1 Introduction

The modeling of transport in porous media continues to be an important and challenging problem with applications in groundwater pollution, bioremediation of soils, petroleum engineering, food science engineering, drug delivery systems, and blood flow in tissues to name a few. Over the past several decades the need for a multidisciplinary approach to this problem has been recognized and collaborative work is becoming the rule rather than the exception. A combination of hydrologists, mathematicians, chemists, microbiologists, engineers, and physicists is needed to maintain progress in the modeling and prediction of flow and transport in porous media for both nonreactive and reactive solutes. This chapter focuses on the nonreactive case while the subsequent chapter examines the reactive case.

We employ the language commonly used in hydrology, but the reader should keep in mind that the transport problem is not limited to this discipline. The current understanding of transport of tracers (dissolved or suspended) is examined with emphasis on passive tracers. Due to the natural variability of geologic formations, that is, heterogeneity, the problem is extremely complex. Early theories assumed homogeneity of the medium but later this assumption was found to be inadequate for natural formations; now, sophisticated stochastic models and approaches to account for natural heterogeneity are the rule. The mathematical and physical challenges involved in model development, the design of new experiments to determine parameters and verify the models, plus the need for better numerical methods to solve the resulting equations in reasonable computational time are all necessary components for new theories.

We begin with a discussion of different types of heterogeneities and the importance of scale, as well as a discussion of the most important driving processes that lead to dispersion. Models can be developed from two perspectives, Eulerian or Lagrangian and models may be either deterministic or stochastic. The classical deterministic model is presented along with a variety of advanced models. These models are subsequently compared and the advantages and disadvantages discussed. The chapter concludes with a brief discussion on laboratory and field-scale experiments.

18.2 Hierarchical Heterogeneity

The concept of homogeneity is inherently linked to the concept of the scale of observation and the existence of a representative elementary volume (REV) (in the sense of Bear, 1972). Porous media may appear homogeneous at one scale and heterogeneous at another, and hence, the scale of observation is critically important. Heterogeneous media vary widely in structure and function, but are invariably hierarchical.

Hierarchical heterogeneity can be classified as either *structural* or *functional*. In a structural hierarchy, the porous media can be decomposed into successively nested, interacting, physical subunits. Functional hierarchy relates to the transport processes within the medium. Often the two types of hierarchy are intimately connected.

One can further break structural (functional) hierarchy into *discrete* and *continuous* types. In a discrete hierarchical medium, a finite number of nested structural subunits (subprocesses) exist as opposed to a continuous hierarchy where no clear-cut decomposition is in evidence and the number of subunits goes to infinity. In discrete hierarchical media, every level has a specific set of state variables of relevance. Examples include the pore-scale velocity at the pore scale and the Darcy velocity in a homogenized system. As one moves up the hierarchy, only portions of the information from the level below are retained by the system; this loss of information leads to the appearance of new constitutive variables at each scale. The windows associated with the experimental apparatus must correspond to the discrete hierarchical structure of the porous medium to decouple the scales and propagate information over scales.

Continuous hierarchy is associated with “self-organization” and is evident in long-range correlation among the dynamic or static processes. One example is a fractal porous medium whose properties have infinite correlation lengths (Wheatcraft and Tyler, 1988). Information transfer in such media cannot be decomposed as in the discrete media, but can be scaled (compressed). The constitutive variables for such a system are often wave vector (dual to spatial displacement) and frequency (dual to time elapsed) dependent and appear in nonlocal theories.

In the following section we discuss the measurement and theoretical issues associated with multiple scales.

18.3 Role of Multiple Scales

It is important to understand the role played by multiple scales when developing models and hence also in the design of experiments. Heterogeneity may evolve over many orders of magnitude of space and time and, depending on the nature of the problem, different models may be required at different scales. The requisite

physics can be rigorously investigated using upscaling techniques such as mixture theory, mathematical homogenization, stochastic perturbation tools, and central limit theorems (Cushman et al., 2002). The assumptions involved in the mathematical analysis depend on scale separation and scale of observation.

The scale of the window of observation must be accounted for in the models. The attribute that one wants to measure or describe must be well defined at that scale. When one measures an attribute it is often a “point” measurement, where a “point” is defined by the appropriate scale for the problem. Changing the resolution or changing the scale may radically change the value measured and care should be taken in measurement to ensure that the appropriate attribute and the appropriate resolution are used to provide a meaningful value for the model. When the window of observation or the resolution increases, plateaus in measured attributes may exist indicating a discrete hierarchy, while at other times they will not, indicating an evolving (continuous) heterogeneity. In the case of discrete hierarchies, constitutive relations will be local in the asymptotic limit while in the continuous case they will be nonlocal. Discussions of measurement techniques for hierarchical porous media can be found in Cushman (1990, 1997).

18.4 Dispersion

Dispersion is a measure of solute spreading from the mean concentration and can be influenced by a variety of factors. The scale of observation and the processes of interest are key in determining the dominant dispersive processes. Several types of dispersion are listed below:

1. *Diffusion driven dispersion* is the result of particle interactions at the pore scale. The scale at which this is significant will depend on the particle size as well as the observation window. Diffusion takes place regardless of the presence of a porous structure, but may be affected by the porous structure.

2. *Heterogeneity driven dispersion* is that most commonly discussed in porous media literature. The porous matrix causes velocity fluctuations to occur over a variety of scales. Variations in the hydraulic conductivity, possibly over several orders of magnitude (Gelhar, 1986) lead to velocity fluctuations which in turn affect transport of a dissolved solute. Heterogeneous systems naturally display larger velocity fluctuations than homogeneous systems and hence greater mixing. The characterization of this is usually evident in the macrodispersivity tensor defined at the Darcy or higher scales. In general, larger scales lead to larger macrodispersivity tensors.

3. *Viscosity driven dispersion* occurs when two immiscible liquids have different viscosities. Viscous fingering leads to dispersive mixing that would not have occurred without the presence of viscous forces and surface tension. Parlange has done significant work on fingering (Liu et al., 1994; Selker et al., 1996).

4. *Buoyancy induced dispersion* occurs when the fluids or constituents have varying density. Examples include: Rayleigh–Benard convection where fluids of different temperatures drive mixing; air bubbles in water; and mixtures of DNAPLs (dense nonaqueous phase liquids) and LNAPLs (light nonaqueous phase liquids).

5. In other situations the transported particles themselves may enhance dispersion; two examples include microbial and colloidal systems. The transport of microbes in a fluid may have increased dispersion due to microbial motility (Berg, 2000; Bonilla and Cushman, 2002). Charged or magnetic colloids may also be affected by the presence of externally applied electric or magnetic fields.

18.5 Eulerian and Lagrangian Perspectives

Transport may be modeled from two different perspectives, Eulerian and Lagrangian or, in some cases, a mixture of these. Models can be continuous or discrete. The perspective depends on the mathematical approach one wishes to employ which in turn may be dictated by the situation as well as available data. In the Lagrangian approach, a particle is referenced from its initial location and a description of its evolution is developed. Hence in the Lagrangian approach the viewer observes the world from the location of a particle rather than a fixed location in space and uses the particle pathline or its statistics to construct

models. The Eulerian perspective describes the physics and attribute evolution at a fixed location in space. Translation between the two modeling perspectives is always possible in principle, but not always possible in practice without simplifying assumptions. Additionally, it is difficult to transfer data from one perspective to the other.

18.6 Classical Deterministic Models

Most classical deterministic models for transport employ Darcy's law in the flow problem to obtain the velocity field which can then be utilized with Fick's law and mass conservation of a solute. These conservation laws rely on a discrete scale separation (e.g., Darcy vs. pore). The classical deterministic advection-dispersion equation (ADE) can be derived from rigorous approaches that allow for specific characterization of the material parameters (conductivity, dispersivity). These approaches include homogenization (Sanchez-Palencia, 1980), generalized Taylor–Aris–Brenner (Shapiro and Brenner, 1988), volume averaging in the sense of Quintard and Whitaker (1987), mixture theory and hybrid mixture theory (Cushman et al., 2002), and renormalization (Creswick et al., 1992). A number of these tools are reviewed in Cushman et al. (2002). These models revolve around assumptions made at either the microscale (pore scale) and/or the macroscale (in this case the Darcy scale) to yield the constitutive theory. Theories that lead to more complex and generally non-local models for flow and transport will be discussed in the subsequent section. In this section we present the deterministic ADE without derivation.

The localized mass balance equation for a constituent is

$$\frac{\partial(nC)}{\partial t} + \nabla \cdot \mathbf{F} = nr \quad (18.1)$$

where C is the concentration, n is the porosity (volume fraction in mixture theory), \mathbf{F} is the mass flux, and r is the rate of solute mass produced per unit volume. Since this chapter considers only nonreactive solutes, $r = 0$ unless there is mass added from an exterior source. In general however, $r = r(\mathbf{x}, t)$ for a conservative tracer and $r = r(C, \mathbf{x}, t)$. By employing an expression for the flux that includes macroadvection as well as local dispersion, the ADE is

$$\frac{\partial(nC)}{\partial t} + \nabla \cdot (n\mathbf{V}C) - \nabla \cdot (n\mathbf{D} \cdot \nabla C) = nr. \quad (18.2)$$

\mathbf{D} is the local (symmetric) dispersion tensor. Equation 18.2 can be regarded as an equation for the average concentration on a scale large enough so that the effects of individual pores are not observed. At scales smaller than the REV this will not hold due to variations in the pore-scale velocity and similarly, in heterogeneous systems, at scales much larger than the REV this equation breaks down. Often \mathbf{D} is taken as the effective dispersion tensor or the macrodispersivity tensor at the larger scales. After solving the flow problem, with the definition of the velocity depending on the scale of measurement and interest, the transport equation is solved.

As the deterministic ADE has been found to break down for many natural and laboratory media, we examine some alternate deterministic approaches and stochastic approaches in the next two sections that lead to nonlocal generalizations of the ADE.

18.7 Alternate Approaches

18.7.1 Statistical Mechanical

Generalized hydrodynamics utilizes statistical mechanical tools with appropriate probability densities to examine the evolution of the concentration in space and time. This approach was developed by Cushman and Ginn (1993) and is described in detail in Cushman (1997).

In a statistical mechanical approach, the N particles of the solute are labeled $1, \dots, N$ and this collection of particle locations by $\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_N)$. One then examines the probability, f , of particles having a certain displacement. The concentration, C , is defined by

$$C(\mathbf{x}, t) = \sum_{i=1}^N \int_{V^N} \delta(\mathbf{x} - \tilde{\mathbf{X}}_i) f(\tilde{\mathbf{X}}) d\tilde{\mathbf{X}} \quad (18.3)$$

with δ the Dirac delta function, V is the volume of possible displacements for a particle, i the particle label, and tilde indicates particle displacement from the initial time. It is assumed that the probability measure for the ensemble is conserved in time and that the mean increment of the displacement depends on time lag alone and not on the particle label. If the mean velocity is not dependent on space, then the latter assumption holds even if the velocity is nonsteady. The model can be used for a wide class of media that have no scale separation. The resulting equation for the concentration is

$$\begin{aligned} \frac{\partial C}{\partial t} &= -\nabla \cdot (\mathbf{V}C) + \nabla_x \cdot \int_0^t \int_{\mathbf{R}^3} \mathbf{D}_1(\mathbf{y}, t, \tau) C(\mathbf{x} - \mathbf{y}, t - \tau) d\mathbf{y} d\tau \\ &\quad + \nabla_x \cdot \int_0^t \int_{\mathbf{R}^3} \mathbf{D}_2(\mathbf{y}, t, \tau) \cdot \nabla_{\mathbf{x}-\mathbf{y}} C(\mathbf{x} - \mathbf{y}, t - \tau) d\mathbf{y} d\tau \end{aligned} \quad (18.4)$$

The first term on the right-hand side results from mean convection where \mathbf{V} is the average velocity of the particles. The second and third terms are nonlocal terms containing information from the convective and dispersive fluxes, respectively. This equation is exact with the appropriate values of the dispersion tensors (from a deterministic modeling viewpoint).

This general model will reduce to the ADE in the limit of long time and large distances which can be seen by a Taylor series expansion in Fourier-Laplace space. The dispersion tensor \mathbf{D}_2 resembles the classical dispersion tensor, but is a generalization since it is non-constant and shows up in an integral. The term \mathbf{D}_1 plays the role of a nonlocal convective velocity. If these two dispersion tensors depend only on τ and \mathbf{x} , which occurs when mean displacement depends on time lag alone, then Equation 18.4 is called “convolution-Fickian.”

Particle tracking experiments (Section 18.10.1) have been performed to examine this theory and calculate the dispersion tensor when \mathbf{D}_1 is zero. In the large spatial limit (hence long time) the dispersion tensor \mathbf{D}_2 may go to the expected value of the effective dispersion tensor as estimated by the velocity covariance (Figure 18.1). This indicates experimentally that the classical ADE is valid for some media at large scales, but at smaller scales a more general approach is always necessary.

18.7.2 Continuous Time Random Walks

Like the previous method, Continuous Time Random Walk (CTRW) models may be used for highly heterogeneous systems. One can consider the medium as a random network where the cloud of particles executes a series of transitions with variable velocity. Since the CTRW is for highly heterogeneous systems, averaging over an REV is not useful and the effective volume contributing to particle flux (hence change in concentration) can be allowed to vary over the system. The main ideas and connections to the ADE are presented below. Additional details and information on the CTRW can be found in a variety of references (e.g., Scher and Montroll, 1975; Metzler and Klafter, 2000; Berkowitz et al., 2002; Dentz and Berkowitz, 2003; Cortis and Berkowitz, 2004).

A “Master Equation” is used to express the change of concentration in time via the transition rate from one spatial location to another. This master equation represents the transition density for trajectories of

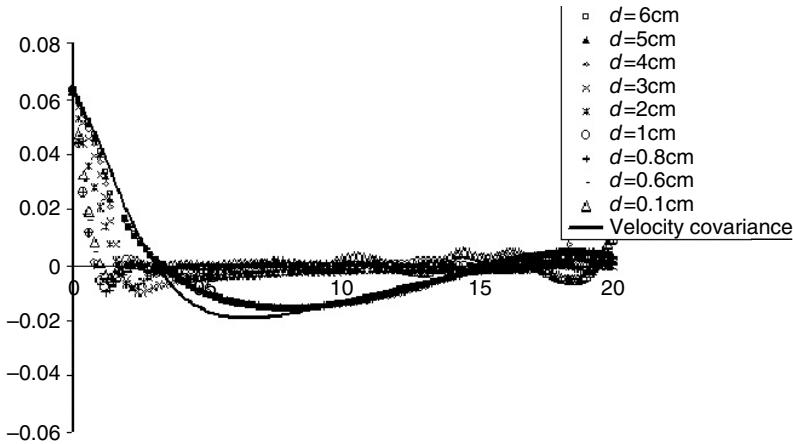

FIGURE 18.1 The generalized dispersion tensor for the transverse direction of the homogeneous porous medium compared to the velocity covariance. Here $k = 2\pi/d$ where k is the magnitude of the wave vector dual to the wave vector for the transverse direction. Increasing d corresponds to increasing the scale of observation for the system. In the Fickian limit the time integral of the velocity covariance is the dispersion tensor. As the spatial scale increases, the generalized dispersion tensor approaches the value of the classical dispersion tensor. (Figure 20 in Moroni and Cushman, 2001, *Phys. Fluids* 13, 81–91.)

a solute particle. An ensemble average over all possible paths is used to develop the Generalized Master Equation (GME):

$$\frac{\partial C(\mathbf{s}, t)}{\partial t} = - \sum_{\mathbf{s}'} \int_0^t \phi(\mathbf{s}' - \mathbf{s}, t - t') C(\mathbf{s}, t) dt' + \sum_{\mathbf{s}'} \int_0^t \phi(\mathbf{s} - \mathbf{s}', t - t') C(\mathbf{s}', t) dt' \quad (18.5)$$

where $C(\mathbf{s}, t)$ is the concentration, ϕ is a function of $\psi(\mathbf{s}, t)$ which is the probability rate per unit time for displacement \mathbf{s} in time t . The GME is equivalent to the CTRW

$$R(\mathbf{s}, t) = \sum_{\mathbf{s}'} \int_0^t \psi(\mathbf{s} - \mathbf{s}', t - t') R(\mathbf{s}', t') dt'$$

with

$$C(\mathbf{s}, t) = \int_0^t \left[1 - \int_0^t \sum_{\mathbf{s}'} \psi(\mathbf{s}, t') dt' \right] R(\mathbf{s}, t') dt' \quad (18.6)$$

where $R(\mathbf{s}, t)$ is the probability a walker arrives at \mathbf{s} at time t . The term in brackets is the probability a walker remains at a fixed site.

The GME does not separate terms based on advection and dispersion, but this can be accomplished by assuming relatively homogeneous regions exist and concentration varies slowly over a finite length scale. Additionally one defines the “effective velocity”, \mathbf{v}_ψ , and “dispersion tensor”, Φ_ψ , as:

$$\mathbf{v}_\psi \equiv \sum_{\mathbf{s}} \phi(\mathbf{s}, t) \mathbf{s} \quad \text{and} \quad \Phi_\psi \equiv \sum_{\mathbf{s}} \phi(\mathbf{s}, t) \frac{1}{2} \mathbf{s} \mathbf{s}^\top \quad (18.7)$$

yielding the form of the GME

$$\frac{\partial C(\mathbf{s}, t)}{\partial t} = \sum_{\mathbf{s}'} \int_0^t dt' \left[\phi(\mathbf{s}' - \mathbf{s}, t - t') (\mathbf{s}' - \mathbf{s}) \cdot \nabla C(\mathbf{s}, t') \right. \\ \left. + \phi(\mathbf{s} - \mathbf{s}', t - t') \frac{1}{2} (\mathbf{s}' - \mathbf{s})(\mathbf{s}' - \mathbf{s}) : \nabla \nabla C(\mathbf{s}, t') \right] \quad (18.8)$$

The colon represents the tensor product. This equation has the same form as Equation 18.4 with the integral in Equation 18.4 replaced by the summation in Equation 18.8. Thus this CTRW is a special case of the generalized hydrodynamics approach. If ψ has finite first and second moments in t , then an expansion can be performed to relate the GME to the ADE. Additionally, it can reduce to equations that are fractional in time or fractional in space (FADE) which will be discussed in the next section. As mentioned, most of these models are variants of the generalized model in Section 18.7.1.

18.7.3 Fractional Advection-Dispersion

The Fractional Advection-Dispersion Equation (FADE) generalizes the ADE and creates nonlocality through the presence of fractional (spatial) derivatives. Although it has been shown that both the generalized hydrodynamics approach (Cushman and Ginn, 2000) and the CTRW approach (Berkowitz and Scher, 2001; Berkowitz et al., 2002) can be simplified using certain assumptions to obtain the FADE, it is worthwhile to treat the FADE (Meerschaert et al., 1999; Benson et al., 2000, 2001) as a separate topic for discussion due to the extensive theoretical, experimental and numerical background that has been developed for this approach. In particular, the one-dimensional FADE has useful closed-form solutions (Benson et al., 2001).

The FADE was developed for advective-dispersive transport in flow fields that are nonuniform on multiple scales. If the tails of a concentration plume are power laws, that is, “heavier” than the standard Gaussian process, anomalous dispersion is taking place and the FADE is often applicable. In multidimensional form, the FADE is given by

$$\frac{\partial C}{\partial t} = -\mathbf{V} \cdot \nabla C + \mathbf{D} \nabla_M^\alpha C \quad (18.9)$$

where \mathbf{V} is the drift velocity, \mathbf{D} is the dispersion tensor that helps describe the spread of the process, and ∇_M^α is the fractional derivative that specifies the weight of the tails of the plume (α) and M , the skewness of the movements (a random measure on the unit sphere). The fractional derivative is defined by its Fourier transform and hence incorporates nonlocality into the model. This can be seen easily in one-dimension, with a uniform M , the fractional derivative has a real space representation:

$$\frac{d^\alpha f(x)}{d(\pm x)} = \frac{(\pm 1)^n}{\Gamma(n - \alpha)} \frac{d^n}{dx^n} \int_0^\infty \xi^{n-\alpha-1} f(x \mp \xi) d\xi \quad (18.10)$$

where n is the smallest integer greater than α . Through this expression one sees that nonlocality is incorporated into the FADE through the fractional derivative. If $\alpha = 2$, the plumes are Gaussian and the fractional derivative with a uniform mixing measure reduces to the standard Laplacian and thus the ADE is recovered. The FADE is closely connected to Lévy flights as the equation can be used to describe the transition density for such a flight.

To model transport, one needs to estimate the order of the fractional derivative and constant \mathbf{D} . Solutions to Equation 18.9 are obtained via Laplace or Fourier transforms. Benson et al. (2001) has examined the FADE for experimental data from the MADE site (Figure 18.2). The data is from large-scale natural gradient tracer tests with strong heterogeneity. Both *a priori* and *a posteriori* parameter estimation

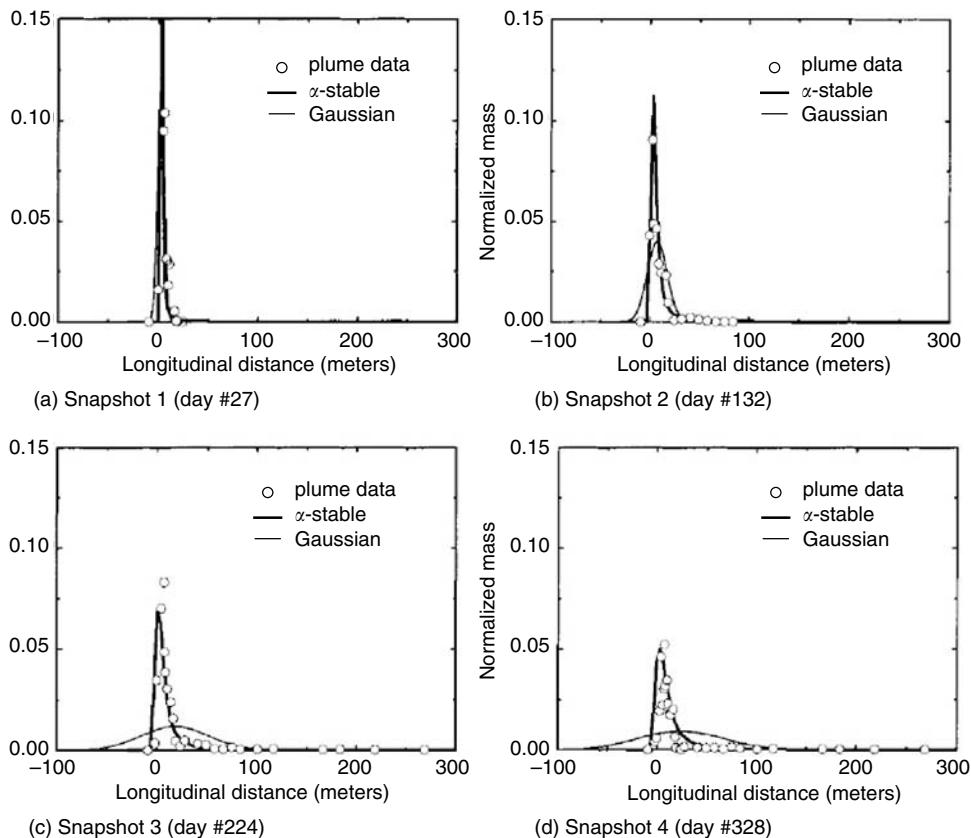

FIGURE 18.2 MADE tracer test plume comparisons compared to the predictions from the FADE(α -stable) and the ADE. The measured heavy tail plumes are much better suited to prediction from the FADE than the ADE. Analytic solutions for the FADE and ADE were obtained by numerical integration. (Figure 4 from Benson et al., 2000, *Water Resour. Res.* 36, 1413–1423.)

were investigated and it was found that although the ADE fails to model the conservative tracer accurately, the FADE concentration profiles are more accurate over all spatial and temporal scales than classical models. An alternate way the parameter α can be determined is from Lagrangian data via the finite size Lyapunov exponent (Kleinfelter et al., 2005).

18.7.4 Stochastic Perturbation

Stochastic tools have been extensively employed to model flow and transport in porous media over the past three decades. While all methods cannot be discussed in detail here, we will highlight some of the main approaches and some simple resulting equations. Stochastic analysis assumes we have incomplete knowledge of the system and can incorporate this uncertainty into the model through probability distributions of material parameters of the system (i.e., conductivity). In stochastic analysis of transport, the concentration is assumed to be a random function of space and time and can be examined spatially in terms of its mean, variance, and higher moments.

18.7.4.1 Fourier Transform Method and Green's Function Approaches

Consider the traditional ADE with C and V random functions,

$$\frac{\partial C}{\partial t} + \nabla \cdot (VC) - \nabla \cdot (\mathbf{D} \cdot \nabla C) = 0 \quad (18.11)$$

and decompose C and \mathbf{V} into their mean and fluctuating parts,

$$C = \bar{C} + c \quad \text{and} \quad \mathbf{V} = \bar{\mathbf{V}} + \mathbf{v}. \quad (18.12)$$

It is assumed the conductivity field is spatially random resulting in a stochastic velocity and thus randomness in C . The overbar, which indicates an average or expectation, is the average over all realizations of porous formations consistent with the specific conductivity distribution.

As a simple example of this method, assume an infinite domain with a diagonal dispersion tensor, constant diagonal elements, and constant mean velocity in the direction of mean flow (call this direction x_1). Using Equation 18.12, the mean for Equation 18.11 can be rewritten as

$$H\bar{C} = -\nabla \cdot \bar{\mathbf{v}} \quad (18.13)$$

and the mean removed equation (Equation (18.12) minus (18.13)) written as

$$Hc = -\mathbf{v} \cdot \nabla \bar{C} - \nabla \cdot (\mathbf{v}c) + \nabla \cdot (\bar{\mathbf{v}}c) \quad (18.14)$$

where the operator H is given by

$$H = \frac{\partial}{\partial t} + \bar{V}_1 \frac{\partial}{\partial x_1} - \nabla \cdot (\mathbf{D} \cdot \nabla) \quad (18.15)$$

with the assumption that the velocity is divergence free $\nabla \cdot \mathbf{v} = 0$. One can use Green's functions to get the equation for the concentration fluctuation:

$$\begin{aligned} c(\mathbf{x}, t) = & \int_0^t \int_{\mathbb{R}^3} B(\mathbf{x} - \mathbf{y}, t - \tau) [-\mathbf{v} \cdot \nabla \bar{C}(\mathbf{y}, \tau) - \nabla \cdot (\mathbf{v}(\mathbf{y}) \bar{C}(\mathbf{y}, \tau))] \\ & + \nabla \cdot (\bar{\mathbf{v}}(\mathbf{y}) c(\mathbf{y}, \tau)) d\mathbf{y} d\tau \end{aligned} \quad (18.16)$$

with

$$B(\mathbf{x}, t) = \prod_{i=1}^3 \exp \left[-\frac{(x_i - \bar{V}_i t)^2}{4D_{ii}t} \right] (4\pi D_{ii}t)^{-1/2}. \quad (18.17)$$

Notice that Equation 18.13 contains a forcing function on the RHS, and Equation 18.16 can be used to estimate this term. Multiply Equation 18.16 by \mathbf{V} and then take the average. Assume that $\partial v_i(\mathbf{y}) v_j(\mathbf{y}) c(\mathbf{y}, \tau) / \partial y_i$ is small compared to the other terms and that the velocity covariance function is stationary. If one further assumes that the gradient of the mean concentration varies slowly relative to the remainder of the integrand, it may be removed and the resulting equation is:

$$\mathbf{q} = \overline{\mathbf{V}(\mathbf{x}, t) c(\mathbf{x}, t)} = - \left[\int_0^t \int_{\mathbb{R}^3} B(\mathbf{y}, t - \tau) \mathbf{R}(\mathbf{y}) d\mathbf{y} d\tau \right] \cdot \nabla \bar{C} = -\mathbf{D}'(t) \cdot \nabla \bar{C} \quad (18.18)$$

Equation (18.18) is called quasi-Fickian and \mathbf{R} is the velocity covariance. The mass balance is $\partial C / \partial t = -\nabla \cdot \mathbf{q}$. Classical Fickian dispersion is obtained when $\mathbf{D}'(t)$ is replaced by $\mathbf{D}'(\infty)$. This is the classical result

of Gelhar et al. (1979) obtained through spectral integral representation. If the flux is convolution-Fickian, then the mass balance takes the form

$$\frac{\partial \bar{C}}{\partial t} + \bar{V}_1 \frac{\partial \bar{C}}{\partial x_1} - \nabla \cdot (\mathbf{D} \cdot \nabla \bar{C}) - \int_0^t \int_{\mathbb{R}^3} \mathbf{D}'(\mathbf{x} - \mathbf{y}, t - \tau) \cdot \nabla_y \bar{C} d\mathbf{y} d\tau = 0 \quad (18.19)$$

where $\mathbf{D}'(\mathbf{x}, t) = B(\mathbf{x}, t)\mathbf{R}(\mathbf{x})$ is the generalized dispersion tensor. Equation 18.18 can be written as an algebraic expression by converting it to Fourier–Laplace space, solved and then numerically inverted back to real space.

The above discussion can be generalized to a finite domain and Equation 18.16 and Equation 18.17 will still be obtained, but boundary conditions can be imposed and the solution for c would look the same, but the B would now be a Green's function with the integral over appropriate domain and include boundary integrals. Neuman has pioneered work in this area (Hsu et al., 1996).

18.7.4.2 Lagrangian Perturbation Approach

Next we discuss a Lagrangian approach pioneered initially by Simmons (1982) and generalized by Dagan (1994) and Dagan et al. (1992). In the Lagrangian perturbation approach, one again assumes the classical ADE holds with steady, divergence free, Darcy velocity and the mean flow aligned in the x_1 direction and add in the condition of no dispersion. Label the trajectory of a fluid ‘particle’ by \mathbf{Y} originating at the spatial point $\mathbf{y} = \mathbf{y}^0$ at $t = t^0$. \mathbf{Y} satisfies

$$\frac{d\mathbf{Y}}{dt} = \mathbf{V}(\mathbf{Y}) \quad (18.20)$$

where $\mathbf{y} = \mathbf{Y}(t; t^0, \mathbf{y}^0) = \mathbf{Y}(t - t^0; \mathbf{y}^0)$. Change to the natural coordinates

$$\tau(\mathbf{y}; \mathbf{y}^0) = t - t^0 \quad \eta(\mathbf{y}; \mathbf{y}^0) = X_2(\tau; \mathbf{y}^0) \quad \xi(\mathbf{y}; \mathbf{y}^0) = X_3(\tau; \mathbf{y}^0) \quad (18.21)$$

with positive velocity in the mean flow direction. The travel time, τ , to reach the control plane $t_1 = X_1(t - t^0; \mathbf{y}^0)$ is obtained by inverting Equation 18.20. The time, τ , is the “first passage time” for a particle to cross a control plane at x_1 . The coordinates (τ, η, ξ) satisfy

$$\begin{aligned} \frac{d\tau}{dy_1} &= \frac{1}{V_1(y_1, \eta, \xi)}; \quad \frac{d\eta}{dy_1} = \frac{d\eta}{d\tau} \frac{d\tau}{dy_1} = \frac{V_2(y_1, \eta, \xi)}{V_1(y_1, \eta, \xi)} \\ \frac{d\xi}{dy_1} &= \frac{d\xi}{d\tau} \frac{d\tau}{dy_1} = \frac{V_3(y_1, \eta, \xi)}{V_1(y_1, \eta, \xi)} \end{aligned} \quad (18.22)$$

subject to $\tau = 0$, $\eta = y_2^0$, and $\xi = y_3^0$ for $y_1 = y_1^0$. Hence for the steady velocity, $y_2 = \eta(y_1; \mathbf{y}^0)$ and $y_3 = \xi(y_1; \mathbf{y}^0)$ are equations of the streamlines. In this coordinate system along the above streamlines,

$$\frac{\partial C}{\partial t} + \frac{\partial C}{\partial \tau} = 0 \quad (18.23)$$

This equation has been solved to give

$$C(\mathbf{y}, t) = \int_{V^0} \frac{C_0(\mathbf{y}^0)}{V_1(y_1, \eta, \xi)} \delta(y_2 - \eta) \delta(y_3 - \xi) d\mathbf{y}^0 \quad (18.24)$$

where the integral is over the region where the initial concentration is nonzero.

To compare the results of the Fourier transform (Green's function) method and the Lagrangian perturbation methods, one can examine the centered spatial moments as long as d_{ij} is set to zero in the former method. The zeroth and first order moments can easily be seen to be equivalent, but the other moments must be evaluated numerically. If a model for fluctuating conductivity covariance is assumed, then comparisons can be made. It was found that at least up through the third moments the two methods agree. A more detailed discussion of the comparison can be found in Cushman (1997, Chapter 6).

18.8 Locally Stationary Systems

Many of the stochastic approaches require simplifying assumptions such as a stationary hydraulic conductivity field, steady state flow with no boundaries, or uniform mean velocity in space. Violation of any of these may lead to nonstationary groundwater flow. A novel method of moments was first developed by Lee and Cushman (1993) for inverse problems and subsequently for forward problems by Hu and coworkers (Wu et al., 2003a, 2003b; Zhang et al., 2000) for flow and solute transport in non-stationary, heterogeneous media with deterministic local boundaries. In the forward method, solute flux statistics are derived through Lagrangian perturbation and are expressed in term of the pdfs (probability density functions) of the particle travel time and transverse displacement. The pdfs are evaluated through the first two moments of travel time and transverse displacement using the assumed solute pdf form. Due to the complexity of the governing equations and the boundary initial conditions, numerical methods are used to solve the problem and the efficiency is greater than from Monte Carlo numerical simulation.

We follow the discussion of Cushman et al. (2002). Consider incompressible, saturated groundwater flow in an aquifer with spatially variable hydraulic conductivity, $K(x)$. The groundwater seepage velocity $\mathbf{V}(x)$ satisfies Darcy's Law, $\mathbf{V}(x) = -(K/n)\nabla h$ where h is the hydraulic head, and n is the effective porosity. $K(x)$ is assumed piecewise stationary because of small-scale boundaries, but globally nonstationary, and this in turn causes \mathbf{V} to be spatially nonstationary. A solute is injected with mass, M , with a known release rate $\phi(t)$ over an area A_0 . Let $\rho_0(\mathbf{a})$ be the area density of the solute mass at \mathbf{a} in A_0 . For $t > 0$, the solute plume is advected toward a (y,z) -control plane (CP). The (nonreactive) solute flux orthogonal to the CP at x over a sampling area $A(y)$ centered at $y(y,z)$ is

$$q(t, \mathbf{y}; x, A) = \frac{1}{A} \int_{A_0} \int_A \rho_0(\mathbf{a}) \phi(t - \tau) \delta(\mathbf{y}' - \boldsymbol{\eta}) d\mathbf{y}' d\mathbf{a} \quad (18.25)$$

Here $\tau \equiv \tau(x; \mathbf{a})$ is the travel time of the advective particle from \mathbf{a} to the control plane at x and $\boldsymbol{\eta} \equiv (\eta(x; \mathbf{a}), \xi(x; \mathbf{a}))$ is the transverse location of a particle passing through the control plane. τ and $\boldsymbol{\eta}$ in Equation 18.25 are random variables that are functions of the underlying velocity field. The expected value in the case of point sampling ($A \rightarrow 0$) is

$$\langle q(t, (x, \mathbf{y})) \rangle = \int_{A_0} \rho_0(\mathbf{a}) \phi(t - \tau) f_1[\tau = t, \boldsymbol{\eta} = \mathbf{y}] d\tau d\mathbf{a} \quad (18.26)$$

where $f_1[\tau, \boldsymbol{\eta}]$ is the joint pdf of a travel time τ for a particle from \mathbf{a} to reach x and the corresponding transverse displacement is $\boldsymbol{\eta}$ (recall τ and $\boldsymbol{\eta}$ are functions of x and \mathbf{a}). The average variance of the solute flux can be expressed with a two-dimensional joint density function. The averages of τ and $\boldsymbol{\eta}$ can be written as functions of the mean Eulerian velocities. Due to the nonstationarity of flow, a numerical approach needs to be implemented to obtain the means and covariances of τ and $\boldsymbol{\eta}$. If τ and $\boldsymbol{\eta}$ obey log-normal and normal distributions, then the joint pdf for one and two particle statistics needed for mean solute flux and covariance representations can be obtained. The input for the model is the hydraulic conductivity distributions specified by the means, variances and correlation lengths for various models

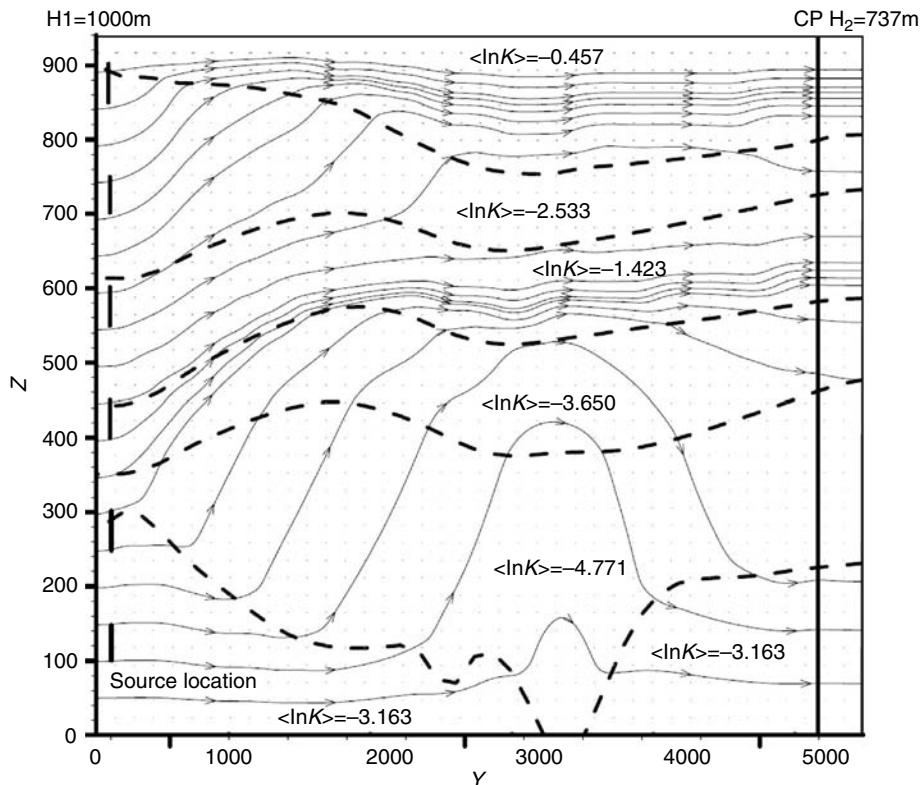

FIGURE 18.3 Nonstationary conductivity field for Yucca Mountain used in the stochastic convective nonstationary approach results shown in Figure 18.4. The six different source lines used are close to the left boundary with the control plane near the right boundary. The mean of the log of conductivity is shown in each layer and dashes represent the layers in the medium. Mean flow lines are shown and indicate the main flow is through the high-conductivity layers. More detail on the set-up and computational time can be found in Cushman et al. (2002). (Figure 1 from Cushman et al., 2002, *Adv. Water Resour.* 25, 1043–1067.)

(i.e., log-normal) and local boundary data. A sample conductivity field is shown in Figure 18.3 with the results of the mean solute discharge and variance for such a field shown in Figure 18.4.

A more general method for globally nonstationary, but piecewise stationary solute transport has been developed by Winter and Tartakovsky (2000) and Winter et al. (2002) by including random local boundaries. It is not likely that the exact boundaries for the changes in hydraulic conductivity will be known so the boundaries having uncertainties makes the model more realistic.

18.9 Spreading vs. Dilution

Since anomalous dispersion has become more widely modeled and evidenced in experiments, the difference between spreading and dilution has also become of interest. Spreading is connected to the stretching and deformation of the contaminant plume while dilution is connected to the change in the volume of fluid the solute occupies (Kitanidis, 1994). When dispersion coefficients are estimated, they give a macroscopic measure of the rate of spreading which may not necessarily correspond to rate of dilution. The peak concentration is one measure of the dilution since if the peak concentration is lower, the solute is more dilute overall. Kitanidis (1994) further quantified the notion of dilution by introducing the concepts of the “dilution index” and “reactor ratio” which are used to measure how uniformly the solute is dispersed in the plume.

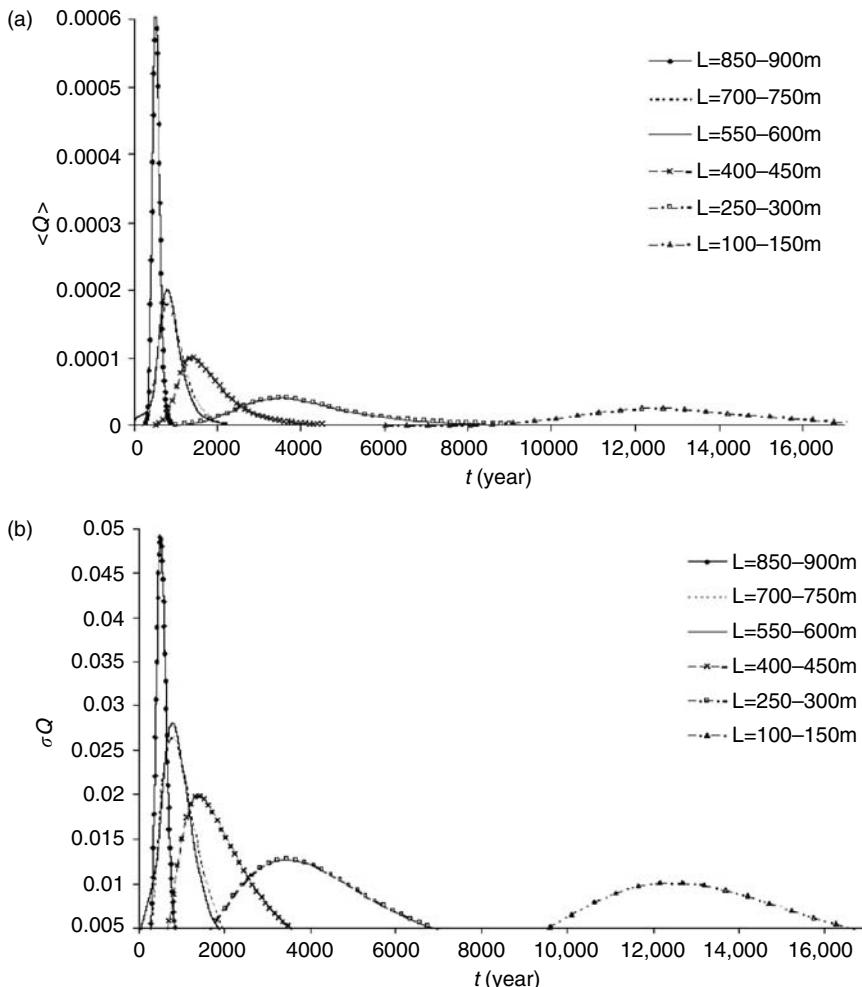

FIGURE 18.4 Q is the total solute flux over the control plane. (a) Expected solute breakthrough curves with the source line at different locations. (b) Variances about the mean predictions. (Figure 2 from Cushman et al., 2002, *Adv. Water Resour.* 25, 1043–1067.)

Consider the normalized concentration, $C(\mathbf{x}, t)$. The dilution index $E(t)$ is an entropy-like measure defined by

$$E(t) = \exp \left[- \int_V C(\mathbf{x}, t) \ln C(\mathbf{x}, t) dV \right] \quad (18.27)$$

The theoretical maximum of this quantity can be considered for systems and the dilution index compared to this maximum quantity, yielding the reactor ratio. The dilution index and reactor ratio have been thoroughly explored for unbounded domains via the advection-dispersion equation with constant coefficients as well as other systems. In addition, $E(t)$ has been related to the concentration variance (Kitanidis, 1994; Kapoor and Kitanidis, 1997; Pannone and Kitanidis, 1999).

Kapoor and Gelhar (1994) examined spreading vs. dilution in the Cape Cod bromide tracer data via peak concentration. They found that the macroscale dispersion tensor was not a very accurate predictor of the peak concentration (their measure of dilution) and that, at best, the macroscale dispersion tensor

can be used to describe the plume spread in terms of the second moment of concentration. Additionally, it was found through numerical simulations in a heterogeneous conductivity field that an n -fold increase in the covariance of the concentration in the mean flow direction does not result in an n -fold decrease in the peak concentration as would occur in a homogeneous conductivity field. A hundred fold decrease in covariance resulted in only a tenfold decrease in peak concentration. This indicates in heterogeneous aquifers that care should be taken in contamination transport in relating dilution and spreading.

18.10 Experiments

18.10.1 Lab Experiments

The majority of laboratory experiments involve the analysis from an Eulerian perspective by looking at solute concentration (breakthrough curves), porosity, pore-velocity, and hydraulic conductivity and employ a Fickian estimate for the dispersion tensors by using the velocity covariance (Harleman and Rumer, 1963; Klotz et al., 1980; Eidsath et al., 1983; Rashidi et al., 1996). An alternative method that allows greater freedom in analysis and more detailed information is Particle Tracking Velocimetry (PTV).

Particle Tracking Velocimetry has been utilized by Moroni and Cushman (2001) in the investigation of the generalized hydrodynamic approach (Section 18.7.1) and to study the validity of the ADE. PTV has the benefit that Lagrangian trajectories of the passive tracer are obtained for analysis. In a time stationary system one can then convert this information to an Eulerian frame.

To utilize PTV in a porous medium the matrix must be made invisible. This can be accomplished using a fluid and matrix that have matching refractive indices (matched-index system). One naturally occurring system is cryolite and water, however to develop a laboratory system another possibility is glycerol and Pyrex at 23°C in natural light. Moroni and Cushman (2001) used Pyrex beads and cylinders to create both homogeneous and heterogeneous media. Air bubbles, of an appropriate size, were used as the passive tracer (they have a different refractive index than the glycerol and Pyrex) and the flow of the bubbles in the glycerol was tracked with different flow velocities in the various media. Through reconstruction techniques, three-dimensional (3D) trajectories of the air bubble paths were followed and analyzed. A sample of 3D trajectories from the “homogeneous” medium is shown in Figure 18.5. It was found that all media have anomalous flow characteristics at some scale, even “homogeneous” media, (see Figure 18.5) and thus reinforces the notion that homogeneity is a scale dependent concept.

18.10.2 Field Experiments

Many large scale field experiments have been performed over the past several decades to examine and compare theories of macrodispersion. The largest such natural gradient experiments are the Borden, Cape Cod, and the MADE tests. A comprehensive discussion of field-scale dispersion experiments can be found in Gelhar (1992).

The Borden aquifer, located in Canada, is a sand quarry with medium and fine-grained sands. Chloride and bromide were used as the conservative tracers. Discussions of this test can be found in Sudicky (1986) and Freyberg (1986). Scale-dependent dispersion is present in this experiment and has mainly been studied using the ADE. The Cape Cod (Massachusetts) site is a sand and gravel aquifer with a low level of heterogeneity and both reactive and nonreactive tracers were used. The Cape Code site has been analyzed with stochastic theories and the first and second moments of the tracer plumes have fit well with these theories (Garabedian et al., 1991; Kapoor and Gelhar, 1994), but these theories have not held up well in the more heterogeneous case of the MADE site. The concept of spreading vs. dilution has also been investigated for the Cape Cod site through the covariances. The MADE site (Mississippi) is substantially more heterogeneous than the other sites and also involved the use of reactive and nonreactive tracers (Adams and Gelhar, 1992; Boggs et al., 1992; Benson et al., 2000). The FADE has been studied relative to this data as discussed in Section 18.7.3. Further discussion on the MADE site can be found in Chapter 26 (C. Zheng).

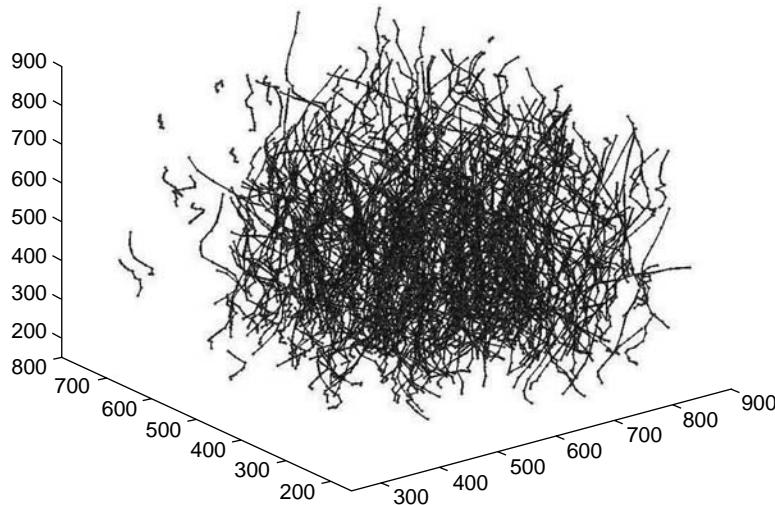

FIGURE 18.5 Example of trajectories obtained via Particle Tracking velocimetry through a bench scale porous medium. Trajectories are of length greater than 12 sec. (Figure 7 in Moroni and Cushman, 2001, *Phys. Fluids* 13, 81–91.)

These large-scale field experiments are providing a basis for the testing of new theories and a better understanding of when classical theories break down; it is expected that they will continue to play an important role in the modeling of transport in porous media.

Glossary

Passive tracers Solute that does not react with the porous medium or the suspending solution.

Conservative tracer Solute that maintains its mass in the fluid volume.

Heterogeneity The occurrence of variability of the values of field properties in space.

Stochastic model A mathematical model that involves spatially or temporally material parameters or a random forcing function.

Structural vs. functional hierarchy Structural hierarchy refers to nested physical subunits of the medium whereas functional hierarchy refers to nested processes.

Discrete vs. continuous hierarchy Discrete hierarchy involves a finite number of nested subunits (subprocesses) whereas in a continuous hierarchy the number of such subunits goes to infinity.

Pore scale The scale of the pore. The pore velocity is the velocity measured at this scale.

Darcy scale A scale large enough so that Darcy's law holds. The Darcy velocity is the velocity used at the Darcy scale.

Hydraulic conductivity The constant of proportionality in Darcy's law between the Darcy velocity and the gradient of the hydraulic head.

Macrodispersivity tensor The dispersivity tensor in the ADE when it is used on a Darcy scale or higher.

Pathline A particles trajectory in time.

Nonlocal constitutive law One that involves integral or higher order gradients.

Covariance The average of the product of a random variable at two different spatial points (example velocity covariance $C_v(x, y) = E[v(x)v(y)]$).

Steady flow A flow where the properties do not depend explicitly on time.

Stationarity May be temporal or spatial. Refers to dependence of a property only on the time lag or spatial displacement instead time and location. In a random variable the most common types are

strict stationarity (statistically homogeneous) and second order or weak stationarity. Strict stationarity means that the probability density function is invariant to spatial shifts. In weak stationarity the mean and variance are constant and the covariance depends only on the displacement vector between the two points and is symmetric.

Probability density function Function describing the probability of event. The sum (or integral) over all possible events must be 1.

Further Information

We have presented a brief outline of some of the methods and resources that have been employed in the study of conservative tracers. Zhang (2002) provides a good introduction to stochastic methods for the flow problem. An introduction to stochastic numerical methods can be found in Bouleau and Lépingle (1994). The books of Adler (1992), Brenner and Edwards (1993), Cushman (1990, 1997), Dagan (1989), and Gelhar (1993) are useful references on transport problems.

19.1 Introduction

We extend the discussion of the previous chapter to a setting wherein the dissolved chemical reacts with its environment. The catalogue of natural geochemical reactions and transformations associated with man-made contaminants that have entered the saturated zone is essentially limitless, but for the most part these reactions can be categorized according to speed, reversibility, and phase association. A relevant subset of the classification scheme of Rubin (1983) includes the four cases (1) reactions that are fast (equilibrium) and reversible involving aqueous–aqueous or (2) aqueous–solid phase interactions; and (3) reactions that are not fast (nonequilibrium) involving aqueous–aqueous or (4) aqueous–solid phase interactions. The terms “fast” and “not fast” are defined relative to the other transformation processes involved, including other reactions and convective and dispersive transport on the observation time scale. Aqueous–aqueous (Categories 1 and 3) are termed “homogeneous” and aqueous–nonaqueous (2 and 4) are termed “heterogeneous” (regarding phase; not to be confused with spatial variability). This scheme is useful because there is a distinct mathematical approach for each of these categories. The chemical mechanisms driving general reactions and the mass balance approaches for formulating representative transformation models are beyond the present scope, and are summarized at various levels in for instance Rubin (1983), Fetter (1993), Marsily (1986), Sposito (1994), and Lichtner et al. (1996). Here we will be restricted to some of the simpler (but representative) reaction mechanisms in categories 2 (sorption) and 4 (biodegradation), and focus on scaling issues associated with transport in heterogeneous porous media. We begin with a brief summary of reaction-transformation formulations and then describe concepts of heterogeneity, scale, and upscaling. The remainder of the chapter describes current methods for scaling plume behavior involving linear reactions (Eulerian approaches), and for scaling contaminant arrival behavior involving nonlinear reactions (Lagrangian approaches).

We start with a simple illustrative example of an equilibrium heterogeneous reaction, involving the single electrolyte NaCl. Dissolved chloride is a simple anion and generally moves in accordance with the local pore-water velocity, much as the water molecules themselves do (with some exception due to the repulsive electrostatic potential between the anion and the mineral surfaces in, for example, quartzitic or kaolinitic materials). Thus chloride is often reasonably treated as an inert or “passive” tracer using methods described in the previous chapter. Sodium, however, tends to be both transported and exchanged with other cations on the negatively charged mineral surfaces. That is, aqueous sodium reacts with the solid phase by cation-exchange, one of a number of mechanisms by which aqueous species may associate with the mineral surfaces. Other mechanisms include precipitation (e.g., Novak and Sevoulian, 1993), surface complexation (e.g., Dzombak and Morel, 1990), hydrophobic sorption of organic species to organic solids (Karickhoff, 1983), colloid filtration (Tien, 1976), and intergranular diffusion (Wood et al., 1990).

Reaction transformations are formally captured via augmenting the basic solute transport rate equation (Equation 13.1 of the previous chapter) with a generalized mass loss rate, $nr = [\partial C / \partial t]_{\text{transformation}}$, here written as mass transfer to the solid phase, with constant porosity n :

$$\frac{\partial C}{\partial t} + \frac{\partial(V_i C)}{\partial x_i} - \frac{\partial}{\partial x_i} \left(d_{ij} \frac{\partial C}{\partial x_j} \right) = \left(\frac{\partial C}{\partial t} \right)_{\text{transformation}} \equiv -\frac{\rho_b}{n} \frac{\partial S}{\partial t} \quad (19.1a)$$

where C is the aqueous concentration [M/L^3], S is the sorbed concentration per unit mass of solid [M/M], ρ_b is the bulk density of the aquifer material [M/L^3], n is the porosity, and d_{ij} is the symmetric dispersion tensor.

A majority of sorption and other heterogeneous transformations may be represented by specifying this mass transformation rate as a function of the departure of the system from an equilibrium state. The first-order form is

$$\frac{\partial S}{\partial t} = K_r(K_d C - S) \quad (19.1b)$$

where K_r is the desorption rate [1/T] and K_d is the equilibrium distribution coefficient [L³/M]. Equation 19.1b specifies a linear nonequilibrium (“not fast”) reversible mass transformation rate that approximates numerous sorption processes (of category 4) in natural media. Alternatively, one may express the right-hand side of Equation 19.1b as $[K_f C - K_r S]$, where $K_f = K_r K_d$ is the forward sorption rate [1/T]. Reactive solutes undergoing transport according to Equation 19.1 exhibit attenuation. If K_r is very large so that Equation 19.1b responds much more quickly than local conditions change (due to other mass fluxes in Equation 19.1a), then the “local equilibrium assumption” is invoked and the chemical partitioning is taken to occur instantaneously. That is, ironically, the reaction rate in Equation 14.1b is so fast that it occurs over a negligibly short time, and literally most of the time, Equation 14.1b is zero. Note that this is not to be confused with assuming steady state conditions for S ; S will change, instantaneously with changes in C . We may then use the equilibrium solution to Equation 19.1b, $S = K_d C$, as an algebraic relation for S in terms of C in the derivative on the right-hand side of Equation 19.1a (to express the dependence of S on C). Differentiating and grouping terms gives from Equation 19.1a

$$\frac{\partial C}{\partial t} + \frac{1}{R} \frac{\partial(V_i C)}{\partial x_i} - \frac{1}{R} \frac{\partial}{\partial x_i} \left(d_{ij} \frac{\partial C}{\partial x_j} \right) = 0 \quad (19.2)$$

where $R = 1 + \rho_b K_d / n$ is known as the retardation factor. When transport is governed by an equation involving equilibrium reactions such as Equation 19.2, the solute(s) are retarded (as opposed to attenuated), as is clear upon recognizing that R reduces the transport parameters V_i and d_{ij} .

Equation 19.1 and Equation 19.2 illustrate the simplest case of heterogeneous mass transformations of the nonequilibrium and equilibrium types. This example illustrates the different mathematical approaches for the two cases. For nonequilibrium reactions we specify a (“kinetic”) function for

$$\frac{\partial S}{\partial t} \equiv r(S, C)$$

and for equilibrium we specify the algebraic relation (termed “isotherm”) of the form $S = r(C)$, so that

$$\frac{\partial S}{\partial t} \equiv r'(C) \frac{\partial C}{\partial t}$$

and $r(C)$ becomes involved in the transport operator. More complex forms of r arise when the mass transformations are nonlinear in C and in S , when multiple processes are in effect, when the nonaqueous phase (for S) undergoes transformations, and when multiple interacting solutes are involved, to note only a few cases.

In the case of multiple interacting solutes and solid-phase species, an evolution equation is written for each component, and these equations are coupled through the (multiple) reaction terms appearing. Such systems present special issues requiring attention in their solution depending on the character of the reactions (cf. review in Yeh and Tripathi, 1989). When all interactions are at equilibrium, the transport equations are coupled with a set of algebraic equations relating mobile to immobile species that complicate the solution via integration schemes designed for the transport operator alone. Recent approaches use iterative solutions between the algebraic and differential equations (Yeh and Tripathi, 1989) or a decoupling of the system (Rubin, 1990). In the other limiting case where all the reactions have a finite rate, then a sink term appears for each species in the evolution equation and the solution can proceed conventionally through operator-splitting (e.g., Chiang et al., 1990; Valocchi and Malmstead, 1992) or explicit integration schemes (e.g., Widdowson et al., 1988; Celia et al., 1989). Finally, a mixture of both nonequilibrium and equilibrium transformations results in a “differential-algebraic equation” (DAE) system that may be solved, under particular conditions regarding the “index” of the system (Gear and Petzold, 1984; Gear, 1988), through specialized iterative or noniterative decoupling approaches (e.g., Steefel and MacQuarrie, 1996).

We now turn our attention to a demonstration of some of the available approaches for dealing with reactions in the presence of physical and chemical heterogeneities in natural media. The goal of the

scaling approaches is to derive maximum information about the solute fate and transport when data on the spatial variability of the natural media is limited. We describe two such approaches, an Eulerian stochastic-analytic method that is useful for describing expected plume behavior under linear reactions, given statistical (correlation) properties of the spatially variable aquifer flow and reaction characteristics; and a Lagrangian-streamtube approach useful for predicting solute arrivals at observation locations (as opposed to plume evolution) when the reactions involve nonlinear transformations. Beyond the current scope is a third approach that is quite useful when available aquifer data includes conditioning data on the flow and reaction property values on significant scales, such as identification and incorporation of hydrofacies geometry (Bierkens and Weerts, 1994; Scheibe and Freyberg, 1995).

In the following sections, we introduce concepts of heterogeneity defined as spatial variability in physical, or chemical, or microbiological properties, within the context of scales of observation, to set the stage for upscaling or averaging methods, that is the topic of this chapter. We then turn to some basic demonstrations of how one can upscale various occurrences of heterogeneity. This is first described in the Eulerian setting for some elementary single-component reactions. Next, the Lagrangian perspective is described and demonstrated for a multicomponent reaction network with nonlinear kinetics. Finally, we describe a connection between the Eulerian and Lagrangian settings.

This review is not comprehensive either with respect to reactions encountered in the subsurface or with respect to most up-to-date contributions. Our target is rather to demonstrate some of the basic results in upscaling solute fate and transport in heterogeneous formations, for some simple cases of reactions. Thus, our goal is to provide an introductory review of the concepts and some approaches used in dealing with subsurface heterogeneity and its effects on solute fate and transport.

19.2 Physical, Chemical, and Microbiological Heterogeneity

It is clear that transport models for multiple species of reactive and degradable chemicals in a homogeneous environment must be very complicated. Couple this already complicated transport phenomena with heterogeneity, and the resultant problem increases by an order of magnitude in complexity. To date, only the simplest of such problems have been solved analytically, and even Monte Carlo methods have been applied to only moderately complex systems.

Aquifer properties are commonly found to vary on multiple spatial scales in a variety of settings, including alluvial (e.g., Weissman and Fogg, 1999; Schulmeister et al., 2003) and marine depositional (Tompson et al., 1996; DeFlaun et al., 2001) environments. Such heterogeneity arises in part from aquifer depositional structures that exhibit variations from the centimeter (e.g., cross-bedding) to the meter (lithofacies) scales. In the previous chapter, physical heterogeneity was discussed in the context of a random hydraulic conductivity field. There are two other commonly encountered forms of physical heterogeneity: a spatially variable porosity field and a spatially variable “local” dispersivity field. Both are commonly considered of secondary importance to flow and transport, though recent Monte Carlo simulations (Hassan et al., 1998) suggest that the correlation between conductivity and porosity may play a significant role in transport. As in Chapter 18, however, we will equate physical heterogeneity with ignorance about the values of particular parameters and how they vary over space. This will usually be approached by conceptualizing, for example, the hydraulic conductivity as a “random” conductivity field. In such a field the value of a parameter such as conductivity is viewed as a random deviate from a distribution that can be characterized by its moments and the like (mean, standard deviation, etc.). When the moments of the distribution themselves do not depend on space, the random field is termed “stationary” or, equivalently, “statistically homogeneous.” While stationary field representations are among the simplest (and most commonly relied upon), they are not to be confused with “homogeneous” fields where conductivity value is the same everywhere. Another critically important aspect of a “random” field is “ergodicity.” In loose terms, a field is ergodic if the probability distribution of values that can occur at a point in space is equivalent to the frequency distribution of values over space for the given subsurface in question. Ergodicity is critically important because if it holds for a given aquifer, then the statistics for

describing the random field can be estimated to some degree by compiling data from boreholes and other (e.g., geophysical) sources from different locations within the given subsurface in question. Unfortunately, proof of ergodicity would require not only exhaustive characterization of an entire subsurface domain, but also definition and identification of a set of subsurface domains that could arguably serve as a probability space with samples from each one at a consistent point in space — clearly an impossibility. Therefore ergodicity can not be proved.

Superimposed on the random conductivity field is a random geochemical field. Historically and spatially varying distributions of mineral deposition, formation, diagenesis, and weathering and organic matter occurrence and deposition give rise to this natural heterogeneity. Superimposed over both the physically and chemically heterogeneous fields is a dynamic random distribution of microbial populations. The major difference between physical/chemical heterogeneity and microbial heterogeneity is the dynamic nature of the latter. Microbes are transported and adsorbed as much as are chemicals and other colloidal particles, though the adsorptive mechanisms are completely different, with physiologically dependent residence times on surfaces leading in some cases to biofilm formation and eventual decay.

19.3 Scale of Observation and Constitutive Concepts

Engineered porous media are generally designed to be homogeneous when viewed over the scale on which they are to be used in a given technology. Natural porous formations, on the other hand, are almost always inhomogeneous on any relevant scale of observation. As mentioned in the previous section these natural formations are not only inhomogeneous physically, but chemically and biologically as well. However, the degree and type of these heterogeneities depends to a large extent on the scale of observation. It is for this reason that “effective” parameters such as so-called macro dispersivity have little meaning in natural systems.

A primary goal of modelers of transport in heterogeneous media is to develop functional forms for constitutive variables and to know the regions of space-time that are important to their definition. If the constitutive theory depends upon what is happening at a point (here a point has meaning only with respect to the window and scale of resolution associated with the measurement process) in space-time, or a very small neighborhood of the point, then the theory is said to be local. On the other hand, if information is needed to define the constitutive theory from regions of space-time distinct from a neighborhood of the space-time point where evaluation of the theory is to be made, then the model is said to be nonlocal. These ideas will be made more concrete in subsequent sections.

19.4 Upscaling

The concept of “upscale” is one of the most important in modern hydrological modeling circles. Upscaling simply means taking information on scales smaller than those of interest, homogenizing it, and studying the resultant “larger” scale system. The rationale behind the need to upscale is that we simply cannot make enough detailed measurements at the smaller scales to be of much use on the larger scales wherein relevant transport processes are taking place.

There are numerous methods that may be used to upscale physics in hydrology, including matched asymptotic expansions, Taylor–Aris–Brenner method of moments, renormalization group theory, transform methods, volume averaging, particle tracking, and so on. Many of these are illustrated in Cushman et al. (2002) and the interested reader is referred there. The next subsection reviews works regarding mineralogical or otherwise reactivity-associated properties and the effects of heterogeneity therein.

19.4.1 Methods for Chemical Heterogeneity

Here we review some concepts and results in the use of the Lagrangian approach when not only physical but also chemical and microbiological properties are heterogeneous. First, we term any reactive property

of an aquifer “aquifer reactivity.” This includes any immobile reactive component, for example, sorbed organic matter, organic mineral assemblages, (co-)precipitated minerals, mineral-oxide surface coatings, or biotic phases such as microbial colonies or biofilms.

Glassley et al. (2001) characterized a small sample of fractured rock from Yucca Mountain, Nevada, and compared both high-resolution (modeled aquifer porosity and reactivity) and effective-homogeneous models and found that the effect of mineralogical heterogeneity on reactive solute transport depends on how solute flux is distributed over contact times with minerals. At larger scales this dependency is often viewed in the context of how reactive transport depends on the way in which the patterns of geochemical and physical properties are overlain in space. Investigations have involved both deterministic patterns of geochemical and physical properties in experimental (e.g., Knapp et al., 1998) and simulated (e.g., Burr et al., 1994) settings.

In sandy aquifer materials metal (iron, aluminum, manganese) oxides are among the most important solid species that impart the positively charged sites on an otherwise negatively charged silicate surface, thus controlling the sorption of negatively charged solute particles. The occurrence of these microscale heterogeneities in reactivity and the impact on transport of colloidal and viral tracers in particular has been studied by Elimelech and coworkers (e.g., Ryan et al., 1999; Elimelech et al., 2000; Chen et al., 2001; Bhattacharjee et al., 2002). There, negatively charged colloidal depositions are demonstrated to be influenced by the positively charged surface (e.g., Chen et al., 2001). The presence of organic matter absorbed on the mineral surface decreases the electrostatic force between the positively charged surface and negatively charged colloids (Ryan et al., 1999). The overall impacts of such “patchwise” heterogeneity of positively charged metal oxyhydroxide grain coatings, on the transport of virus tracers is described for instance in Bhattacharjee et al. (2002). Larger scales of variation were examined, in that both layered and randomly (log-normally) distributed physical and geochemical heterogeneities were considered.

The most direct and simple approach to upscaling microscale (e.g., patchwise) heterogeneity of reactivity, in both Eulerian and Lagrangian settings, is by replacing the heterogeneous medium with an effective homogeneous medium (HEM) with the same total reactive surfaces available (but distributed now, homogeneously). This usually involves the assumption that the solute has equal access to reactive surfaces occurring within any representative elementary volume (REV) that is complete mixing. In one study without this assumption, Lichtner and Tartakovsky (2003) show that even with a single sorption rate but surface area variable within the REV due to a log-normal grain size distribution, the effective rate is not a constant but varies with time. When complete mixing is assumed and the sorption reaction is fast but involves multiple sorbents (e.g., mineralogies) that are spatially variable at the grain scale, equilibrium models written for homogeneous reactivity can give wrong simulations especially when calibrated in batch but applied in the presence of transport (e.g., Bosma et al., 1993; Wise, 1993; Chen and Wagenet, 1995; Szecsody et al., 1998 for a multicomponent reaction system). When kinetically controlled sorption reactions are involved, this situation can give rise to multi-rate or multi-site reaction kinetics at the continuum and larger scales.

Sposito (1993) points out how multiple reactive mineral phases involved in a surface reaction with a single reversibly sorbing solute give rise to the multi-rate reaction model (e.g., Haggerty and Gorelick, 1995) and under Gamma-distribution of reactivity, a power-law distribution of sorption rates and thus residence times (e.g., Metzler and Klafter, 2002). If some of the reactions in a multi-rate model are fast on the timescale of transport and the remaining reactions, then they can in general be combined to a single equilibrium reaction that operates in parallel with the remaining kinetically controlled reactions. Various combinations of serial and parallel reactions models can be constructed from particular conceptual models of grain surfaces, sometimes involving intra-granular porosity and diffusion limitations approximated as kinetically controlled reactions (e.g., Villermaux, 1981; Valocchi, 1990; Cunningham et al., 1997).

Approaches to dealing with heterogeneity in reactive properties on larger (e.g., meter) scales are often based on hypothesized correlations between macroscopic physical properties and reactive properties. Kabala and Sposito (1991) derive an effective convective-dispersive transport equation for the expected value of a solute undergoing transport and equilibrium sorption in random velocity and distribution coefficient fields, in the absence of microscopic dispersion. Their results are extended to higher moments

and higher order statistics in Kabala and Sposito (1994). Burr et al. (1994) present a numerical study of three-dimensional reactive transport with a geostatistical description of hydraulic conductivity and sorption equilibrium distribution coefficient designed to resemble Borden aquifer characteristics. Using spatial moment analyses on a small Monte Carlo ensemble, the authors showed that a negative correlation between the physical and reactive properties led to an increased spreading of solute plumes, as reflected in the second spatial moment within individual plumes. Similar results are reflected in Dagan (1989), Chrysikopoulos et al. (1990), and Bellin et al. (1993). Tompson et al. (1996) provide nine separate case simulations of multicomponent reactive transport of a uranyl–citric acid mixture in multi-dimensional physically and chemically heterogeneous media, with speciation and surface-complexation (equilibrium) reactions involving hydrous-ferric oxide (goethite) coatings on aquifer materials (sand). The authors highlight the importance of the third space dimension in mixing, the effect of multicomponent interactions, and showed that fate is controlled by the abundance of the oxide as a function of the specific sand surface area as well as by larger scale patterns of oxide occurrence. Burr et al. (1994) also showed that the joint variability induces a pseudokinetic behavior, in that the ensemble mean bulk retardation factor can increase with time and plume displacement distance, even though the sorption reaction is equilibrium. The same result is obtained by Espinoza and Valocchi (1997) in a perturbation analysis and Monte Carlo study of one-dimensional solute transport with kinetically controlled sorption, and by Mishra et al. (1999) for reversible kinetic sorption.

The usefulness of HEM models noted above for upscaling grain-scale reactivity heterogeneity has also been examined at larger scales. For instance, Chen et al. (2001) and Knapp et al. (1998) investigated transports of colloids and bacteria, respectively, in experimental columns with porous media that were physically homogenous but chemically heterogeneous. They compared results to reactivity-homogenized cases where aquifer reactivity patterns were erased and replaced with homogeneous material containing equivalent total reactivity. They concluded that the actual spatial distribution of iron-coated surfaces did not affect the column-scale attenuation and transport of the solutes as long as the overall fractions of reactive surface area in the column were the same. However, these results are restricted to one-dimensional transport with chemical heterogeneity occurring in the same dimension (e.g., varying along the flow path). If reactivity were arranged in a second space dimension, for example, in bands aligned parallel to the direction of the flow, the colloidal and bacterial breakthrough curves would indeed depend on pattern, because some of the solute flux would experience zero reactivity. This dependence is partly reflected in two of the nine experiments of Tompson et al. (1996) that involved banded goethite patterns, although the only pattern tested was banding diagonal to flow that spanned the no flow boundaries (e.g., parallel-to-flow banding was not examined). The authors state that the impact of correlation between reactive surface area and hydraulic conductivity seemed less significant than the overall abundance and distribution of the reactive area, such as the kind of banded goethite patterns observed in a coastal sand body. Finally, studies with unidirectional flow cannot reflect the coupled effects of physical and reactivity heterogeneity that occur via nonuniform flow in multiple dimensions (including dilution, e.g., Tompson et al., 1996). Thus, conclusions for unidirectional flow cases are not generally applicable in naturally heterogeneous porous media because in natural systems solute flux may experience a variety of “frequency of reaction sites” exposures. This is the same notion constructed by Glassley et al. (2001).

19.5 Linearity and Nonequilibrium Eulerian Stochastic Models

19.5.1 Deterministic Nonequilibrium Sorption

It is assumed the chemical is transported by convection and local dispersion under steady, saturated, incompressible groundwater flow in a nondeformable porous medium, of constant porosity. The chemical undergoes first-order linear nonequilibrium kinetics with its surroundings. We assume a natural scale exists, the “Darcy” scale (as in Chapter 18), and we wish to upscale without knowledge of a scale separation between the Darcy and the “Reservoir” scale. Darcy-scale transport is governed by Equation 19.1. It is assumed the mean-flow is in the x_1 -direction, that K_r and K_d are deterministic constants, and as a result

of randomness in $\ln K$, V_i , S , and C are random. Solving for the mean and fluctuation equations for Equation 19.1 and using a transform analysis gives (Cushman et al., 1996), assuming triplet correlation fluxes can be neglected,

$$\begin{aligned} \frac{\partial \bar{C}}{\partial t} + \bar{V}_1 \frac{\partial \bar{C}}{\partial x_1} - \frac{\partial}{\partial x_j} \int_0^t \int_{\mathbb{R}^3} D_{ij}(\mathbf{x} - \mathbf{y}, t - t') \frac{\partial \bar{C}(\mathbf{y}, t')}{\partial y_i} d\mathbf{y} dt' \\ = -K_r K_d \int_0^t \left[\delta(t - t') - e^{-K_r(t-t')} \right] \bar{C}(\mathbf{x}, t') dt' + K_r e^{-K_r t} S_0 \end{aligned} \quad (19.3)$$

where

$$D_{ij}(\mathbf{x} - \mathbf{y}, t - t') = d_{ij} \delta(\mathbf{x} - \mathbf{y}, t - t') + \bar{v}_i \bar{v}_j(\mathbf{x} - \mathbf{y}) G(\mathbf{x} - \mathbf{y}, t - t') \quad (19.4)$$

and

$$G^\circ(\mathbf{k}, \omega) = \left[\omega \left(1 + \frac{K_r K_d}{\omega + K_r} \right) + d_i k_i^2 + i k_1 \bar{V}_1 \right]^{-1} \quad (19.5)$$

where $\bar{v}_i \bar{v}_j$ is the assumed stationary fluctuating-velocity covariance, S_0 and C_0 are initial concentrations, the \circ represents Fourier–Laplace transform where t is dual to ω and \mathbf{x} is dual to \mathbf{k} .

The form of the mean Equation 19.3 is quite different from the original local scale Equation 19.1. This dispersive flux is nonlocal (third term of the left-hand side of Equation 19.3), as is the source (left-hand side of Equation 19.3) term. The upscaling process is the source of nonlocality and it results from a lack of information on the small-scale details of the transport process.

19.5.2 Random Nonequilibrium Sorption

Here the local-scale model is exactly as the previous case except it is assumed K_d is a random spatial field that may be correlated with $\ln K$. In this case, the resultant mean equation is more complicated and given by Hu et al. 1995:

$$\begin{aligned} \frac{\partial \bar{C}}{\partial t} + \bar{V}_1 \frac{\partial \bar{C}}{\partial x_1} - \frac{\partial}{\partial x_j} \int_0^t \int_{\mathbb{R}^3} D_{ij}(\mathbf{x} - \mathbf{y}, t - t') \frac{\partial}{\partial y_i} \bar{C}(\mathbf{y}, t') d\mathbf{y} dt' \\ - \frac{\partial}{\partial x_j} \int_0^t \int_{\mathbb{R}^3} G(\mathbf{x} - \mathbf{y}, t - t') \bar{k}_d \bar{v}_j(\mathbf{x} - \mathbf{y}) \bar{C}(\mathbf{y}, t') d\mathbf{y} dt' \\ = -K_r \left\{ \bar{K}_d \bar{C} - e^{-K_r t} S_0 - K_r \bar{K}_d \int_0^t e^{-K_r(t-t')} \bar{C}(\mathbf{x}, t') dt' - \int_0^t \left[\delta(t - t') - K_r e^{-K_r(t-t')} \right] \right. \\ \times \left[\int_0^{t'} \int_{\mathbb{R}^3} G(\mathbf{x} - \mathbf{y}, t' - t'') \bar{k}_d \bar{k}_d(\mathbf{x} - \mathbf{y}) \bar{C}(\mathbf{y}, t'') d\mathbf{y} dt'' \right. \\ \left. + \int_0^{t'} \int_{\mathbb{R}^3} B(\mathbf{x} - \mathbf{y}, t' - t'') \bar{k}_d \bar{v}_i(\mathbf{x} - \mathbf{y}) \frac{\partial}{\partial y_i} \bar{C}(\mathbf{y}, t'') d\mathbf{y} dt'' \right] dt' \left. \right\} \end{aligned} \quad (19.6)$$

with

$$D_{ij}(\mathbf{x} - \mathbf{y}, t - t') = d_{ij}\delta(\mathbf{x} - \mathbf{y}, t - t') + \overline{v_i v_j}(\mathbf{x} - \mathbf{y})B(\mathbf{x} - \mathbf{y}, t - t') \quad (19.7)$$

$$\overset{\circ}{B}^{-1}(\mathbf{k}, \omega) = \omega \left(1 + \frac{K_r \overline{K_d}}{\omega + K_r} \right) + d_i k_i^2 + i k_1 \overline{V} \quad (19.8)$$

and

$$\overset{\circ}{G}(\mathbf{k}, \omega) = \overset{\circ}{B}(\mathbf{k}, \omega) \frac{\omega K_r}{\omega + K_r} \quad (19.9)$$

The addition of randomness in K_d again increases the complexity of the mean equation. In this case, in addition to nonlocal sources/sinks and dispersion, there is also nonlocality in the convective flux (fourth term on the left-hand side of Equation 19.6).

19.5.3 Random Nonequilibrium Sorption and Equilibrium Microbial Decay

It is possible to generalize the previous results to the case where there is linear first order microbial degradation. In this case, the local scale Equation 19.1 is replaced by

$$\frac{\partial C}{\partial t} + \frac{\partial S}{\partial t} = \frac{\partial}{\partial x_j} \left(d_{ij} \frac{\partial C}{\partial x_i} \right) - \frac{\partial (V_i C)}{\partial x_i} - K_c C - K_s S \quad (19.10)$$

which is coupled with Equation 19.2. Here K_c and K_s are the solute degradation rates in the solution and sorbed phases. The mean equation can be obtained for this problem, but it is too complicated to present here (see Hu et al. [1997] for its presentation and development). In the next subsection we will, however, present some numerical solutions to it.

19.5.4 Numerical Results for Random K_d and No Degradation

To apply Equation 19.6, one needs to know three covariance functions $\overline{v_i v_j}$, $\overline{k_d k_d}$, and $\overline{k_d v_i}$ and where v_i and k_d are the fluctuating velocity in the i th-direction and the fluctuating partition coefficient, respectively. As it is difficult, if not impossible, to measure v_i , it is common to functionally relate v_i to f (the fluctuating log-conductivity) and then to measure the covariance of f and its cross-covariance with k_d . First-order expressions relating v_i to f and v_i to k_d are (Gelhar and Axness, 1983; Hu et al., 1995)

$$\widehat{\overline{v_i v_j}}(\mathbf{k}) = \left(\frac{Q_g}{n} \right)^2 \left[\delta_{i1} - \frac{k_1 k_i}{|k|^2} \right]^2 \widehat{\overline{f f}}(\mathbf{k}) \quad (19.11)$$

and

$$\widehat{\overline{v_i k_d}}(\mathbf{k}) = \frac{Q_g}{n} \left[\delta_{i1} - \frac{k_1 k_i}{|k|^2} \right] \widehat{\overline{f k_d}}(\mathbf{k}) \quad (19.12)$$

where Q_g is the product of the geometric mean conductivity with the mean gradient in the x_1 -direction, n is the porosity, and caret indicates Fourier space transform. Both $\overline{f f}$ and $\overline{f k_d}$ must be obtained from field experiments. For illustrative purposes, we assume various correlation structures for these covariances. For perfect positive correlation (Model A) or perfect negative correlation (Model B) to first order, we have

$$\widehat{\overline{k_d k_d}}(\mathbf{k}) = (K_d^G)^2 e^{\sigma_f^2} \widehat{\overline{f f}}(\mathbf{k}) \quad (19.13)$$

and

$$\widehat{\overline{k_d f}}(\mathbf{k}) = \pm K_d^G e^{\sigma_f^2} \widehat{f\bar{f}}(\mathbf{k}) \quad (19.14)$$

with plus for Model A and minus for Model B, where K_d^G is the geometric mean of $K_d(x)$. For uncorrelated K_d (Model C), to first order,

$$\widehat{\overline{k_d k_d}}(\mathbf{k}) = (K_d^G)^2 e^{\sigma_w^2} \widehat{\overline{WW}}(\mathbf{k}) \quad (19.15)$$

and

$$\widehat{\overline{f k_d}}(\mathbf{k}) = 0 \quad (19.16)$$

where W is a normally distributed random space function with zero mean, variance σ_W^2 , and covariance

$$\widehat{\overline{WW}}(z) = \sigma_W^2 e^{-zl/l_w} \quad (19.17)$$

where l_w is the integral scale of W and l is the correlation length of $\ln K$.

We take the initial concentration C_0 to be constant, C_m over a rectangular prism $2a_1 \times 2a_2$ and assume $S_0 \equiv 0$. The log-conductivity is chosen to be exponential

$$\overline{f}(z) = \sigma_f^2 \exp[-|z|^2/l^2] \quad (19.18)$$

Model D will correspond to deterministic and constant K_d .

In Figure 19.1 (from Hu et al., 1995, Figure 3), we plot the various spatial moments as a function of nondimensional time $t' = t\bar{V}/\bar{R}l$ where $\bar{R} = 1 + \overline{K_d}$. It is seen that the first moment is little affected by the models irrespective of K_r . Relative to the uncorrelated model, negative correlation between the chemical heterogeneity and physical heterogeneity increases the second longitudinal moment and positive correlation decreases it. The difference between the three models becomes larger as K_r increases. Deterministic K_d can produce significantly different results from random K_d . Figure 19.1c shows the difference in the second transverse moments between the four models is small, but distinct at large time.

19.5.5 Numerical Results with Random Chemical and Microbiological Conditions

The mean concentration for this case can be obtained given a much larger number of covariance functions, $\overline{v_i v_j}$, $\overline{v_i k_d}$, $\overline{v_i k_c}$, $\overline{v_i k_s}$, $\overline{k_d k_d}$, $\overline{k_d k_s}$, $\overline{k_d k_c}$, $\overline{k_c k_c}$, $\overline{k_s k_s}$, and $\overline{k_s k_c}$. We call the case without degradation model D. In this case, $K_s \equiv K_c \equiv 0$. We again must relate v_i , k_d , k_c , and k_s to f and in general, it follows to first order (with $a = d, c, s$).

$$\widehat{\overline{k_a k_a}}(\mathbf{k}) = \frac{Q_g}{n} \left[\delta_{il} - \frac{k_l k_i}{|k|^2} \right] \widehat{f k_a}(\mathbf{k}) \quad (19.19)$$

For illustrative purposes, we assume k_c and k_s are Gaussian and

$$\overline{k_c k_s} = \sigma_c \sigma_s \exp[-r^2/l_c^2] \quad (19.20)$$

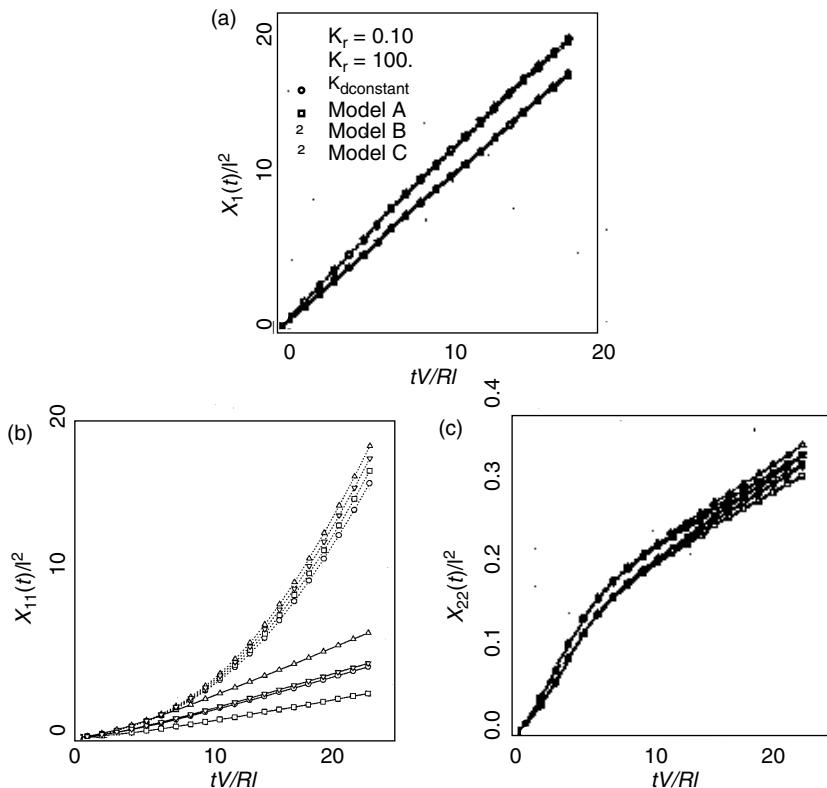

FIGURE 19.1 Spatial moments for various models with $K_d^G = 0.2$: (a) first moment, (b) second longitudinal moment, c) second transverse moment. (Adapted from Figure 3 of Hu et al., 1995, *Water Resour. Res.* 31(9):2219–2237.)

We assume positive (Model A), negative (Model B), and uncorrelated (Model C) covariance structures in the form

$$\begin{aligned}\overline{k_cf} &= \pm \sigma_c \sigma_f \exp[-r^2/l_{cf}^2] \\ \overline{k_sf} &= \pm \sigma_s \sigma_f \exp[-r^2/l_f^2]\end{aligned}$$

where + is for Model A, and - for Model B, and k_d is linearly negatively correlated with f . Use the same initial data as the previous case with $l_c = l_{cf} = l_f = 1.0$ m, $\sigma_f^2 = 0.2$, $V_1 = 1.0$ m/day, $d_1 = 0.05$ m²/day, $d_2 = 0.005$ m²/day, $c_m = 1$, $\bar{K}_d = 1$ /day, $\bar{K}_c = 0.01$ /day, $\bar{K}_s = 0.003$ /day, $\sigma_c^2 = 0.01$, $\sigma_s^2 = 0.003$.

Figure 19.2 plots mean concentration contours for the various models at 80 days. Models A, B, and C produce similar mean distributions. The shape of Model D's contours are similar to the others, but they are larger in area and have higher mean concentrations, owing to a lack of degradation.

19.6 Upscaling Microbial Dynamics

Even when microbes do not stick to the porous medium, they should be considered as reactive. This is because their self-motility allows them to move in a nonpassive way. They can move against the mean flow, transverse to it, or move rapidly in the direction of the mean flow and effectively can behave as retarded or enhanced particles. Initially this behavior was modeled as enhanced diffusion, however, in recent years researchers have begun to model microbial transport as nonlocal via Lévy motions (see Figure 1, Park et al., 2005a, 2005b). One of the biggest challenges faced when modeling microbial dynamics is how to

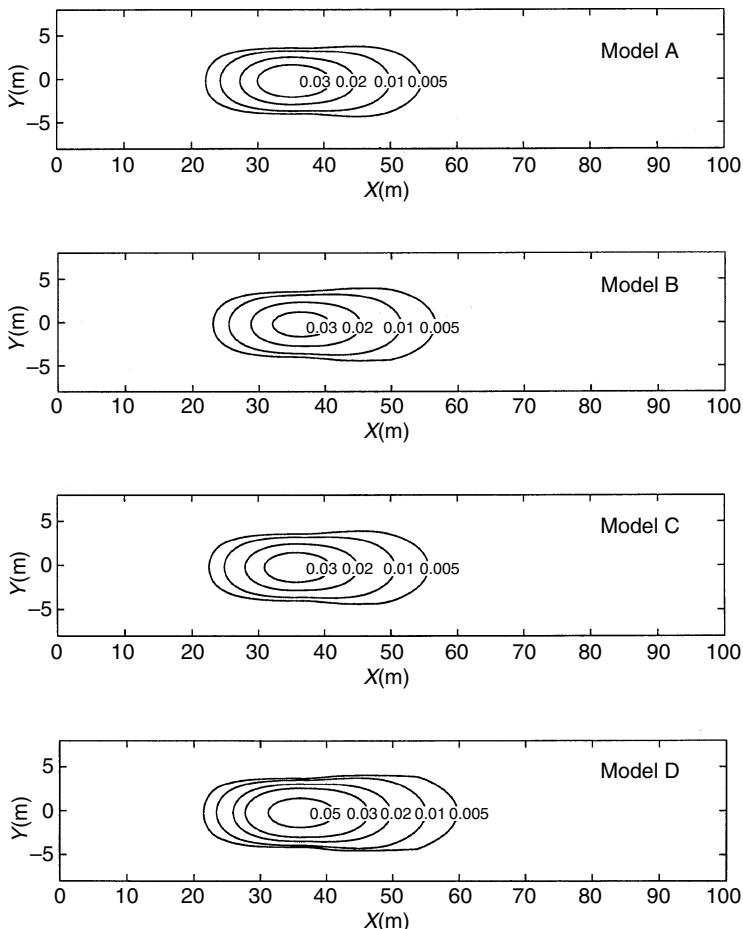

FIGURE 19.2 Concentration contours for various models at $t = 80$ days for $K_r = \bar{K}_d = 1/\text{day}$, $\bar{K}_c = 0.01/\text{day}$, and $\bar{K}_s = 0.003/\text{day}$. (Adapted from Figure 1 of Hu et al., 1997, *Adv. Water Resour.* 20(5–6):293–308.)

upscale from the pore to the Darcy to the field scale, especially when the field scale may be fractal. One method of attack, proposed in Park et al. (2005a, 2005b) is via the use of generalized central limit theorems (CLT). Essentially one writes the stochastic differential equation that the microbe obeys on the smallest scale and then applies the CLT to upscale. We present only a rudimentary summary of the results here.

On the pore scale, the stochastic ordinary differential equation (SODE) the motile particle is assumed to satisfy has the form

$$X^{(0)}(t) = X^{(0)}(0) + \int_0^t v^{(0)}(X^{(0)}(r))dr + \rho^{(0)}L^{(0)}(t) \quad (19.21)$$

where the drift velocity $v^{(0)}(X^{(0)}(r))$ is assumed stationary, ergodic, and Markov with mean \bar{v} and the fluctuating position $L^{(0)}(t)$ is α_1 -stable Lévy and accounts for the self-motility. A classical CLT (Bhattacharya, 1982; Bhattacharya and Gupta, 1990) coupled with the fact that Lévy motions dominate Brownian shows $X^{(0)}(nt) \rightarrow L^{(1)}(t)$, where $L^{(1)}(t)$ is a Darcy-scale Lévy motion which is a renormalized pore trajectory.

Thus the Darcy scale SODE is

$$X^{(1)}(t) = X^{(1)}(0) + \int_0^t v^{(1)}(X^{(1)}(r))dr + \rho^{(1)}L^{(1)}(t) \quad (19.22)$$

where $v^{(1)}(X^{(1)})$ is the Lagrangian velocity, $V^{(1)}$. In form, the previous two equations are identical, but mathematically $v^{(1)}(X^{(1)}(r))$ is rarely stationary and so the classical CLT cannot be applied to obtain the field scale trajectory $X^{(2)}$. However, generalized CLTSs can be proved (Park, 2005a) and applied if it is assumed the Lagrangian drift velocity at the Darcy scale can be modeled as an α_ν -stable Levy process. With this assumption and a few technical constraints, it can be shown that at the field scale the ADE for the transition density (concentration) in 1-D is

$$\frac{\partial f}{\partial t} = -v^{(2)} \frac{\partial f}{\partial x} + D(t) \frac{\partial^{\alpha_\nu} f}{\partial x^{\alpha_\nu}} \quad (19.23)$$

where

$$v^{(2)} = [v^{(1)}] + \mu_l^{(1)} \quad (19.24a)$$

$$[v^{(1)}] = E \left[\frac{1}{|A| |B|} \int_A \int_B v^{(1)}(t, x_0) dt dx_0 \right] \quad (19.24b)$$

$$A = A(x_0(\omega)) = \{x_0(\omega) : x_0(\omega) \in [0, 1]\} \quad (19.24c)$$

$$B = B(t, \omega) = \left\{ t \geq 0; \int_0^t X^{(1)}(\tau, \omega) d\tau \in [0, 1] \right\} \quad (19.24d)$$

where ω is an elementary event. The α_ν derivative $\partial^{\alpha_\nu} f / \partial x^{\alpha_\nu}$ is the well-known fractional derivative, and $D(t) = -(t\sigma_\nu)^{\alpha_\nu} / \cos(\pi\alpha_\nu/2)$ with σ_ν a parameter in the definition of the α_ν stable Lévy motion; $S_{\alpha_\nu}(t^{1/\alpha_\nu} \sigma_\nu, 1, v^{(1)})$ is the distribution for the Lévy motion.

19.7 Lagrangian Stochastic Models for Nonlinear Reactions

Mass transfer equations representing natural biological and chemical transformations in saturated subsurface systems typically involve strongly nonlinear transformations among multiple species. Eulerian methods that result in ensemble-averaged expected plume behavior have been successful in upscaling the effects of idealized heterogeneities on the fate and transport of linearly sorbing solutes at both equilibrium (e.g., Berglund and Cvetkovic, 1996) and nonequilibrium rates (e.g., above, cf. also Dagan and Cvetkovic, 1993; Quinodoz and Valocchi, 1993; Andricevic, 1995), and solutes undergoing linear decay (e.g., Hu et al., 1995; Miralles-Wilhelm and Gelhar, 1996). These methods are however, generally inappropriate for the application to reactive transport where nonlinearities exist in nonequilibrium transformations or in multicomponent (coupled) dependencies. Sudicky et al. (1990) point out that the ergodic requirement (that, simply, the solute domain is large relative to the dominant scale of heterogeneity) is invalid for a nonconservative (e.g., sorbing or degraded) solute whose domain shrinks with time. Also, the use of a macrodispersion parameter effectively represents as mixing what may actually be plume deformation due to nonuniform convections, as described in the previous chapter. In the case of dually-limiting reactants (interior and exterior to the plume, such that reactions only occur at the mixing fringe), this artificial mixing will significantly overestimate the reaction sink. The scaling procedure, as an equation averaging operation, is valid when the averaging operator commutes with the (linear) kinetic reaction operator, so

that the average of quantities *within* the reaction term may be obtained. When nonlinearities exist in the kinetics of transformation, the averaging and reaction operations do not generally commute, and so the scaling approach fails to generate useful equations for average plume behavior.

An approach to scaling complex reactive transport in heterogeneous materials may be obtained when one first applies the reaction operation to solute parcels as they follow nonuniform convective paths, and then averages the resulting reacted solute convections over the appropriate convective paths contributing to an observation. In this approach, known as the solute flux-based (Cvetkovic and Dagan, 1996; Cvetkovic et al., 1998) or stochastic-convective reaction (SCR) method (Simmons et al., 1995), the reactions are cast in terms of the solute residence-time during convection. The method is based in the stochastic-convective representation of dispersive transport of a passive tracer (Simmons, 1982). The travel-time of the solute is defined as the time of residence of solute moving through the aquifer, from the point of spill or contamination entry to the system, to the observation location or regulatory boundary. Solute particles that enter the system and arrive at the observation location follow particular paths, or streamtubes, and the set of streamtubes delivering solutes to an observation sampler (point), line (well), or plane (regulatory boundary) makes up an ensemble of travel paths, and so the travel-time describing the ensemble is a distributed quantity, characterized by a distribution function. When the reactive transport model along any given streamtube can be expressed in terms of travel-time, the solution to the model is in terms of travel-time, and the solute arrival at the observation is recovered by averaging the solution of the model against the travel-time distribution function.

The advantages of this approach are (1) the reliance upon travel-time, a global measure of the effects of locally-varying Eulerian velocities, as opposed to estimates of the full nonuniform velocity field, and (2) the solution for each streamtube equation system can be obtained before averaging, thus eliminating the operator commutation problem with scaling nonlinearly reactive transport. This latter feature, it should be noted, results from the assumption that lateral mixing between streamtubes is negligible, that is, the flow in which the transport occurs is “segregated.” Recent work by Viswanathan and Valocchi (2004) and by Robinson and Viswanathan (2003) provides some innovative effective methods to deal with the occurrence of lateral mixing. This scaling approach is usually applied to provide predictions of observed solute arrivals at observation samples, or arrivals at an imaginary control plane. It is a direct although cumbersome matter to use the SCR approach to reconstruct estimates of plume evolution, which may be done if the travel-time distribution function is given or estimated at many points in the aquifer. Similar streamtube principles have been used to gain computational speedup in two- and three-dimensional reactive transport simulations in a deterministic setting (Thiele et al., 1995a, 1995b).

The method proceeds in three basic steps. First, the existence of an ensemble of streamtubes that is suitable for averaging must be ensured by checking the validity of the SCR assumptions for the particular reaction system, initial, and boundary conditions. Second, the reaction system must be solved for the streamtube ensemble (or canonical streamtube, defined below, when it exists). Finally, the travel-time distribution function must be determined for the particular flow regime and initial and boundary conditions. The following two subsections borrow heavily from Simmons et al. (1995).

19.7.1 Streamtube Formulation

The concept of the streamtube as a path taken by solute parcels from a source to an observation is made under the requirement that flow in it (a subset of the total flow domain) is constant for both space and time. The assumptions under which such an ensemble of streamtubes may exist are as follows: The members of the ensemble are physically independent, with no mass transfer among streamtubes. This allows treatment of the solute paths as integral, averagable quantities. This restricts diffusive/dispersive mass transports lateral to streamtubes; for example, this representation is incapable of incorporating local transverse dispersion. For simplicity we ignore also longitudinal mixing processes, although this is not a requisite assumption as a longitudinal mixing may be incorporated within the streamtube (Ginn, 2001). Second, the streamtube orientation in Eulerian space is arbitrary save that it must of course connect the source to the measurement location, and that the projection of its axis, s , onto the x -axis connecting the

source and observation be one-to-one (such that the $x(s)$ is monotone increasing). This assumption allows us to associate with each streamtube a 1D velocity function $v(x)\epsilon\{v(x)\}$ that is positive, and so allows the definition of an associated travel-time function. Further, each streamtube obeys a known reaction function r . A streamtube in three-space (which may have variable areal cross section) is defined such that its average cross-sectional velocity $v_s(x')$ times the corresponding cross-sectional water content $n_s(x')$ is a constant, q . To represent a streamtube in three-dimensions with an equivalent 1D streamtube with the same flow q we must honor the velocity to preserve the transport characteristics. Velocity is defined by $v_s(x') = q/n_s(x')$ in the streamtube and by $v(x') = q/n(x')$ in the equivalent 1D system. Mass balance implies $v_s(x')n_s(x')A_s(x') = v(x')n(x')A_0$ where A_0 is a (constant) reference area, and so we may define an effective porosity $n(x') = n_s(x')A_s(x')/A_0$ to give $v(x') = v_s(x')$ along the equivalent 1D system. Under this construction the convective-reactive transport along a given streamtube is represented in the 1D form

$$\frac{\partial(nC)}{\partial t} + \frac{\partial(nvC)}{\partial x} = nr \quad (19.25)$$

By construction $n(x)v(x) = q$ is a constant of x , and n is assumed constant of t , so Equation 19.25 simplifies to

$$\frac{\partial C}{\partial t} + v(x)\frac{\partial C}{\partial x} = r \quad (19.26)$$

A simple change of variables in Equation 19.26 allows expression of velocity in terms of solute travel-time. The travel-time corresponding to the streamtube velocity $v(x)$ is the time elapsed as a tracking particle is transported from x_0 to x ,

$$T(x; x_0) = \int_{x_0}^x dx'/v(x') = \int_0^x dx'/v(x') - \int_0^{x_0} dx'/v(x') = T(x) - T(x_0) \quad (19.27)$$

where $T(x)$ means $T(x', 0)$. By positivity of velocity, $T(x)$ is a monotone increasing function in x and the inverse function, $\Xi(T'(x)) = T^1(\tau) = x$, exists and is monotone increasing in variable τ . Note that mass loss over the ensemble corresponds to the case where ensemble maximum travel-time is infinity. In this case, a finite T^* would be used that represents the largest travel-time of a tracer particle captured at a measurement location, and the mass lost would be accounted in the specification of the streamtube frequency distribution. Now invoking the chain rule with $dT(x) = dx/v(x)$ and incorporating the inverse function $\Xi(T)$ we may write for Equation 19.26:

$$\frac{\partial C}{\partial t} + \frac{\partial C}{\partial T} = r(\Xi(T), t, C) \quad (19.28)$$

This last form expresses the result that C can be obtained explicitly as a function of global travel-time. Equation 19.7 is the basic streamtube model. Note that if r is streamtube invariant (requiring that r' contain effective streamtube porosity as factor) the solution to Equation 19.26 depends only on v . Any set of streamtubes for which the velocity statistics are identical to those of $\{v\}$ (determined from the observation of conservative tracer breakthrough or from conductivity statistics), and for which r accurately represents the reactions, suffices. A working hypothesis of this approach is that the streamtube model more closely represents the actual conditions for the definition and calibration of the kinetic model r than does the conventional averaging approach. Closed-form solutions to Equation 19.26 may be found under general conditions on r , including nonlinear and dynamic forms (e.g., r depends on a parameter such as microbial mass that evolves according to its own differential equation). We will return to a few examples after introducing the travel-time distribution function.

Ensemble averaging of the solution to Equation 19.28, described next, is greatly simplified when the solution to Equation 19.28 may be written in terms of dimensionless travel-time, and rescaled to fit any particular travel-time. When the solution to the streamtube equation is rescalable over travel-time, the solution is termed “canonical.”

19.7.2 Stochastic–Convective Averaging

Here we examine averaging of the foregoing solutions according to the travel-time pdf, a measure of streamtube frequency. Once a canonical solution of Equation 19.7 is obtained as $C(T, t)$, the streamtube ensemble average solution, $\langle C \rangle(x, t)$, is found by averaging $C(T, t)$ over the travel-time pdf $p(\tau; x)$ for the streamtube travel-times to location x . This pdf is defined over the streamtube ensemble in the frequency sense as (Simmons, 1982; Shapiro and Cvetkovic, 1988; Dagan and Nguyen, 1989)

$$p(\tau; x) = \langle \delta(\tau - T(x)) \rangle \quad (19.29)$$

where δ is the Dirac distribution function and the angle brackets indicate average over the streamtube ensemble. The expectation can be expressed as

$$\langle C \rangle(x, t) = \int_0^{\infty} C(\tau, t) p(\tau; x) d\tau \quad (19.30)$$

In Equation 19.30, $p(\tau; x)$ is the pdf for random travel-time τ to a plane normal to the major flow axis at x , measured along that axis (Simmons, 1982; Dagan and Nguyen, 1989). The averaging in Equation 19.30 is over the realizations of (random) travel-time at a certain point in x space, and not over the deterministic measure of travel-time $T(x)$ itself. That is, the average in the right-hand side of Equation 19.30 is exactly the streamtube ensemble average, as is demonstrated on substitution of Equation 19.29:

$$\int_0^{\infty} C(\tau; t) p(\tau; x) d\tau \equiv \int_0^{\infty} C(\tau; t) \langle \delta(\tau - T(x)) \rangle d\tau = \left\langle \int_0^{\infty} C(\tau; t) \delta(\tau - T(x)) d\tau \right\rangle = \langle C(T(x), t) \rangle \quad (19.31)$$

The numerical calculation Equation 19.31 via discrete integration requires first the enumeration of the surfaces $C_i(T, t)$ for each realization of travel-time function $T_i(x)$. When a canonical solution is available this is accomplished by simply rescaling the travel-time axis of the canonical solution $C(T, t)$ to the indicated $T_i(x)$. This approach is used by Wise and Carbeneau (1994), whose averaging is associated with the measured cumulative passive breakthrough (which they term the “fractional breakthrough,” that is the integral part of our travel-time pdf).

Finally, one may also introduce heterogeneity into the reaction term through either the space-time dependency or the solute component dependency in the right-hand side of Equation 19.30 (for instance, when $r(x, t, C) = g(x, t)h(C)$, and g indicates concentration of reactive iron oxides or attached biomass). Further, correlations between the flow properties and the reaction properties may be cast as a conditioning of the travel-time pdf upon the value of the reaction properties. When such heterogeneity is represented through pdfs of the random properties and when these pdfs are known, the expectation may be computed in many cases by simple sequential averaging of $C(T, t)$ according to each random property (with pdfs appropriately conditioned to reflect correlations). Suppose, for instance, randomness in the case of a factorable hyperbolic kinetic decay (e.g., biodegradation following Michaelis–Menten kinetics), is such

that we write Equation 19.30 as

$$r(x, t, C) = \{g\}(x, t)h(C) \quad (19.32)$$

where g represents time evolution of a random space function selected from the ensemble $\{g\}$. That is, Equation 19.32 is the reactive term written for one realization (streamtube) of the random pathways. In this case (Simmons et al., 1995) the streamtube solution is cast in terms of not only travel-time (cumulative reciprocal velocity) but also cumulative “reaction property” G , defined as the integral of g along the streamtube coordinate. Then the travel-time averaging in Equation 19.30 is followed by averaging over the ensemble distribution of G , appropriately conditioned;

$$\langle C(x, t) \rangle_G = \int_0^\infty C(\tau, t) p(\tau; x|G) d\tau \quad (19.33a)$$

$$\langle C(x, t) \rangle = \int_{-\infty}^\infty \langle C(\tau, t) \rangle_G p(G; x) dG \quad (19.33b)$$

19.7.3 Travel-Time Distribution Function

The travel-time $T(x)$ determines the mapping of the random velocity along a streamtube onto a random velocity field for an equivalent one-dimensional system with distance coordinate x . Thus the travel-time pdf is experimentally observed as the conservative tracer breakthrough curve at the control plane at x in response to a unit Dirac- δ input function. Alternatively, the pdf may be deconvolved from the observed response to other known input functions (e.g., Ginn et al., 1995). In either case, it should be noted that pore-scale mixing processes (such as diffusion and pore-scale dispersion) serve to smooth the observed breakthrough curve in an irreversible way. One may also hypothesize forms for $p(\tau; x)$, a priori, such as lognormal or inverse-Gaussian (Simmons, 1982).

Frequently, tracer test results are not available for characterizing transport between a source and an observation location. It is possible to estimate the expected travel-time distribution function that corresponds to the average arrival time distribution over an ensemble of flow fields. To derive the expected travel-time distribution for particles arriving at an observation point at distance x_1 from source centroid, $g(t; x_1)$, at first order, we follow Dagan (1989, chap. 5.8; see also Appendix A in Cvetkovic and Dagan 1996). For simplicity it is assumed that all particles start within a finite plane source that is oriented normal to the average flow direction. A particle starts at coordinates $(0, a_2, a_3)$, at initial velocity parallel to x -axis $v_0 = V_1(0, a_2, a_3)$. The probability that a solute particle has crossed the regulatory control plane (assumed normal to the flow direction \bar{x} , located at x_1) at time $t = \tau$ is the same as the probability that the particle’s displacement along the flow axis is larger than the distance to the control plane, that is, $X_1 > x_1$. Hence, with $\phi(X_1, v_0; t)$ as the joint pdf of X_1, v_0 , at time t , one has for the cumulative arrival distribution

$$G(\tau; v_0, x_1) = \int_{x_1}^\infty \phi(X_1; v_0, \tau) dX_1 \quad (19.34)$$

It is important to note that the concentration probability function ϕ is a statistical construction that is not equivalent to any particular physical realization unless the transport is ergodic, for example, that the lateral domain of the source is large compared to the heterogeneity scale. Various models for ϕ have been derived based on different constructs of the statistical description of the controlling (conductivity) field and boundary conditions (Dagan, 1991; Dagan et al., 1992). The expected travel-time pdf is obtained from the cdf G by averaging Equation 19.34 over possible initial velocities v_0 (where v_0 is assumed Gaussian

with mean U) and differentiating with respect to τ .

$$g(\tau; x_1) = \frac{1}{U} \int v_0 g(\tau, v_0; x_1) dv_0 = \frac{1}{U} \frac{\partial}{\partial \tau} \int_0^\infty \int_{x_1}^\infty v_0 \phi(X_1, v_0; \tau) dX_1 dv_0 \quad (19.35)$$

For instance, for asymptotic conditions where the impact of v_0 and τ correlations vanish, g is given by

$$g(t; x_1) = -\frac{1}{\sqrt{2\pi}} \exp\left(\frac{-(x_1 - Ut)^2}{2X_{11}}\right) \frac{\partial}{\partial \tau} \left(\frac{x_1 - Ut}{\sqrt{X_{11}}} \right) \quad (19.36)$$

where X_{11} is the longitudinal particle covariance, a measure of the ensemble-averaged longitudinal second spatial moment, and U is the source-averaged initial velocity.

19.7.4 Some Reaction System Examples

Here we summarize some recent examples of reaction systems that have been constructed for particular biogeochemical systems and used in streamtube-ensemble reactive transport models. The examples include a generalized linear sorption model, and a model of aerobic biodegradation with microbial transport.

Lassey (1988) provided a generalized formulation of a model combining equilibrium, kinetic-reversible, and kinetic-irreversible sorption processes and its solution for particular boundary conditions. The solution to the streamtube Equation 19.30 with r given by the kinetic reversible sorption model of Equation 19.1a and Equation 19.1b (e.g., $r = -(\rho_b/n)\partial S/\partial t$), in the case of an instantaneous injection at the upstream boundary, is adopted from Lassey (1988; cf. Also Cvetkovic and Dagan, 1996; Cushman et al., 1996)

$$C(\tau, t) = e^{-K_r K_d t} \delta(t - \tau) + K_r^2 K_d \tau e^{[-K_r K_d t - K_r(t-\tau)]} \bar{I}_1[K_r^2 K_d \tau(t - \tau) H(t - \tau)] \quad (19.37)$$

where $\bar{I}_1(z) = z^{-1/2} I_1(2z^{1/2})$, and I_1 is the modified Bessel function of the first kind of order one. This solution is appropriate for averaging as indicated in Equation 19.30. Note that as pointed out in Simmons et al. (1995) and Theile (1995a), the so-called initial value problems, for example, those involving the initial distribution of a reactant (such as attached biomass) in space, impose certain restrictive assumptions on the use of the streamtube approach. In the most restrictive case, uniformity of the distributed property over the streamtube ensemble is required. (This is only slightly less restrictive than the requirement of spatial biochemical homogeneity overall.) In the event of spatially nonuniform initial distribution of biomass, full averaging of the streamtube-component evolution equations is feasible, but requires the joint probability of biomass occurrence and streamtube travel-time (as in Equation 19.33).

Biogeochemical and biodegradation systems involving attached phase biomass or biofilms are typically formulated as initial value problems, and thus may be complicated by heterogeneity in not only initial microbial distributions, but also by the dynamic microbial heterogeneity associated with microbial growth. This is the case in the next example, involving nonlinear degradation of an organic solute by a microorganism that is initially uniformly attached to the solid phase but partitions to the aqueous phase according to a nonequilibrium and nonlinear rate equation. This example describes meter-scale laboratory experiments in aerobic biodegradation in physically heterogeneous media, and is greatly condensed from Murphy et al. (1997) and Ginn et al. (2001). Simplified evolution equations for the organic substrate benzoate, oxygen, mobile microbes, immobile microbes, and passive tracer bromide, are shown here in one-dimensional (streamtube projection) format. Because we have retained one-dimensional longitudinal dispersivity d in the transport operation in Equation 19.38, to preserve the mixing between oxygenated and oxygen-depleted waters that is important to degradation, the equations are cast in terms of their streamtube velocity projected onto the x -axis, as opposed to travel-time. This aspect, and the possibility

of nonuniformities in the initial biomass concentrations, violates the requirements for a travel-time (i.e., constant-velocity) representation of streamtube velocities. Nevertheless for simplicity in calculating the SCR predictions, a constant velocity ensemble, corresponding to an equivalent travel-time ensemble, is used as an approximation of the transport.
